The Sheath Transport Observer for the Redistribution of Mass (STORM) instrument is a prototype soft X-ray camera also successfully flown on the DXL sounding rocket. STORM uses newly developed slumped micropore ("lobster eye") optics to focus X-rays onto a position sensitize chevron configuration microchannel plate detector. The slumped micropore optics have a 75 cm curvature radius, a collecting area of 32 cm?, and a polyimide/aluminum filter bonded to its surface. STORM's large field-of-view makes it ideal for imaging SWCX with exospheric hydrogen for future missions. STORM represents the first flight of lobster-eye optics in space.

8859-37, Session 8

Flight performance and first results from the sub-orbital local interstellar cloud experiment (SLICE)

Kevin France, Nicholas Nell, Robert Kane, Univ. of Colorado at Boulder (United States); Matthew Beasley, Planetary Resources, Inc. (United States); Eric B. Burgh, Univ. of Colorado at Boulder (United States); Keri Hoadley, Christopher Moore, James C. Green, Univ. of Colorado at Boulder (United States)

We present the flight performance and preliminary science results from the first flight of the Sub-Orbital Local Interstellar Cloud Experiment (SLICE). SLICE is a rocket-borne far-ultraviolet instrument designed to study the diffuse interstellar medium. The SLICE payload comprises a Cassegrain telescope with LiF-coated aluminum optics feeding a Rowland Circle spectrograph operating at medium resolution (R ~ 6000) over the 102 – 107 nm bandpass. The details of the instrument design and calibration are presented in a companion proceeding; we focus on first results from the spring 2013 launch of SLICE in this work. SLICE was launched aboard a Terrier-Black Brant IX sounding rocket from White Sands Missile Range to observe four hot stars sampling different interstellar sightlines. The instrument acquired approximately 300 seconds of on-target time for the primary science targets. We observe atomic and molecular transitions (HI, OI, CII, H2) tracing a range of temperatures, ionization states, and molecular fractions in diffuse interstellar clouds. Initial spectral synthesis results and future plans are discussed.

8859-38, Session 8

The OGRESS sounding rocket payload

Thomas D. Rogers, Univ. of Colorado at Boulder (United States); Randall McEntaffer, Ted Schultz, The Univ. of Iowa (United States); Benjamin R. Zeiger, NASA Goddard Space Flight Ctr. (United States); Phillip H. Oakley, Massachusetts Institute of Technology (United States); Webster Cash, Univ. of Colorado at Boulder (United States)

We present an overview of the OGRESS (Off-plane Grating Rocket for Extended Source Spectroscopy) sounding rocket payload based at the University of Colorado and the University of Iowa. OGRESS is designed to perform high resolution (R ~ 50-100) spectroscopy of diffuse celestial x-ray sources between 0.1 – 1 keV. A wire grid collimator constrains light from diffuse sources into a converging beam that feeds an array of diffraction gratings in the extreme off-plane mount. The spectrum is focused onto GEM (Gaseous Electron Multiplier) detectors. OGRESS is the first payload to use GEMs for space-born applications. Thus, we intend to increase the flight readiness of GEMs to TRL-6, for potential use on future orbital missions. Scheduled to launch in 2014, OGRESS will obtain accurate physical diagnostics of the Vela supernova remnant.

8859-29, Session PMon

The optomechanical design of the sub-orbital local interstellar cloud experiment (SLICE)

Robert Kane, Nicholas Nell, Univ. of Colorado at Boulder (United States); Ted Schultz, The Univ. of Iowa (United States); Kevin France, Univ. of Colorado at Boulder (United States); Matthew Beasley, Planetary Resources, Inc. (United States); Eric B. Burgh, Ames Research Ctr. (United States); Rachel Bushinsky, Keri Hoadley, Univ. of Colorado at Boulder (United States)

We present the fabrication and testing of the Sub-orbital Local Interstellar Cloud Experiment (SLICE), a rocket-borne payload for ultraviolet astrophysics in the 1020 to 1070 Å bandpass. The SLICE optical system is comprised of an ultraviolet-optimized telescope feeding a Rowland Circle spectrograph. The telescope is an 8-inch Cassegrain operating at f/7, with Al optics overcoated with LiF for enhanced far-ultraviolet reflectivity. The holographically ruled grating focuses light at an open-faced microchannel plate detector employing an opaque RbBr photocathode. In this proceeding, we describe the design trades and calibration issues confronted during the build-up of this payload. We place particular emphasis on the technical details of the design, modifications, construction and alignment procedures for SLICE in order to provide a roadmap for the optimization of future ruggedized experiments for ultraviolet imaging and spectroscopy.

8859-39, Session PMon

The EXCEED mission (Earth-orbiting EUV spectrometer for planets)

Ichiro Yoshikawa, The Univ. of Tokyo (Japan)

An earth-orbiting Extreme Ultraviolet spectroscopic mission, EXtreme ultraviolet spectrosCope for ExosphEric Dynamics explore (EXCEED) is ready for the launch (2013 August). The EXCEED mission will carry out out-of-atmosphere observations of Extreme Ultraviolet (EUV: 60-145 nm) emissions from tenuous plasmas around the planets (Mercury, Mars, Venus, Jupiter, and exo-solar planets). In this paper, we will introduce the general mission overview, the instrument, and the scientific targets.

8859-40, Session PMon

Status of the EPIC thin and medium filters on-board XMM-Newton after more than 10 years of operation, Part I: laboratory measurements on back-up filters

Marco Barbera, Univ. degli Studi di Palermo (Italy); Alfonso Collura, INAF - Osservatorio Astronomico di Palermo (Italy); Fabio Gastaldello, INAF - IASF Milano (Italy); Ugo Lo Cicero, INAF - Osservatorio Astronomico di Palermo Giuseppe S. Vaiana (Italy); Nicola La Palombara, INAF - IASF Milano (Italy); Andrea Tiengo, Istituto Univ. di Studi Superiori Pavia (Italy) and INAF - IASF Milano (Italy); Salvatore Varisco, INAF - Osservatorio Astronomico di Palermo Giuseppe S. Vaiana (Italy)

After more than ten years of operation of the EPIC camera on board XMM-Newton we have reviewed the status of its thin and medium filters by performing both laboratory measurements on back-up filters, and analisys of data collected in-flight.

We have selected one thin and one medium back-up filters among those still available in the EPIC consortium, and have investigated their status by laboratory measurements including: UV/VIS transmission measurements, X-ray transmission measurements, IR spectroscopy, and microscopic investigations. We report the results of these measurements and point out some lessons learned for the development and calibration programs of filters for X-ray detectors in future Astronomy missions.

8859-41, Session PMon

Status of the EPIC thin and medium filters on-board XMM-Newton after more than 10 years of operation, Part 2: analysis of in-flight data

Fabio Gastaldello, INAF - IASF Milano (Italy); Marco Barbera, Alfonso Collura, Univ. degli Studi di Palermo (Italy); Ugo Lo Cicero, INAF - Osservatorio Astronomico di Palermo Giuseppe S. Vaiana (Italy); Nicola La Palombara, Nicola Sartore, INAF - IASF Milano (Italy); Andrea Tiengo, Istituto Univ. di Studi Superiori Pavia (Italy) and INAF - Osservatorio Astronomico di Palermo (Italy); Salvatore Varisco, INAF - Osservatorio Astronomico di Palermo Giuseppe S. Vaiana (Italy)

After more than ten years of operation of the EPIC camera on board XMM-Newton we have reviewed the status of its thin and medium filters by performing both analysis of data collected in-flight and laboratory measurements on on-ground back-up filters.

We have investigated the status of the EPIC thin and medium filters by performing an analysis of the optical loading in the PN offset maps to gauge variations in the optical and UV transmission of the filters. We both investigated repeated observations of single optically bright targets and performed a statistical analysis of the extent of loading versus visual magnitude at different epochs. Variations in the X-ray transmission have been investigated by continuous monitoring of the isolated neutron star RXJ 1856-3754 which shows an extremely soft spectrum well modeled by a blackbody with kT of about 60 eV. We report the results of these measurements.

Conference 8860: UV/Optical/IR Space Telescopes and Instruments: Innovative Technologies and Concepts VI

SPIE Optics+Photonics
Optical Engineering + App.

Sunday - Monday 25–26 August 2013

Part of Proceedings of SPIE Vol. 8860 UV/Optical/IR Space Telescopes and Instruments: Innovative Technologies and Concepts VI

8860-1, Session 1

Status and overview of the James Webb Space Telescope Observatory *(Invited Paper)*

Mark Clampin, NASA Goddard Space Flight Ctr. (United States)

The James Webb Space Telescope (JWST) is a large aperture (6.5 meter), cryogenic space telescope with a suite of near and mid-infrared instruments covering the wavelength range of 0.6 ?m to 28 ?m. JWST's primary science goal is to detect and characterize the first galaxies. It will also study the assembly of galaxies, star formation, and the formation of evolution of planetary systems. JWST is a segmented mirror telescope operating at ~40K, a temperature achieved by passive cooling of the observatory, via a large, 5-layer membrane-based sunshield. We present an overview of the observatory design and the mission science objectives. With construction of the observatory progressing rapidly across all major observatory systems, we will report on recent highlights such as the completion of all the mirrors in JWST optical chain We will also review the predicted performance of the JWST observatory, based on initial measurements of the telescope optics and instrumentation.

8860-2, Session 1

The James Webb Space Telescope science goals

Jonathan P. Gardner, NASA Goddard Space Flight Ctr. (United States)

The James Webb Space Telescope is the scientific successor to the Hubble and Spitzer Space Telescopes. As a large, cold facility-class space telescope it will address nearly every aspect of astronomy through deep infrared imaging and spectroscopy. The science goals for JWST include the formation of the first stars and galaxies in the early universe; the chemical, morphological and dynamical buildup of galaxies and the formation of stars and planetary systems. Recently, the goals have expanded to include additional studies of dark energy, dark matter, active galactic nuclei, exoplanets and Solar System objects. In this paper, we review the original four science themes and discuss how the scientific output of Webb will extend to these new areas of research.

8860-3, Session 1

Status of the James Webb Space Telescope integrated science instrument module

Matthew A. Greenhouse, NASA Goddard Space Flight Ctr. (United States); Victoria Balzano, Space Telescope Science Institute (United States); Pamela S. Davila, Michael P. Drury, Jamie L. Dunn, Stuart D. Glazer, Ed M. Greville, Gregory I. Henegar, Jason E. Hylan, Ray A. Lundquist, John C. McCloskey, Raymond G. Ohl IV, Robert A. Rashford, Mark F. Voyton, NASA Goddard Space Flight Ctr. (United States)

The Integrated Science Instrument Module (ISIM) of the James Webb Space Telescope (JWST) is discussed from a systems perspective with emphasis on integration & test and overall status to launch. The ISIM is one of three elements that comprise the JWST space vehicle and is the science instrument payload of the JWST. The major subsystems of this flight element and their build status are described.

8860-4, Session 1

Reducing the read noise of the James Webb Space Telescope (JWST) near infrared spectrograph using improved reference sampling and subtraction

Bernard J. Rauscher, NASA Goddard Space Flight Ctr. (United States)

The Near Infrared Spectrograph is the James Webb Space Telescope's (JWST) primary spectrograph. For most observations, NIRSpec is likely to be detector noise limited. A team at NASA Goddard is working to push NIRSpec's H2RG and SIDECAR ASIC-based detector system toward the ultimate noise floor that is achievable with the hardware. In this talk, we describe the overall Improved Reference Sampling and Subtraction (IRS^2) formalism, the detailed characterization that was done to enable it, and the noise results that have been achieved so far. These include total noise less than 6 electrons rms per 1000 second science exposure using 88 up-the-ramp non-destructive reads.

IRS^2 differs from conventional H2RG readout in that the clocking pattern interleaves reference pixels and regular pixels throughout the readout much more extensively than if the pixels were to be readout in their physical order. The reference output, the additional interleaved reference pixels, and blanked off real pixels used as references are all included in a Principal Components Analysis which givens an eigensystem that can be used to treat the noise as linearly independent noise components. This differs from the more traditional approach in astronomy which averages pixels together in the image plane. Knowledge of the eigensystem guides subtraction of the reference information using a Wiener-optimal formalism. IRS^2 is results in reference subtraction that is optimal in a least squares sense.

8860-6, Session 2

Engineering specifications for a 4-meter class UVOIR space telescope derived from science requirements

W. Scott Smith, H. Philip Stahl, NASA Marshall Space Flight Ctr. (United States); Marc Postman, Space Telescope Science Institute (United States); William R. Arnold, NASA Marshall Space Flight Ctr. (United States); Charles S. Kirk, ITT Exelis (United States); Ryan M. Bevan, NASA Marshall Space Flight Ctr. (United States)

An advanced large aperture UV, optical, near IR, UVOIR, space telescope is required for the next generation of astrophysics and exoplanet science. As an initial study a 4 meter aperture was chosen as the largest monolithic mirror that can fit in current launch vehicles. The science requirements of proposed exoplanet and astrophysics missions were used to determine the encircled energy, point spread function stability and thermal environment requirements. These requirements then determine the optical wavefront specification for the telescope assembly. The optical wavefront specification becomes the top level of the error budget that is split into various sources that control the structural, thermal and optical design.

8860-7, Session 2

The high-orbit ultraviolet-visible satellite, HORUS

Paul Scowen, Arizona State Univ. (United States); Matthew Beasley, Planetary Resources, Inc. (United States); Rolf H. Jansen, Arizona State Univ. (United States); Brian C. Cooke, Jet Propulsion Lab. (United States); Robert A. Woodruff, Lockheed Martin Space Systems Co. (United States); Jeffrey A. Wynn, ITT Corp. (United States); Harold W. Yorke, Jet Propulsion Lab. (United States); David Ardila, California Institute of Technology (United States); Daniela Calzetti, Univ. of Massachusetts Amherst (United States); Ranga-Ram Chary, California Institute of Technology (United States); Steve Desch, Arizona State Univ. (United States); Kevin France, Univ. of Colorado at Boulder (United States); Alex W. Fullerton, Space Telescope Science Institute (United States); John S. Gallagher, Univ. of Wisconsin-Madison (United States); Heidi B. Hammel, Association of Universities for Research in Astronomy, Inc. (United States); Patrick Hartigan, Rice Univ. (United States); Amanda Hendrix, Planetary Science Institute (United States); Sangeeta Malhotra, Arizona State Univ. (United States); Jason Melbourne, California Institute of Technology (United States); Shouleh Nikzad, Jet Propulsion Lab. (United States); Robert W. O'Connell, Univ. of Virginia (United States); Sally Oey, Univ. of Michigan (United States); Deborah L. Padgett, NASA Goddard Space Flight Ctr. (United States); James E. Rhoads, Arizona State Univ. (United States); Aki Roberge, NASA Goddard Space Flight Ctr. (United States); Oswald H. Siegmund, Univ. of California, Berkeley (United States); Nathan Smith, The Univ. of Arizona (United States); Jason Tumlinson, Space Telescope Science Institute (United States); Rogier A. Windhorst, Arizona State Univ. (United States)

The High-ORbit Ultraviolet-visible Satellite (HORUS) is a 2.4-meter class space telescope that will conduct a comprehensive and systematic study of the astrophysical processes and environments relevant for the births and life cycles of stars and their planetary systems, to investigate and understand the range of environments, feedback mechanisms, and other factors that most affect the outcome of the star and planet formation process. HORUS will provide 100? greater imaging efficiency and more than 50? greater UV spectroscopic sensitivity than has existed on the Hubble Space Telescope (HST). The HORUS mission will contribute vital information on how solar systems form and whether habitable planets should be common or rare. It also will investigate the structure, evolution, and destiny of galaxies and the universe. This program relies on focused capabilities unique to space that no other planned NASA mission will provide: near-UV/visible (200-1100nm) wide-field, diffraction-limited imaging; and high-sensitivity, high-resolution UV (100-320nm) spectroscopy. From its semi-stable Earth-Sun L2 orbit HORUS will enjoy a stable environment for thermal and pointing control, and long-duration target visibility. The core HORUS design will provide wide field of view imagery and high efficiency point source FUV spectroscopy using a novel combination of spectral selection and field sharing. The HORUS Optical Telescope Assembly (OTA) design makes optimal use of the SALSO capabilities using a three-mirror anastigmatic configuration to provide excellent imagery over a large FOV. The UV/optical Imaging Cameras use two 21k x 21k Focal Plane Arrays (FPAs) consisting of multiple tiled Si CCD elements. The FUV spectrometer uses cross strip anode based MCPs improved from HST-COS technology.

8860-8, Session 2

Experimental characterization of deployable outer barrel assemblies for large space telescopes

Peter A. Warren, Physical Sciences Inc. (United States); Mark J. Silver, MIT Lincoln Lab. (United States); Benjamin J. Dobson Jr., Diverse Systems Engineering (United States); Howard A. MacEwen, Reviresco LLC (United States)

Abstract to be provided upon government approval

8860-9, Session 3

In-space infrastructures: astrophysics and exploration missions synergisms

Howard A. MacEwen, Reviresco LLC (United States)

Although current budget realities (US and international) discourage optimism regarding future development of large spaceborne astronomical telescopes, it is prudent to identify options to leverage other systems and capabilities that may enhance the cost-benefit equation for astronomy, possibly enabling opportunities sooner rather than later. Using a 20 meter UV-Optical-IR (UVOIR) telescope assembled in space and operating in Sun-Earth L2 halo orbit as a primary baseline, this paper will analyze proposed concepts and technologies for human and robotic missions that could present such opportunities and will provide a summary of the opportunities that can be recognized at the current time. The paper will also explore the possibility that a large space telescope system itself could be leveraged to benefit other missions, for example through shared use of ground infrastructure, in-space operational experience, or other forms of collaboration.

Topics to be considered include the following:

• Launch and orbital transfer systems.

• The International Space Station and its orbital neighborhood.

• Advanced robotics and telerobotics.

• In-space servicing, maintenance, and upgrading.

• Human exploration of deep space objects, including asteroids, the Moon, or Mars.

• Commercial operations and missions.

• Modifications to the baseline space telescope concept generated from interactions with other systems.

Possible partners include other offices within NASA itself; international partners such as ESA and JAXA; and commercial concerns seeking to engage in resource extraction, deep space tourism, and so on.

8860-10, Session 3

Advancing toward far-infrared interferometry in space through coordinated international efforts

David T. Leisawitz, NASA Goddard Space Flight Ctr. (United States)

The international far-infrared astrophysics community is eager to follow up Spitzer and Herschel observations with sensitive, high-resolution imaging and spectroscopy, for such measurements are needed to understand merger-driven star formation, AGN, and chemical enrichment in galaxies, star and planetary system formation, and the development and prevalence of water-bearing planets. Through concerted efforts worldwide, the key enabling technologies are maturing. NASA sponsored the SPIRIT Probe and SPECS flagship-class mission concepts during the past decade. Experiments involving interferometry testbeds are

underway in the UK and the US. With new EU Seventh Framework Programme support, the European community is undertaking science definition studies and investing in enabling technology for a future space far-IR interferometry mission. The Japanese balloon-borne far-IR interferometer FITE is ready for its maiden flight, and NASA's BETTII balloon interferometer is under development, with contributions from the UK. This paper reviews recent technical progress, summarizes mission design tradeoffs, and offers a vision for space-based far-IR interferometry involving international collaboration.

8860-11, Session 3

Optical design and adaptive optics for next generation earth observation systems

Vincent Costes, Ctr. National d'Études Spatiales (France)

High resolution optical systems need bigger and bigger telescopes. The design of such telescopes is a key issue for the satellite design. In order to improve the imaging resolution with low impact to the satellite, a great effort must be made to improve the compactness of the telescope.

This paper will describe the comparative study of several compact optical designs. Different apertures, from F/5 to F/20, and different concepts, TMA (Three Mirror Anastigmat), catadioptric concept and Korsch concept have been studied. We will point out advantages and disadvantages of each design.

For a High resolution earth observing system, the Korsch concept is the classic solution. It is interesting to compare it to others concepts and to reconsider the optical design of such a Korsch Telescope taking into account the possibility to implement adaptive optics.

We will show how compact can be a high resolution telescope: a diffraction limited telescope can be less than ten times shorter than its focal length. A constraining consequence of this compactness is the huge increase of the sensitivity factors. The impacts on the optics and on the opto-mechanical tolerances have been analysed. The need to implement active optics raises.

Our analyses and recent developments in adaptive optics technologies will be presented. In particular, our recent studies and developments in lightweight mirrors and in adaptive deformable mirrors will be described.

8860-12, Session 3

Compact infrared camera (CIRC) for earth observation adapting athermal optics

Eri Kato, Haruyoshi Katayama, Masataka Naitoh, Masatomo Harada, Ryoko Nakamura, Ryota Sato, Japan Aerospace Exploration Agency (Japan); Koji Nakau, Hokkaido Univ. (Japan)

We have developed the compact infrared camera (CIRC) with an uncooled infrared array detector (microbolometer) for space application. The main mission of the CIRC is the technology demonstration of the wildfire detection using a large format (640?480) microbolometer. Wildfires are major and chronic disasters affecting numerous countries, especially in the Asia-Pacific region, and may get worse with global warming and climate change.

Microbolometers have an advantage of not requiring cooling systems such an a mechanical cooler, and is suitable for resource-limited sensor systems or small satellites. Main characteristic of the CIRC is also an athermal optics. The athermal optics compensates the defocus due to the temperature change by using Germanium and Chalcogenide glass which have different coefficient of thermal expansion and temperature dependence of refractive index. The CIRC achieves a small size, light weight, and low electrical power by employing the athermal optics and a shutter-less system.

Two CIRCs will be carried as a technology demonstration payload of ALOS-2 and JEM-CALET, which will be launched in JFY 2013 and 2014, respectively. We have finished the ground calibration test of the CIRC Proto Flight Model (PFM). Athermal optical performance of the CIRC have been confirmed by measuring modulation transfer function (MTF) in a vacuum environment and at environmental temperature from -15 to 50 °C. As a result, MTF was found to be effective at capturing clear images across the entire range of operating temperatures. We also provide an overview of the CIRC and radiometric test results in this presentation.

8860-13, Session 3

A small space telescope for large spectroscopic surveys of galaxies

Sara R. Heap, Qian Gong, Lloyd R. Purves, NASA Goddard Space Flight Ctr. (United States); Massimo Robberto, Space Telescope Science Institute (United States); Tony Hull, The Univ. of New Mexico (United States)

One of the goals of NASA's astrophysics program is to answer the question, How did galaxies evolve into the spirals and elliptical galaxies that we see today? This question can be answered by a large spectroscopic survey of galaxies at redshifts, z>1. We will describe our concept for a survey space telescope (~1.5 m) intended for a NASA MidEx mission. It includes a multi-object spectrograph (~500 galaxies per exposure) which has 3 channels to cover the spectral range, 0.2-1.6 microns at a resolving power, R~400. For a redshift z=1 galaxy, these parameters translate to a restframe spectral coverage of 0.1-0.8 microns and R=800. The mission concept takes advantage of two new technological advances: (1) the Digital Micromirror Device (DMD) to be used as a slit selector in a multi-channel (UV, optical, NIR), multi-object slit spectrograph, and (2) light-weighted, wide field of view telescope mirrors.

8860-14, Session 4

Wide-field infrared survey telescope (WFIRST) 2.4-meter mission study *(Invited Paper)*

David A. Content, NASA Goddard Space Flight Ctr. (United States); Laura B. Abplanalp, ITT Exelis (United States); Kevin R. Anderson, Richard W. Capps, Zensheu Chang, Jennifer A. Dooley, Jet Propulsion Lab. (United States); Robert M. Egerman, ITT Exelis (United States); Renaud Goullioud, Daniel B. Klein, Jet Propulsion Lab. (United States); Jeffrey W. Kruk, Mark E. Melton, John A. Ruffa, NASA Goddard Space Flight Ctr. (United States); Michael Underhill, David Van Buren, Jet Propulsion Lab. (United States)

The most recent study of the Wide Field Infrared Survey Telescope (WFIRST) mission is based on reuse of an existing 2.4m telescope. This study was commissioned by NASA to examine the potential science return and cost effectiveness of WFIRST by using this significantly larger aperture telescope. We review the science program envisioned by the WFIRST 2012-2013 Science Definition Team, the telescope design and status, and an overview of the mission concept. Comparisons against the previous 1.3m and reduced cost 1.1m WFIRST design concepts are discussed. A significant departure from past point designs is the option for serviceability and the geostationary orbit location which enables servicing and replacement instrument insertion later during mission life. Other papers at this conference provide more in depth discussion of the wide field instrument and the optional exoplanet imaging coronagraph instrument.

8860-15, Session 4

Wide field instrument preliminary design for the wide field infrared survey telescope

David A. Content, NASA Goddard Space Flight Ctr. (United

States); Nerses V. Armani, SGT, Inc. (United States); Charles L. Baker, John P. Hawk, NASA Goddard Space Flight Ctr. (United States); Clifton E. Jackson, NASA Goddard Space Flight Ctr. (United States) and SGT, Inc. (United States); Duncan M. Kahle, Jeffrey W. Kruk, John P. Lehan, Mark E. Melton, John E. Mentzell, Joseph J. Miko, David J. Palace, Bert A. Pasquale, Hume L. Peabody, NASA Goddard Space Flight Ctr. (United States); Brian S. Smith, Stargazer Systems (United States); Walter F. Smith, Jeffrey W. Stewart, David A. Vaughnn, Thomas E. Wallace, NASA Goddard Space Flight Ctr. (United States)

We present the Wide Field Infra-Red Survey Telescope (WFIRST) instrument concept based on reusing a 2.4m telescope recently made available to NASA. Two instrument channels are described, a wide field channel (~0.8x0.4degrees, 300Mpix), and an integral field unit (3x3 arcsec, 1Mpix, R{2pixel} ~100 over 0.6-2.0um). For this mission concept, the instruments and spacecraft are in a geosynchronous orbit and are designed for serviceability. This instrument can accomplish not only the baseline exoplanet microlensing, dark energy, and infrared surveys for WFIRST, but also can do so at higher angular resolution and with deeper observations, which enables significant opportunities for much more capable general observer programs. The emphasis on achieving very good imaging stability is maintained from the previous work.

8860-16, Session 4

A tolerancing approach taking into account the interferometric alignment scheme of the EUCLID NISP space optics

Frank U. Grupp, Max-Planck-Institut für Extraterrestrische Physik (Germany) and Univ.-Sternwarte München (Germany); Andreas Bode, Max-Planck-Institut für Extraterrestrische Physik (Germany); Eric Pietro, Observatoire Astronomique de Marseille-Provence (France); Ralf Bender, Max-Planck-Institut für Extraterrestrische Physik (Germany) and Univ.-Sternwarte München (Germany)

The ESA-EUCLID space mission has entered phase B2. A new, more advanced tolerancing approach for the NISP near infrared spectrometer and photometer is presented with this paper. The new approach takes into account the interferometric, hologram based and highly accurate alignment scheme as well as the mechanical interface structure of the NISP instrument. Alignment accuracies of <5mu are desired for the mission. A matter unprecedented for large >150mm transmissive space optics.

8860-18, Session 5

Point spread function and photon transfer of a proton-damaged CCD for space-based astronomy

Edgar A. H. Allanwood, The Open Univ. (United Kingdom); Neil J. Murray, e2v Ctr. for Electronic Imaging at The Open Univ. (United Kingdom); David J. Hall, Konstantin D. Stefanov, The Open Univ. (United Kingdom); Andrew D. Holland, e2v Ctr. for Electronic Imaging at The Open Univ. (United Kingdom); David J. Burt, e2v technologies plc (United Kingdom)

The Euclid VISible instrument (VIS) and Near-Infrared Spectrometer-Photometer (NISP) will survey the shapes of galaxies and their red-shifts respectively, to assist in building a three-dimensional map of the Dark Universe. A weak gravitational lensing survey has high requirements, particularly with regard to the stability of the Point Spread Function (PSF) of the imaging system. In this case an array of thirty-six 4k ? 4k pixel e2v CCD273s will be utilised for the focal plane.

A proton-irradiated front-illuminated CCD273 is tested qualitatively, with particular attention paid to spot PSF measurement techniques and single pixel Photon Transfer Curve (PTC) generation under experimental device operating regimes. Variation in ellipticity of the PSF is evaluated against signal level and rate of incoming optical flux. Development of an optical test bench and the subsequent mitigation of systematic errors affecting spot projection consistency are also discussed.

Data is presented for irradiated and un-irradiated regions of a CCD273 with accompanying inferences of the impact of these measurements during the mission.

8860-19, Session 5

OSIRIS-REx OCAMS detector assembly characterization

Jed J. Hancock, Blake G. Crowther, Mitch Whiteley, Robert Burt, Michael Watson, Joel Nelson, Utah State Univ. Research Foundation (United States); Charles W. Fellows, Bashar Rizk, Ellyne K. Kinney-Spano, Marcus L. Perry, Mark R. Hunten, The Univ. of Arizona (United States)

The OSIRIS-Rex asteroid sample return mission carries a suite of three cameras refered to as OCAMS. The Space Dynamics Lab at Utah State University is providing the CCD-based detector assemblies for OCAMS to the Lunar Planetary Lab (LPL) at the University of Arizona . Working with the LPL, SDL has designed the electronics to operate a 1K by 1K frame transfer Teledyne DALSA Multi Pinned Phase (MPP) CCD. The detector assembly electronics provides the CCD clocking, biasing, and digital interface with the OCAMS payload Command Control Module (CCM). A prototype system was built to verify the functionality of the detector assembly design and to characterize the detector system performance at the intended operating temperatures. The characterization results are described in this paper.

8860-20, Session 5

Tri-level parallel clocking of CCDs for: improving charge transfer efficiency, clearing persistence, clocked anti-blooming, and generating low-noise backgrounds for pumping

Neil J. Murray, The Open Univ. (United Kingdom); David J. Burt, e2v technologies plc (United Kingdom); Andrew D. Holland, Konstantin D. Stefanov, Jason P. D. Gow, Calum MacCormick, The Open Univ. (United Kingdom); Mark S. Cropper, Mullard Space Science Lab. (United Kingdom)

A tri-level clocking scheme has been developed to improve the parallel CTE of four-phase CCDs by supressing the effects of traps located in the transport channel under barrier phases by inverting one of these phases throughout the transfer sequence.

In parallel, it was apparent that persistence following optical overload in both Euclid VIS and LSST detectors would lead to undesirable signal released in subsequent rows and frames and that a suitable scheme for flushing this signal would be required. With care, the negatively biased electrodes during the tri-level transfer sequence can be made to pin the entire surface, row-by-row, and annihilate the problematic charges.

This process can also be extended for use during integration to significantly reduce the unusable area of the detector, as per the clocked anti-blooming techniques developed many years ago; however, with the four-phase electrodes architecture of modern CCDs, we can take precautionary measures to avoid the problem of charge pumping and clock induced charge within the science frames.

Clock induced charge is not all bad! We also propose the use of on-orbit trap-pumping for Euclid VIS to provide calibration input to ground based correction algorithms and as such a uniform, low noise background is require. Clock induced charge can be manipulated to provide a very suitable, low signal and noise background to the imaging array.

Here we describe and present results of tri-level parallel clocking schemes for use in four-phase CCDs that could improve performance of high precision astronomy applications such as Euclid VIS and LSST.

8860-21, Session 5

UV/visible detector arrays and coatings for efficient optical systems

Shouleh Nikzad, Michael E. Hoenk, Alexander G. Carver, Todd J. Jones, Timothy M. Goodsall, John Hennessy, April D. Jewell, Jet Propulsion Lab. (United States); Erika T. Hamden, Columbia Univ. (United States)

Ultraviolet detectors and system technologies have received increased attention from all the fields of science and engineering, due to a wide variety of applications in cosmology, wafer inspection, lithography, life detection, planetary atmospheric studies, skin cancer detection, and mineralogy, and astronomy. UV photons interact with the outermost layers of materials, and are therefore highly sensitive to surface effects, including especially surface/interface defects and traps in back-illuminated detectors. Therefore, surface bandstructure modifications and nano-engineered materials are especially important for UV detectors, sensors, optics and instruments. Recent advances in nanotechnology and nano-engineering lead to opportunities to radically improve detector spectral range, sensitivity, and dark noise and system performance. In parallel, new system developments, allow these bandstructure modification to be performed at large scale both in size and in numbers. We will present our latest results achieving high efficiency in various platforms including photon counting (PC), solid-state detector arrays. The high QE achieved are made possible using back illumination and precision interface band engineering of Molecular Beam Epitaxy (MBE) and Atomic Layer Deposition (ALD). Similar concepts and techniques used in achieving higher efficiency optics will also be presented.

8860-22, Session 5

Narrow bandpass steep edge optical filter for the JAST/T80 telescope instrumentation

Steffen Reichel, SCHOTT AG (Germany); Ulf G. Brauneck, SCHOTT Guinchard (Switzerland); Antonio Marín-Franch, Ctr. de Estudios de Física del Cosmos de Aragón (Spain); Sébastien Bourquin, SCHOTT Swiss SA (Switzerland)

The Observatorio Astrofisico de Javalambre in Spain observes with its telescope galaxies in the Local Universe in a systematic study. This is accomplished with a multi-band photometric all sky survey called Javalambre Photometric Local Universe Survey (JPLUS). A wide field camera receives the signals from universe via optical filters. In this presentation the development and design of a narrow bandpass steep edge filter with wide suppression will be shown. The filter has a full width half maximum in the range of 13-15 nm (with <1 nm tolerance) with central wavelengths in the range 350-860nm and an average transmission larger than 90% in the passband. Signals beyond the passband (blocking range) have to be suppressed down to 250nm and up to 1100nm (spectral regime), where a blocking of OD 5 (transmission < 10-5) is required. The edges have to be steep for a small transition width from 5% to 80%. The spectral requirements result in a large number of layers which are deposited with magnetron sputtering. The transmitted wavefront error of the optical filter must be less than lambda/2 over the 100mm aperture and the central wavelength uniformity must be better than +/- 0.4% over the clear aperture. The filter consists of optical filter glass and a coated substrate in order to reach the spectral requirements. The substrate is coated with more than 120 layers. The total filter thickness was specified to be 8.0mm. Results of steep edge narrow bandpass filters will be demonstrated fulfilling all these demanding requirements.

8860-37, Session 5

The relationship between pumped traps and signal loss in buried channel CCDs

Neil J. Murray, Andrew D. Holland, The Open Univ. (United Kingdom); David J. Burt, e2v technologies plc (United Kingdom); David J. Hall, The Open Univ. (United Kingdom)

Pocket-pumping is an established technique for identifying the locations of charge trapping sites within the transport channels of CCDs. Various parameters of the pumping process can be manipulated to increase the efficiency, or allow characterisation of the trap sites effective during nominal operating modes.

A CCD273 was irradiated in a triangular region by protons to a 10 MeV equivalent fluence of 1.2E9 p.cm2, ensuring a suitably low trap density for ease of automated trap recognition. X-rays of 5,898 eV were incident on the CCD above the region irradiated with the triangle, such that events could be analysed having passed through an increasing length of irradiated silicon and hence number of trapping sites.

Here we present the relationship between the number of traps identified by pocket pumping within the parallel transport channels of a CCD273 and the amount of signal that is deferred by the trapping process during readout.

8860-23, Session 6

Radiation damage to five selected optical materials

Reinhard Katterloher, Norbert Geis, Max-Planck-Institut für Extraterrestrische Physik (Germany); Frank U. Grupp, Ralf Bender, Max-Planck-Institut für Extraterrestrische Physik (Germany) and Univ.-Sternwarte München (Germany)

Five optical materials, LF5, LF5G15, S-FTM16, CaF2 and Suprasil 3001are being tested for their radiation hardness in the spectral range between 920nm and 2000nm. Additional information for the VIS spectral range is presented with reduced spectral resolution. The material is radiated with 80 and 10MeV protons in two steps. Total dose (in Si) corresponds to 5 and 10kRad.

8860-24, Session 6

Benefits of ion milling ULE as compared to glass ceramics

Joseph F. Ellison, Gerald P. Cox, Corning Tropel Corp. (United States); Larry J. Sutton, Andrew Fox, Corning Incorporated (United States); Thomas A. Sebring, Xoptx LLC (United States)

Corning's ULE® is an ultra-low expansion glass used for machine tool blocks to astronomical mirrors. Its main competition is a glass ceramic. In many applications, ion beam milling is used for final surface figuring. Ion milling removes material at an atomic level and is typically a slow, expensive process. Experiments have determined the upper limits of removal rate for ion beam milling during optical figuring. The goal was to increase the power density of the ion beam during figuring to achieve higher removal rates with no negative effects on surface properties. Testing results show that the removal rate on ULE® is about 57% higher than on glass ceramic under the same conditions. With an increase in material removal rate, both ULE® and the glass ceramic show an increase in surface roughness, 17% and 24% respectively. Average

birefringence of both materials show a slight increase after milling, 20% for ULE® and 5% for the glass ceramic; however the actual level of birefringence in the glass ceramic is 7 times larger than for ULE®. One unexpected result was as the power was increased, material removal rate for both materials plateaued. This results when ion implantation is balanced by material removal. Angling the sample relative to the incident ion beam will reduce the implantation and further increase material removal. Therefore using higher ion milling power densities, the surface figuring of ULE® can be accelerated to produce shorter processing times. This can help lower the cost for manufacture of ULE® optics.

8860-25, Session 6

ZERODUR®: progress in CTE characterization

Ralf Jedamzik, Clemens Kunisch, Thomas Westerhoff, SCHOTT AG (Germany)

In 2010 SCHOTT introduced a method for the modeling of the thermal expansion behavior of ZERODUR® under arbitrary temperature profiles for an optimized production of material for the upcoming Extremely Large Telescope (ELT) projects. In 2012 a new product was introduced based on this method called ZERODUR® TAILORED. ZERODUR® TAILORED provides an evolution in the specification of the absolute Coefficient of Thermal Expansion (CTE) value by including the individual customer requirements in this process. This paper presents examples showing the benefit of an application oriented approach in the design of specifications using ZERODUR®. Additionally it will be shown how the modeling approach has advanced during the last years to improve the prediction accuracy on long time scales.

ZERODUR® is known not only for its lowest CTE but also for its excellent CTE homogeneity as shown in the past for disc shaped blanks typical for telescope mirror substrates. Additionally this paper presents recent results of CTE homogeneity measurements in the single digit ppb/K range for a rectangular sized plate proving that the excellent CTE homogeneity is independent of the production format.

8860-26, Session 6

Overview and recent accomplishments of the advanced mirror technology development (AMTD) for large aperture UVOIR space telescopes project

H. Philip Stahl, NASA Marshall Space Flight Ctr. (United States)

ASTRO2010 Decadal Survey stated that an advanced large-aperture ultraviolet, optical, near-infrared (UVOIR) telescope is required to enable the next generation of compelling astrophysics and exoplanet science; and, that present technology is not mature enough to affordably build and launch any potential UVOIR mission concept. AMTD is the start of a multiyear effort to develop, demonstrate and mature critical technologies to TRL-6 by 2018 so that a viable flight mission can be proposed to the 2020 Decadal Review. AMTD builds on the state of art (SOA) defined by over 30 years of monolithic & segmented ground & space-telescope mirror technology to mature six key technologies: Large-Aperture, Low Areal Density, High Stiffness Mirror Substrates; Support Systems; Mid/High Spatial Frequency Figure Error Correction; Segment Edges Control; Segment to Segment Gap Phasing; and Integrated Model Validation. AMTD is pursuing multiple design paths to provide the science community with options to enable either large aperture monolithic or segmented mirrors with clear engineering metrics traceable to science requirements. This paper will provide an overview of the study objectives and summarize recent accomplishments.

8860-27, Session PMon

Khayyam: a tunable spatial heterodyne spectrometer for observing diffuse target emission lines

Sona Hosseini, Walter M. Harris, Jason B. Corliss, Univ. of California, Davis (United States)

We describe first-light results from a new instrument-telescope configuration that combines all of the capabilities necessary to obtain high resolving power visible band spectra of diffuse targets from small aperture telescopes where significant observing time can be obtained. This instrument, Khayyam, is a tunable all-reflective spatial heterodyne spectrometer (TSHS) that is mounted to a fixed focal plane shared by the 0.6m Coude auxiliary telescope on Mt. Hamilton, CA. Khayyam has up to 55 arcsec input field of view, resolving power up to 176000, and a tunable bandpass covering >100nm. Khayyam is being field tested to study spatially extended solar system targets where high resolving power is necessary to separate multimodal signals, crowded molecular bands, and to sample low (<10 km/s) velocities at rapid temporal cadence. Here we will discuss the design considerations going into this new system and the initial results of the installation and testing and the future plans.

8860-28, Session PMon

Differential measurement method for atmospheric refraction

Jian-jun Cao, Lixin Zheng, Shanghai Astronomical Observatory (China)

In traditional astronomical observation, it is seldom to observe objects with altitude lower than 15 degree because of the effect of atmospheric refraction. But for the complete theoretical research of the atmospheric refraction, it is necessary to observe such objects, even with the altitude close to 0 degree. Also in the field of monitoring of space targets, some objects at large zenith distance need to be observed. Taking the differential observation principle of Hipparcos astrometric satellite as reference, a new differential method is designed to measure atmospheric refraction: two reflection mirrors with fixed angle that can be rotated accurately are installed in front of the incident light stop of a 20cm telescope, which make it possible to observe two sky regions at one time. First we can determine the practical angle by observing the two sky regions near the zenith. Then the two regions of different altitudes at one azimuth are observed. The atmospheric refraction of low altitude can be calculated by combining the arc length from star catalog coordinates and the practical angle of the mirrors. The differential method is simple relatively and it can improve the ability of monitoring objects at large zenith distance with high precision.

8860-29, Session PMon

Infrared metal mesh bandpass filter supported by ultrathin freestanding polyimide

Bruce M. Lairson, David A. Grove, Heidi C. Lopez, Travis Ayers, Luxel Corp. (United States); Joseph D. Adams, Cornell Univ. (United States)

Metal slot mesh grids can be used to form bandpass filters in the wavelength range from 10 microns to 1000microns. We investigated fabrication of metal-absent slot grids comprised of thin gold on ultrathin freestanding polyimide membranes. Prototype filters were made for evaluation on the SOFIA FORCAST instrument. The filters had peak transmission of up to 87% at a wavelength 30 microns, measured at room temperature, with bandwidths of 25-35%. Fits to the transmission spectra, with the transmission loss attributed to polyimide absorption, yields an extinction coefficient k=0.04, similar to previously reported values in these resonant structures. We discuss the feasibility of this

structure for the construction of dichroic air-gap bandpass filters, with improved rejection and bandpass characteristics, for use in the 10-200micron wavelength range.

8860-30, Session PMon

Elimination of linear astigmatism in off-axis three-mirror telescope and its applications

Seunghyuk Chang, Off-Axis Optics Lab. (Korea, Republic of)

Increasing interest in off-axis reflecting telescopes has been observed recently since their obstruction-free configuration can provide superior optical performance compared to conventional on-axis reflecting telescopes. Linear astigmatism is the dominant field aberration of off-axis reflecting telescopes. It was shown in my previous work [SPIE 626548] that the linear astigmatism can be eliminated in off-axis two-mirror telescope by designing the system to satisfy a closed-form equation. It was also shown that the field of view of a linear-astigmatism-free off-axis two-mirror telescope is equivalent to that of an conventional on-axis telescope. However, in general, a two-mirror telescope has limited field of view due to residual third-order astigmatism and field curvature. Three-mirror design is essential for a wide field telescope since these aberrations can be compensated. In this work, an exact analytic solution for the elimination of linear astigmatism in off-axis three-mirror telescope is presented. Several design examples based on the equation are also presented and compared to the similar designs reported previously.

8860-31, Session PMon

Pixel-level modelling and verification for the EUCLID VIS CCD

Andrew S. Clarke, David J. Hall, Jason P. D. Gow, Neil J. Murray, Andrew D. Holland, The Open Univ. (United Kingdom)

Euclid is an M-class mission selected for the next phase of ESAs long-term cosmic vision programme. The missions primary aim is to provide insight into the physical cause of the accelerating universe which will be achieved by investigating the nature of dark energy, dark matter and gravity. The investigation will involve the measurement of the effects of intervening gravitational potentials on visible light from distant galaxies, a process known as weak gravitational lensing.

The CCD273 was designed by e2v for the Euclid mission, and is based on an older design for the CCD204, with changes designed and implemented to improve operation under irradiation. These changes include a narrower buried channel in the serial register to reduce trap interactions during readout. Pixel level models have been developed to improve knowledge of charge packet distribution within the CCD273 and CCD204 using Silvaco TCAD, enabling predictions to be made about device functionality before and after irradiation which can be immediately tested on both devices.

This paper is focussed on latest results, with particular reference to the on-going model verification, designed to build confidence in the device models and provide feedback to further improve the modelling effort.

8860-32, Session PMon

Calibrating apodizer fabrication techniques for high-contrast coronagraphs on segmented and monolithic space telescopes

Anand Sivaramakrishnan, Space Telescope Science Institute (United States); G. Lawrence Carr, Randy Smith, Xiaoxiang Xi, Brookhaven National Lab. (United States); Neil T. Zimmerman, Max-Planck-Institut für Astronomie (Germany); Christophe Dorrer, Univ. of Rochester (United States)

Segmented or full aperture telescopes' terrestrial planet finding and characterizing coronagraphic designs often include apodization to mitigate diffraction and aberrations from mirrors' edges, and discontinuities from inter-segment or secondary support structure gaps. When apodizing screens' microdot sizes are comparable to the wavelength of light, surface plasmon effects cause complex chromatic transmission variations. Broadband coronagraphic performance can be severely compromised by such chromaticity. Our far-field transmission measurements of test patches between 0.55–1.1 ?m, using an FTIRS on Brookhaven's National Synchrotron Light Source (NSLS) U10B beamline, revealed ±5% departure from as-designed transmissions. These departures are smaller than those measured on the same test patches between 1.2–2.5 ?m measures on the NSLS' U4IR beamline. We also suggest experimental refinements to improve our calibration accuracy, with the goal of measuring patches as dense as OD3 to better than a percent.

8860-33, Session PMon

Innovative CCD readout technology for use in large focal plane array development

Todd Veach, Paul Scowen, Arizona State Univ. (United States)

Future mission studies will be expecting Hubble-class resolution and extremely wide areal coverage in order to provide the best science return per investment dollar. The only way to combine high resolution imaging with wide areal coverage is to design large FPAs with very small pixel plate scales. The design and construction of a modular imager cell (MIC) using embedded controllers to ameliorate the power, mass, and cost for the large format CCD focal plane arrays, can provide a robust, low-risk, high-reward solution to mitigate possible mission failures by providing a way to assemble large FPAs using a modular "plug and play" solution. By placing the detector and the associated readout electronics on a single module, one can easily remove and replace any single module without adversely affecting other detectors in the FPA. In this paper, I present a prototype design and results for an MIC for use with a delta-doped LBNL 3.5k ? 3.5k CCD. This prototype design is comprised of the CCD preamplification circuitry and CCD control signal filtering circuitry and is scheduled for flight in an upcoming sub-orbital rocket payload.

8860-34, Session PMon

ACCESS: design and subsystem test performance

Mary E. Kaiser, Matthew J. Morris, Stephan R. McCandliss, Johns Hopkins Univ. (United States); Bernard J. Rauscher, Jeffrey W. Kruk, Randy A. Kimble, NASA Goddard Space Flight Ctr. (United States); Edward L. Wright, Univ. of California, Los Angeles (United States); Paul D. Feldman, H. Warren Moos, Russell Pelton, Adam G. Riess, Johns Hopkins Univ. (United States); David B. Mott, Yiting Wen, Dominic J. Benford, Jonathan P. Gardner, NASA Goddard Space Flight Ctr. (United States); Ralph C. Bohlin, Susana E. Deustua, William V. Dixon, David J. Sahnow, Space Telescope Science Institute (United States); Robert Kurucz, Harvard-Smithsonian Ctr. for Astrophysics (United States); Michael Lampton, Saul Perlmutter, Univ. of California, Berkeley (United States)

Improvements in the precision of the astrophysical flux scale are needed to answer fundamental scientific questions ranging from cosmology to stellar physics. ACCESS, Absolute Color Calibration Experiment for Standard Stars, is a series of rocket-borne sub-orbital missions and ground-based experiments that will enable improvements in the precision of the astrophysical flux scale through the transfer of absolute laboratory detector standards from the National Institute of Standards and Technology (NIST) to a network of stellar standards with a

calibration accuracy of 1% and a spectral resolving power of 500 across the 0.35 to 1.7 micron bandpass. The Cassegrain telescope feeds a compact (Rowland circle design) spectrograph with a cross dispersing Fery prism. The detector, a HST/WFC3 heritage 1024x1024 HgCdTe array, is sensitive across the full 0.35 to 1.7 micron bandpass Ground based characterization of the detector, fabrication of the payload and fabrication, integration, and automation of the ground-based calibration subsystem are in progress. The ACCESS design, calibration strategy, and ground-based integration and test results will be presented. Launch is expected within the year. NASA sounding rocket grant NNX08AI65G and DOE DE-FG02-07ER41506 support this work.

8860-35, Session PMon

A design and trial production of the image slicer unit for the mid-infrared spectrograph

Itsuki Sakon, The Univ. of Tokyo (Japan); Hirokazu Kataza, Japan Aerospace Exploration Agency (Japan); Naofumi Fujishiro, Kyoto Sangyo Univ. (Japan) and Kyoto-Nijikoubou (Japan); Yuji Ikeda, Photocoding (Japan); Hitoshi Tokoro, Nano-Optonics Research Institute (Japan); Hiroyuki Nakagawa, Okiharu Kirino, Crystal Optics (Japan); Kenji Mitsui, Norio Okada, National Astronomical Observatory of Japan (Japan)

An integral field spectroscopic function plays an extremely important role for next generation infrared instruments in, for example, understanding the dust condensation processes around massive stars with active mass loss, unveiling the complicated structures of circumstellar medium around late-type red giants, and characterizing the properties of proto-planetary disks and envelopes. In particular, an image slicer is highly in demand for an integral field unit (IFU) spectrograph of the next generation infrared telescopes. We have obtained the optical layout of the image slicer for SPICA mid-infrared Camera and Spectrometer (MCS) medium resolution spectrometer (MRS). In this case, the refocused image with a field-of-view size of 6 arcsec by 12 arcsec is divided into 5 slitlets by the slice mirror and, then, the image of each slitlet refocused by the spherical pupil mirror is aligned on the pseudo slit mirror and, finally, a pseudo slit image is obtained. We also have carried out the trial production of the key optical elements including the monolithic small format slice mirror (with 5 slices), the monolithic pupil mirror, and the monolithic pseudo slit mirror. In this presentation, we present the results of the processing precision evaluation for those optical elements.

8860-36, Session PMon

Conceptual design of a NIR imaging spectrometer for the Korean next small satellite 1

Bongkon Moon, Sung-Joon Park, Kwijong Park, Woong-Seob Jeong, Dae-Hee Lee, Youngsik Park, Uk-Won Nam, Wonyong Han, Jeonghyun Pyo, Wonki Park, Il-Joong Kim, Duk-Hang Lee, Korea Astronomy and Space Science Institute (Korea, Republic of)

Since end of 2012, Korea Astronomy and Space Science Institute (KASI) has been developed the Near-infrared Imaging Spectrometer for Star formation history (NISS), which is a payload of the Korean next small satellite 1 (NEXTSat-1) and will be launched in 2016. NISS has a cryogenic system, which will be cooled down to around 200K by a radiation cooling in space. NISS is a catadioptric telescope with 200mm aperture and F-number 4.2, which covers the observation wavelengths from 0.95um to 3.8um by using the linear variable filter (LVF) for the near infrared spectroscopy. The field of view is 1.7deg. x 1.7deg. and the pixel scale is around 6 arcsec. Optical elements consist of hyperbolic primary and secondary mirrors and one corrector lens to suppress field curvature. The main requirement for the optical performance is that the RMS spot diameters for whole fields are smaller than the detector pixel, 18um. Two LVFs will be used for 0.9-1.9um and 1.9-3.8um, whose FWHM is less than 2%. We will use the coated aluminum mirrors and employ the H1RG 1024x1024 detector made by Teledyne. This paper presents the conceptual design of NISS.

8860-39, Session PMon

Physical optics effects on PSF: amplitude, phase, polarization

James B. Breckinridge, College of Optical Sciences, The Univ. of Arizona (United States)

The point spread function (PSF) for telescopes and instruments is determined by the optical aberrations in the telescope - instrument system. In this paper we will examine in detail the three aberration sources that dominate image quality in optical systems: amplitude, phase and polarization. The primary mirror modifies the polarized light content of the scene. Optical elements and devices further on in the optical system modify this polarization further to affect the quality of radiometry, the shape of the point spread function and the image quality. Interactions occur between amplitude, phase and polarization aberrations to degrade image quality across the FOV of most optical systems used for precision remote sensing.

8860-40, Session PMon

The Geospace Dynamics Observatory: a paradigm-changing Geospace mission

James F. Spann, NASA Marshall Space Flight Ctr. (United States); Patrick J. Reardon, Kenneth Pitalo, The Univ. of Alabama in Huntsville (United States); H. Philip Stahl, Randall C. Hopkins, NASA Marshall Space Flight Ctr. (United States)

The Geospace Dynamics Observatory (GDO) mission will observe Geospace with unprecedented resolution, scale and sensitivity. At a distance of 60 Re in a near-polar circular orbit and a 27-day period, GDO will image the earth's full disk with (1) three far ultraviolet imagers, (2) an extreme ultraviolet imager of the plasmasphere, and (3) a spectrometer in the near to far ultraviolet range that will probe any portion of the disk and simultaneously observe the limb.

The exceptional capabilities of the GDO mission include (1) unprecedented improvement in signal to noise for global-scale imaging of Earth's space environment that enable changes in the Earth's space environment to be resolved with orders of magnitude higher in temporal and spatial resolution compared to existing data and other approaches, and (2) unrivaled capability for resolving the temporal evolution, over many days, in local time or latitude with a continuous view of Earth's global-scale evolution while simultaneously capturing the changes at scales smaller than are possible with other methods.

This combination of new capabilities is a proven path to major scientific advances and discoveries. The GDO mission will (1) have the first full disk imagery of the storm and circulation systems of the upper atmosphere, (2) be able to image the ionosphere on a global and long time scale basis (3) be able to probe the mechanisms that control the evolution of planetary atmospheres, and (4) be able to test our understanding of how the Earth is connected to the Sun.

This talk will explore the optical and technical aspects of the GDO mission and the implementation strategy. Additionally, the case will be made that GDO will address a significant position of the priority mission science articulated in the recent Solar and Space Physics Decadal Survey.

8860-41, Session PMon

The LBT experience of adaptive secondary mirror operations for routine seeing- and diffraction-limited science operations

Julian C. Christou, Juan Carlos Guerra, Douglas L. Miller, Michael Wagner, Large Binocular Telescope Observatory (United States); Guido Brusa, Steward Observatory (United States)

The Large Binocular Telescope (LBT) is unique in that it is currently the only large telescope (2 x 8.4m primary mirrors) with permanently mounted adaptive secondary mirrors (ASMs). These ASMs have been used for regular observing since early 2010 on the right side and since late 2011 on the left side. They are currently regularly used for seeing-limited observing as well as for selective diffraction-limited observing and are required to be fully operational every observing night. By comparison the other telescopes using ASMs, the MMT and more recently Magellan, using fixed secondaries of seeing-limited observing and switch in the ASMs for diffraction-limited observing. We will discuss the night-to-night operational requirements for ASMs specifically for seeing-limited but also for diffractionlimited observations based on the LBT experience. These will include preparation procedures for observing (mirror flattening and resting as examples); hardware failure statistics and how to deal with them such as for the actuators; observing protocols; and current limitations of use due to the ASM technology such as the minimum elevation limit (25 degrees) and the hysteresis of the gravity-vector induced astigmatism. We will also discuss the impact of ASM maintenance and preparation on science observing time and describe our experience of the systems' performance and calibration reliability.

8861-59, Session PMon

Concept study X-ray testing for NICER's X-ray concentrators

Erin Balsamo, Univ. of Maryland, Baltimore County (United States) and The Ctr. for Research and Exploration in Space Science and Technology (United States) and NASA Goddard Space Flight Ctr. (United States); Keith Gendreau, NASA Goddard Space Flight Ctr. (United States); Zaven Arzoumanian, NASA Goddard Space Flight Ctr. (United States) and The Ctr. for Research and Exploration in Space Science and Technology (United States) and Universities Space Research Association (United States); Takashi Okajima, NASA Goddard Space Flight Ctr. (United States); Lalit Jalota, NASA Goddard Space Flight Ctr. (United States) and The Ctr. for Research and Exploration in Space Science and Technology (United States) and Univ. of Maryland, Baltimore County (United States); Yang Soong, NASA Goddard Space Flight Ctr. (United States) and The Ctr. for Research and Exploration in Space Science and Technology (United States) and Universities Space Research Association (United States); Peter Serlemitsos, Bhalvinder Gulati, Steven Kenyon, NASA Goddard Space Flight Ctr. (United States); Devin J. Hahne, Johns Hopkins Univ. Applied Physics Lab. (United States); David Fickau, Nicholas Spartana, Stinger Ghaffarian Technologies (United States); Steve Lentine, Rensselaer Polytechnic Institute (United States); Ceili Burdhimo, Massachusetts Institute of Technology (United States); Billy Barrios, California State Univ., Los Angeles (United States); Lisa Wu, Urbana High School (United States); Teru Enoto, NASA Goddard Space Flight Ctr. (United States) and RIKEN (Japan)

We performed a series of X-ray tests to measure and assess the current performance of the X-ray concentrators to be used for the Neutron star Interior Composition ExploreR (NICER) during the mission's concept study stage. NICER will use 56 grazing incidence X-ray concentrators (XRCs) as the optical system with each module focusing the incoming photons to co-aligned silicon drift detectors with a 2 mm aperture. Successful X-ray timing and navigation studies require optimal signal to noise. Thus by optimizing high throughput concentrators with a large collecting area we can minimizing the PSF and reduce the aperture size in the detector, reducing background. To analyze the optics' performance we used a 600 meter X-ray beam line to collimate the photons, a soft X-ray source, and an X-ray CCD as the detector. A series of different engineering test units were used to perform these studies by measuring the effective area, producing vignetting functions, analyzing current resolution, and comparing the effects on the module after vibration. We have shown that the concentrators are satisfying the mission's minimum requirements.

8861-60, Session PMon

Improvement of microroughness in slumped glass foils for X-ray telescopes via dip coating

Bianca Salmaso, Andrea Bianco, Oberto Citterio, Giovanni Pareschi, Laura Preserpio, Daniele Spiga, INAF - Osservatorio Astronomico di Brera (Italy)

A dip-coating technique is investigated to improve the surface smoothness and consequently the image quality, of X-ray glass segmented mirrors manufactured by hot slumping. This kind of mirrors is currently developed at INAF Osservatorio Astronomico di Brera using the direct slumping technique, in which the shape of a mandrel is replicated on the optical surface of the mirror being produced. To date, the best results were achieved with a mould in Zerodur K20 and glass foils made of aluminum-borosilicate glass type AF32 by Schott. Nevertheless, several factors in the fabrication process trigger deviations from the desired surface microroughness. In order to reduce the microroughness, a suitable coating has been applied to the replicated glass surface by means of dip-coating technique. In this paper we describe the coating technique, the different implemented processes and the results obtained.

8861-61, Session PMon

Reflective and antireflective coatings for the optical chain of the ASTRI prototype

Giacomo Bonnoli, Rodolfo Canestrari, Giovanni Pareschi, INAF - Osservatorio Astronomico di Brera (Italy)

ASTRI, a flagship project of the Italian Ministry of Research (MIUR), is devoted to the realization, operation and scientific validation of an end- to-end prototype for the Small Size Telescope (SST) envisaged to be-come part of the Cherenkov Telescope Array (CTA). The ASTRI proto-type is a dual mirror Imaging Air Cherenkov Telescope (IACT), following the Schwarzschild-Couder design, and adopts an innovative Silicon Photo Multiplier (SiPM) camera. With its 4m wide primary the telescope will be sensitive to multi-TeV Very High Energy (VHE) gamma rays up to 100 TeV and above, with a point spread function of _ 2 arcminutes and a wide (semiaperture 4.8?) field of view. Fully dielectric multi-layer coatings for the primary mirror have been developed and tested, aiming to filter out the large Night Sky Background contamination at wavelengths _ & 650 nm. A reimaging system based on thin (2.5 mm thick) pyramidal light guides will be installed on the focal plane aiming to minimize dead areas. An anti-reflective coating optimized for a wide range of incident angles faraway from normality was developed to enhance the UV-optical transparency of these elements. The issue, strategy, simulations and experimental results are thoroughly presented.

8861-62, Session PMon

Extreme and near ultraviolet experimental facility for calibration of space instrumentation

Alain Jody Corso, Vanessa Polito, Univ. degli Studi di Padova (Italy); Paola Zuppella, Sara Zuccon, IFN-CNR LUXOR Lab. (Italy); Marco Nardello, Piergiorgio Nicolosi, Univ. degli Studi di Padova (Italy); Jean-Luc Maria, Jean Francois Mariscal, Nicolas Rouanet, Eric Quémerais, Lab. Atmosphères, Milieux, Observations Spatiales (France); Maria Guglielmina Pelizzo, IFN-CNR LUXOR Lab. (Italy)

Calibration of optical systems is a fundamental step in the development of a space instrumentation which requires dedicated tools. For these kinds of activities, a new facility devoted to space instruments characterization in the Extreme and Near ultraviolet has been developed and its characterization is presented in this work. A monochromator working in the 40-350 nm wavelength range is coupled with a chamber (a tube of 80 cm diameter, and 2 m length) served by a vacuum system able to reach a pressure of 10-7mbar. Inside, a two axis platform allows the rotation of the instrument with respect to the collimating beam coming from the monochromator, in order to test the response of the instrument to light coming from different points of the field of view. Different sources can be adopted such as spectral lamps or brighter hollow cathode

lamps. The next usage of this facility is foreseen during the ground calibration activities of PHEBUS, the spectrometer that will be onboard of Bepicolombo.

8861-1, Session 1

The ASTRI prototype for the next generation of Cherenkov telescopes: structure and mirrors

Rodolfo Canestrari, INAF - Osservatorio Astronomico di Brera (Italy); Enrico Giro, INAF - Osservatorio Astronomico di Padova (Italy); Giovanni Pareschi, INAF - Osservatorio Astronomico di Brera (Italy)

The next generation of IACT (Imaging Atmospheric Cherenkov Telescope) will explore the uppermost end of the VHE domain up to about few hundreds of TeV with unprecedented sensibility, angular resolution and imaging quality.

To this end, INAF (Italian National Institute of Astrophysics) is currently developing a scientific and technological telescope prototype for the implementation of the CTA (Cherenkov Telescope Array) observatory. ASTRI (Astrofisica con Specchi a Tecnologia Replicante Italiana) foresees the full design, development, installation and calibration of a Small Size 4 meter class Telescope. It has an aplanatic, wide field, double reflection optical layout in a Schwarzschild-Couder configuration.

In this paper we report about the technological solutions adopted for the telescope and for the mirrors. In particular the structural and electro-mechanical design of the telescope, now under fabrication, and the results on the optical performances retrieved from mirror prototypes.

8861-2, Session 1

Status of the technologies for the production of the Cherenkov Telescope Array (CTA) mirrors

Giovanni Pareschi, INAF - Osservatorio Astronomico di Brera (Italy)

The Cherenkov Telescope Array (CTA) is the next generation very high energy gamma-ray observatory, with at least 10 times higher sensitivity than current instruments. CTA will comprise several tens of Imaging Atmospheric Cherenkov Telescopes (IACTs) operated in array-mode and divided into three size classes -- large, medium and small telescopes. The total reflective surface could be up to 10,000 m^2 requiring unprecedented technological efforts. The properties of the reflector directly influence the telescope performance and thus constitute a fundamental ingredient to improve and maintain the sensitivity. The R&D status of lightweight, reliable and cost-effective mirror facets for the CTA telescope reflectors for the different classes of telescopes will be reviewed in this talk.

8861-3, Session 1

Schwarzschild-Couder telescope for the Cherenkov Telescope Array: development of the optical system

Julien Rousselle, Univ. of California, Los Angeles (France); Valerie Connaughton, NASA Marshall Space Flight Ctr. (United States) and The Univ. of Alabama in Huntsville (United States); Manel Errando, Barnard College (United States) and Columbia Univ. (United States); Brian Humensky, Columbia Univ. (United States); Reshmi Mukherjee, Barnard College (United States) and Columbia Univ. (United States); Daniel Nieto Garcia, Columbia Univ. (United States); Akira Okumura, Nagoya Univ. (Japan); Vladimir V. Vassiliev, Univ. of California, Los Angeles (United States)

The CTA (Cherenkov Telescope Array) is the next generation ground-?based experiment for very high-?energy (VHE) gamma-?ray observations. It will integrate several tens of imaging atmospheric Cherenkov telescopes (IACTs) with different apertures into a single astronomical instrument. The US part of the CTA collaboration has proposed and is developing a novel IACT design with a Schwarzschild-?Couder (SC) aplanatic two mirror optical system. In comparison with the traditional single mirror Davies-?Cotton IACT the SC telescope, by design, can accommodate a wide field-?of-?view, with significantly improved imaging resolution. In addition, the reduced plate scale of an SC telescope makes it compatible with highly integrated cameras assembled from silicon photo multipliers. In this submission we report on the status of the development of the SC optical system, which is part of the effort to construct a full-?scale prototype telescope of this type at the Fred Lawrence Whipple Observatory in southern Arizona. This project is funded by the NSF Major Research Instrumentation (MRI) program.

8861-4, Session 1

Efficient light collection from crystal scintillators using a compound parabolic concentrator coupled to an avalanche photodiode

Peter A. Jenke, Michael S. Briggs, Patrick Reardon, Valerie Connaughton, Narayana Bhat, The Univ. of Alabama in Huntsville (United States); Colleen Wilson-Hodge, NASA Marshall Space Flight Ctr. (United States)

In support of an improved gamma-ray detector for astrophysics and observations of Terrestrial Gamma-ray Flashes (TGFs), we have designed and tested a new approach for the collection and detection of optical photons from scintillators such as Sodium Iodide and Lanthanum Bromide using a light concentrator coupled to an Avalanche photodiode (APD). The APD has many advantages over traditional photomultiplier tubes such as their low power consumption, their compact size, their durability , and their very high quantum efficiency. The difficulty in using these devices in gamma-ray astronomy has been coupling their relatively small active area to the large scintillators necessary for gamma-ray science. Our solution is to use an acrylic Compound Parabolic Concentrator (CPC) to match the large output area of the scintillation crystal to the smaller photodiode. These non-imaging light concentrators exceed the light concentration of focused optics and are light and inexpensive to produce. We present our results from the analysis and testing of such a system including gains in light collecting efficiency, energy resolution of nuclear decay lines, as well as our design for a new, fast TGF detector.

8861-5, Session 2

Scientific prospects in soft gamma-ray astronomy thanks to the LAUE project

Filippo Frontera, Enrico Virgilli, Vineeth Valsan, Vincenzo Liccardo, Univ. degli Studi di Ferrara (Italy); Vito Carassiti, Univ. degli Studi di Ferrara (Italy) and Istituto Nazionale di Fisica Nucleare (Italy); Ezio Caroli, INAF - IASF Bologna (Italy); Ferdinando Cassese, Luca Recanatesi, DTM S.r.l. (Italy); Claudio Ferrari, Consiglio Nazionale delle Ricerche (Italy); Vincenzo Guidi, Univ. degli Studi di Ferrara (Italy) and Sensors and Semiconductors Lab. (Italy); Sergio Mottini, Massimiliano Pecora, Thales Alenia Space (Italy); Barbara Negri, Agenzia Spaziale

Italiana (Italy); Lorenzo Amati, INAF - IASF Bologna (Italy); Natalia Auricchio, Loredana Bassani, INAF - IASF Milano (Italy); Riccardo Campana, INAF - IASF Roma (Italy); Ruben Farinelli, Cristiano Guidorzi, Univ. degli Studi di Ferrara (Italy); Claudio Labanti, INAF - IASF Bologna (Italy); Raffaella Landi, Angela Malizia, INAF - IASF (Italy); Mauro Orlandini, Vito Sguera, John B. Stephen, INAF - IASF Bologna (Italy); Lev G. Titarchuk, Univ. degli Studi di Ferrara (Italy)

Today, thanks mainly to INTEGRAL and SWIFT, we have a good first idea of the gamma-ray sky in general and about the types of objects that populate this sky. The next obvious step is to zoom-in, focusing on individual objects with the goal of answering specific astrophysical questions about their emission physics, to discover the classes of sources that make the cosmic gamma-ray diffuse background, to solve astrophysical mysteries like the origin of the positron emission line from the Galactic Center region.

All that requires will a significant step in sensitivity comparable to the one done in X-ray by focusing telescopes, like "Einstein" first, after the sky survey obtained with the UHURU satellite.

With the LAUE project, devoted to build a broad band (80-600 keV) lens telescope, we have done a significant step in this direction. With the expected sensitivity and angular resolution that can reached in its passband, we will discuss the new prospects of soft gamma-ray astronomy thanks to Laue lenses .

8861-6, Session 2

The LAUE project and its main results

Enrico Virgilli, Filippo Frontera, Vincenzo Liccardo, Vineeth Valsan, Vito Carassiti, Stefano Chiozzi, Univ. degli Studi di Ferrara (Italy); Stefano Squerzanti, Istituto Nazionale di Fisica Nucleare (Italy); Michele Parise, Univ. degli Studi di Ferrara (Italy); Federico Evangelisti, Univ. degli Studi di Ferrara (Italy) and Istituto Nazionale di Fisica Nucleare (Italy); Marco Statera, Univ. degli Studi di Ferrara (Italy); Vincenzo Guidi, Valerio Bellucci, Riccardo Camattari, Ilaria Neri, Univ. degli Studi di Ferrara (Italy) and Sensors and Semiconductors Lab. (Italy); Ezio Caroli, Natalia Auricchio, Angelo Basili, Stefano Silvestri, John B. Stephen, INAF - IASF Bologna (Italy); Ferdinando Cassese, Luca Recanatesi, DTM S.r.l. (Italy); Claudio Ferrari, Andrea Zappettini, Elisa Buffagni, Consiglio Nazionale delle Ricerche (Italy); Sergio Mottini, Massimiliano Pecora, Thales Alenia Space (Italy); Barbara Negri, Agenzia Spaziale Italiana (Italy)

Focusing telescopes represents a breakthrough for the detection of hard-X and Gamma-rays for Astrophysics. Laue lens is a good candidate to reach the goal of increasing sensitivity and imaging capability with respect to the current direct-viewing telescopes. We will describe the LAUE project, supported by the Italian Space Agency along with a substantial contribution from the Italian industry, whose aim is to demonstrate the capability to build a focusing optics in the hard X-/soft Gamma rays. To show the lens feasibility, a Laue lens petal prototype with 20 m focal length is being built, as a part of an entire lens, made of petals, capable to focus photons in the 80-600 keV energy band. In addition to a detailed description of the new LARIX facility, in which the lens is being assembled, we will report the main results of the project.

8861-7, Session 2

The ground support equipment for the LAUE project

Ezio Caroli, Natalia Auricchio, Angelo Basili, INAF - IASF Bologna (Italy); Stefano Del Sordo, INAF - IASF Palermo (Italy); Filomena Schiavone, Stefano Silvestri, John B. Stephen, INAF - IASF Bologna (Italy); Enrico Virgilli, Vito Carassiti, Stefano Squerzanti, Univ. degli Studi di Ferrara (Italy); Massimiliano Pecora, Thales Alenia Space (Italy); Luca Recanatesi, Ferdinando Cassese, DTM S.r.l. (Italy)

Wide band Laue lens imaging is a challenging technology with possible important applications in hard X- and ?-ray space instrumentation in the coming decades. In the framework of a project funded by the Italian Space Agency dedicated to the development of a reliable technology to assemble a wide band Laue lens for use in space, our group had the responsibility for the realization of the ground support equipment (GSE). The GSE was implemented in a hard X-ray beam line built at the University of Ferrara and had the main purpose of controlling the assembly of crystals on the Laue lens petal and to verify its final performance. The GSE incorporates the management and control of all the movements the beam line mechanical subsystems and of the precision positioner (based on an Hexapod tool) of crystals on the petal, as well as the acquisition, storing and analysis of data obtained from the focal plane detectors (a HPGe spectrometer and a X-ray flat panel imager). The GSE is based on two PC's connected through a local network: one, placed inside the beam line, to which all the movement subsystems and the detector I/O interface and on which all the management and acquisition S/W runs, the other in the control room allows the remote control and implements the off-line analysis S/W of the data obtained from the detectors. Herein we report on the GSE structure with its interface with the beam line mechanical system, with the fine crystal positioner and with the focal plane detector. Furthermore we describe the SW developed for the handling of the mechanical moving subsystems and for the analysis of the detector data with the procedure adopted for the correct orientation of the crystals before their bonding on the lens petal support.

8861-8, Session 2

Results versus expectations obtained with the LAUE project

Vineeth Valsan, Filippo Frontera, Enrico Virgilli, Vincenzo Liccardo, Univ. degli Studi di Ferrara (Italy); Vito Carassiti, Univ. degli Studi di Ferrara (Italy) and Istituto Nazionale di Fisica Nucleare (Italy); Valerio Bellucci, Riccardo Camattari, Vincenzo Guidi, Ilaria Neri, Univ. degli Studi di Ferrara (Italy) and Sensors and Semiconductors Lab. (Italy); Elisa Buffagni, Claudio Ferrari, Consiglio Nazionale delle Ricerche (Italy); Natalia Auricchio, Ezio Caroli, Stefano Silvestri, John B. Stephen, INAF - IASF Bologna (Italy); Luca Recanatesi, DTM S.r.l. (Italy)

As part of the LAUE project for focusing hard X-/gamma rays, a petal of the complete lens is being assembled at the LARIX facility in the Department of Physics, University of Ferrara. The lens petal structure is composed of bent Germanium and Gallium Arsenide crystals in transmission geometry. We will present the test results obtained from the developed petal and compare them with the expectations derived from a mathematical model of the lens petal. The extension of the model for the complete LAUE project in the 80 – 600 keV energy range will be discussed as well.

8861-9, Session 2

Bent crystal selection and assembling for the LAUE project

Vincenzo Liccardo, Enrico Virgilli, Filippo Frontera, Vineeth Valsan, Univ. degli Studi di Ferrara (Italy); Vito Carassiti, Univ. degli Studi di Ferrara (Italy) and Istituto Nazionale di Fisica Nucleare (Italy); Valerio Bellucci, Riccardo Camattari, Univ. degli

Studi di Ferrara (Italy); Elisa Buffagni, Claudio Ferrari, Andrea Zappettini, Consiglio Nazionale delle Ricerche (Italy); Luca Recanatesi, DTM S.r.l. (Italy); Natalia Auricchio, Ezio Caroli, John B. Stephen, Stefano Silvestri, INAF - IASF Bologna (Italy)

Diffractive crystals have been employed for focusing photons in the 80 – 300 keV energy range in the framework of the LAUE project. For the first time, bent crystals have been used, taking advantage of their high reflectivity and excellent PSF with respect to the mosaic flat crystals. Simulations have already shown their excellent focusing capability which makes them the best candidates for a Laue lens whose sensitivity is driven by the dimension of the focused spot. Bent Germanium (perfect, 111) and Gallium Arsenide (mosaic, 220) were selected with the proper curvature to approach the spherical lens petal surface, with a 20 m long focal length. We will present, along with the obtained results, the measurement technique by which we are able to estimate the exact curvature of each tile within a few percent of uncertainty and their diffraction efficiency.

8861-10, Session 2

Quasi-mosaicity as a powerful tool to investigate coherent effects

Valerio Bellucci, Vincenzo Guidi, Riccardo Camattari, Ilaria Neri, Univ. degli Studi di Ferrara (Italy)

Quasi-mosaicity is a mechanical property driven by anisotropy in diamond-like structure crystals such as Si and Ge. QM crystals were recently proposed as optical components of a Laue lens for focusing hard X-rays (with energy larger than 70 keV). In contrast to a Laue lens based on conventional crystals (e.g. mosaic crystals), usage of QM crystals allows focusing the incident beam in a spot smaller than the dimension of the diffracting crystal. Focusing of photons in a small spot would allow an unprecedented resolution and sensitivity, together with a wide-passband response. In astrophysics, a Laue lens implementing QM crystals should allow observations of cosmic phenomena producing X-ray emissions with high sensitivity. As another, a Laue lens would be useful for imaging in nuclear medicine, leading to a lower radioactive dose imparted to the patient because of no need for tomography scanning. Quasi-mosaicity was also used for bending Si crystals in order to steer high-energy particles via coherent effects in crystals, viz. planar channeling and volume reflection. Channeled or reflected light particles are also useful as sources of gamma ray beams with intense flux, which can be either monochromatic or polychromatic.

8861-11, Session 2

Fabrication of quasi-mosaic Ge crystals for the LAUE project

Riccardo Camattari, Alessandro Battelli, Valerio Bellucci, Ilaria Neri, Vincenzo Guidi, Filippo Frontera, Univ. degli Studi di Ferrara (Italy)

Crystals having curved diffracting planes (CDP) are very promising for broad-band Laue lens, because they allow concentrating X-rays with high reflectivity. However, an intriguing effect of anisotropy in crystal deformation can be exploited to combine the high reflectivity of the CDP with the capability of focusing the radiation onto a very small focal spot. Primary curvature imparted to a crystal results in a secondary (quasi-mosaic) curvature of a different plane direction due to quasi-mosaic effect. Since the size of the focal spot can be controlled by the primary curvature and the quasi-mosaic curvature drives an increase of efficiency diffraction, quasi-mosaic crystals allow focusing with very high resolution. A series of 150 quasi-mosaic samples has been fabricated within the framework of the Laue project for the realization of a Laue lens prototype. Samples are 10x30x2 mm^3 Ge crystals, the planes being parallel to the largest surface are the (211), while quasi-mosaic CDP are the (111). To obtain the focalization of X-rays, the primary radius of curvature of samples is fixed at 40 m, i.e., twice the focal length, which is 20 m for the Laue project. The curvature has been imparted to the samples thanks to the grooving method, which makes it possible to realize self-standing curved plates. Bent quasi-mosaic Ge crystals were analyzed through ?-ray diffraction of their (111) CDP at ILL and ESRF (Grenoble), showing that quasi-mosaic curvature amplifies the diffraction efficiency by more than one order of magnitude with respect to an equivalent crystal without quasi-mosaic curvature.

8861-12, Session 3

X-ray diffraction efficiency of bent GaAs (220) mosaic crystals for the LAUE project

Claudio Ferrari, Elisa Buffagni, Elisa Bonnini, Andrea Zappettini, Consiglio Nazionale delle Ricerche (Italy)

In a Laue lens made by single crystals oriented to diffract parallel x-rays at the lens focus, the energy and angular resolution is limited by the crystal size and by the crystal mosaicity. The use of single crystals bent according to the lens curvature provides a better focussing also by using extended crystals, with the resolution given essentially by the crystal mosaicity.

With this approach a crystal mosaicity as low as 15-25 arcsecond, well below the mosaicity value of copper crystals, was found suitable for the new design of the Laue lens.

Flat mosaic GaAs crystals have been studied at synchrotron gamma rays energies up to 500 keV and using x-ray laboratory sources. The diffraction efficiency as a function of the energy has been measured in different samples. Results in reasonable agreement the with the assumption of nearly perfect mosaic crystals have been found.

The reflectivity and transmission profiles and the integrated intensity have been measured in bent GaAs and Si crystals prepared by the method of surface damaging by using sand paper of different grain size. The surface grinding induces a local lattice strain which produces a self standing bent crystal.

Bent crystals with radius of curvature lower than a critical value given by the extinction length behave as perfect mosaic crystals. It is found that the surface grinding does not affect the crystal diffraction efficiency, the damage thickness being limited to a few tens microns near the crystal surface.

8861-13, Session 3

Crystal bending by surface damage in Si and mosaic GaAs crystals for the LAUE project

Elisa Buffagni, Elisa Bonnini, Andrea Zappettini, Claudio Ferrari, Francesca Rossi, Consiglio Nazionale delle Ricerche (Italy)

Curved crystals, instead of perfect or mosaic crystals, can be used as optical elements of a Laue lens for hard x- and gamma-ray astronomy. In this work we propose to achieve the bending of the crystals by a controlled surface damaging, which introduces defects in a superficial layer of few tens nanometers in thickness undergoing a highly compressive strain.

Several (001) oriented silicon and gallium arsenide wafer crystals have been treated. The local and mean curvature radii of each sample have been determined by means of high resolution x-ray diffraction measurements in Bragg condition at low energy (8 keV). Silicon samples showed spherical curvatures, whereas GaAs treated samples evidenced an elliptical curvature with major axes corresponding to the <110> crystallographic directions. Curvature radii between 3 and 70 m were easily obtained in wafers of different thicknesses. The anisotropy of the crystal curvature is interpreted as due to the different dislocations glide velocity along the [110] and [1-10] directions.

Samples of different surface orientations, such as (100), (111) and (110) have been characterized, showing a dependence of the sample bending on the crystallographic orientation. The characterization of GaAs samples

performed in Laue geometry at gamma-ray energy of 120 keV confirmed the increase of the diffraction efficiency in the bent crystals.

8861-14, Session 3

LAUE lens development led by UC Berkeley: status and prospects

Nicolas M. Barrière, John A. Tomsick, Steven E. Boggs, Univ. of California, Berkeley (United States); Colin A. Wade, Univ. College Dublin (Ireland); Michael Jentschel, Institut Laue-Langevin (France); Marcelo D. Ackermann, cosine Research B.V. (Netherlands); Peter von Ballmoos, Gilles Roudil, Institut de Recherche en Astrophysique et Planétologie (France); Pierre Bastie, Lab. Interdisciplinaire de Physique (France); Alexander W. Lowell, Univ. of California, Berkeley (United States)

Laue lenses uniquely enable the concentration of soft gamma rays from a large collecting area onto a focal plane with a reasonably short focal length. In astronomy, they hold the promise of increasing telescope sensitivities by one to two orders of magnitude. The lenses are particularly well suited for observations of faint nuclear gamma ray lines from point sources, but they can also be optimized for continuum sources such as hard X-ray tails from a variety of compact objects.

We report on the status of the Laue lens development effort lead by UC Berkeley, where a dedicated X-ray beamline and a Laue lens assembly station were built, which allowed the realization of a first lens prototype in June 2012. Based on this achievement, and thanks to a new NASA APRA grant, we are moving forward to enable Laue lenses. Several parallel activities are in progress. Firstly, we are refining the method to glue quickly and accurately crystals on a lens substrate. Secondly, we are conducting a study of high-Z crystals to diffract energies up to 900 keV efficiently. And thirdly, we are exploring new concepts of Si-based lenses (for energies below 500 keV) that could further improve the focusing capabilities, increase the angular resolution, and even possibly enable true imaging lenses.

8861-15, Session 3

Bending and bonding Si single crystals for high performance Laue lenses

Marcelo D. Ackermann, Maximilien Collon, Giuseppe Vacanti, Ramses Guenther, Marco W. Beijersbergen, cosine Research B.V. (Netherlands); Nicolas M. Barrière, Univ. of California, Berkeley (United States); Jeroen Haneveld, Micronit Microfluidics BV (Netherlands)

Cosine has developed the technology to bend and directly bond Si mirror plates in order to produce stiff, lightweight X-ray optics which are used for large area space based X-ray telescopes. This technology, Silicon Pore Optics, also allows us to produce other types of high energy optics. Here we present the latest developments in the design and manufacture of a new generation of soft gamma-ray Laue lenses made using SPO technology.

The bending and bonding of 300 ?m thin Si single crystals allows us to fabricate a single crystal with radially curved crystal planes, which strongly improves the focussing properties of a Laue lens. The size of the focal spot is no longer determined by the size of the individual single crystals, but by the accuracy of the applied curvature, which is as low as a few arcseconds. Furthermore, a wedge is incorporated in each individual Si crystal to ensure that all crystals are confocal in the radial direction. A secondary curvature in the axial direction can be used to improve the reflectivity of each crystal, and increase the reflected energy bandwidth. The expected focussing power of this type of Laue lens crystals is so great that even double reflection gamma-ray imaging systems could be considered.

We present the first crystals which are manufactured in the spring of 2013. These are technology demonstrators designed for 125 keV radiation, 5m focal length and 180mm2 frontal area. The first measurements at synchrotron facilities are expected later this year.

8861-16, Session 4

Calibration of the soft x-ray telescopes (SXT) onboard the ASTRO-H satellite

Yang Soong, NASA Goddard Space Flight Ctr. (United States) and The Ctr. for Research and Exploration in Space Science and Technology (United States); Takashi Okajima, Peter Serlemitsos, NASA Goddard Space Flight Ctr. (United States); Devin J. Hahne, Johns Hopkins Univ. Applied Physics Lab. (United States) and NASA Goddard Space Flight Ctr. (United States)

Two soft x-ray telescopes (SXT) onboard ASTRO-H were integrated from four mirror quadrants. Stray-light baffles, in quadrant configuration, were mounted onto the integrated telescope. Thermal control units were also attached to the perimeter of the integrated telescope. The completed instrument went through a series of optical alignment, thus made the quadrant images confocal and their optical axes in parallel to achieve highest throughput possible. Environmental tests were carried out, and optical quality of the telescopes has been confirmed afterwards. The optical and x-ray calibrations include: angular resolution, effective area in the energy range of ~ 0.4 – 12keV, off-axis response, etc. X-ray image half power diameter is at 1 arc-minute level, and the effective area is ~ 87% of the theoretical. PSF of the X-ray image shows the dominant errors of reflectors' figure and of the reflector alignment. Loss of the effective area is mainly due to positional mismatching of their corresponding reflector pairs in the two reflecting stages. Result of the calibrations and suggestions for future improvement will be presented.

8861-17, Session 4

First result from a ground calibration of the hard x-ray telescope onboard ASTRO-H satellite

Takuya Miyazawa, Hiroyoshi Kato, Tadatsugu Demoto, Yuuji Kuroda, Shunya Takizawa, Fumiya Shimasaki, Keisuke Tamura, Yoshito Haba, Kazunori bish Ishibasi, Hironori Matsumoto, Yuzuru Tawara, Hideyo Kunieda, Naoki Ishida, Nagoya Univ. (Japan); Hideyuki Mori, Yoshitomo Maeda, Manabu Ishida, Japan Aerospace Exploration Agency (Japan); Hisamitsu Awaki, Daichi Kurihara, Ehime Univ. (Japan); Kentaro Uesugi, Yoshio Suzuki, Japan Synchrotron Radiation Research Institute (Japan)

We report a first result from a ground-based X-ray calibration of the ASTRO-H Hard X-ray Telescope (HXT) at a synchrotron radiation facility SPring-8. ASTRO-H, to be launched in 2015, is Japan's sixth X-ray satellite mission following to Suzaku satellite. One of the features of ASTRO-H is a simultaneous observation between 0.3 keV to 600 keV with several instruments. ASTRO-H has two HXTs to cover hard x-rays up to 80 keV. HXT, which is one of the key instruments in ASTRO-H, is the conically approximated Wolter-I grazing incidence optics similar to the Suzaku X-ray telescope. Reflector surfaces are coated with depth-graded Platinum and Carbon multilayer to reflect hard X-rays efficiently. In 2011, the integration of the first flight optics (HXT-1) of HXTs were completed, and we performed a ground calibration of HXT-1 at a synchrotron radiation facility, SPring-8 beamline BL20B2 to build a response function of HXT. We use a raster scan method with a pencil beam at the baseline length of 200m. A point spread function and effective area were measured at 30, 40, 50, 60, 70keV. From a preliminary analysis of the data, an angular resolution of 1.5 - 1.9 arcmin. was obtained at five energy bands in the full telescope. The effective area is 170 cm2 at 30 keV and 82 cm2 at 50 keV, respectively. The as-measured effective area at 30 and 50 keV meet the requirement of the ASTRO-H HXT.

8861-18, Session 4

Status of the eROSITA Observatory: testing and calibrating the x-ray mirror assemblies

Vadim Burwitz, Peter Predehl, Peter Friedrich, Heinrich Braeuninger, Elmar Pfeffermann, Wolfgang Burkert, Maria Fürmetz, Gisela Hartner, Benedikt Menz, Max-Planck-Institut für Extraterrestrische Physik (Germany); Gabriele Grisoni, Giuseppe Valsecchi, Fabio Marioni, Media Lario Technologies (Italy)

The eROSITA X-ray observatory that will be launched on board the Russian Spectrum-RG mission comprises seven X-ray telescopes, each with its own mirror assembly (mirror module + X-ray baffle), electron deflector, filter wheel, and CCD camera with its control electronics. The completed flight mirror modules are undergoing many thorough X-ray tests at the PANTER X-ray test facility after delivery, after being mated with the X-ray baffle, and again after both the vibration and thermal-vacuum tests. A description of the work done with mirror modules/assemblies and the test results obtained will be reported here. We will also report on the environmental tests that have been performed on the eROSITA observatory structure / optical bench.

8861-19, Session 4

Development of mirror modules for the ART-XC instrument aboard the Spectrum-Roentgen-Gamma mission

Mikhail V. Gubarev, Brian Ramsey, Stephen L. O'Dell, Ronald F. Elsner, Kiranmayee Kilaru, NASA Marshall Space Flight Ctr. (United States); Carolyn Atkins, The Univ. of Alabama in Huntsville (United States); Mikhail N. Pavlinskiy, Alexey V. Tkachenko, Igor Y. Lapshov, Space Research Institute (Russian Federation)

The Marshall Space Flight Center (MSFC) is developing x?ray mirror modules for the Astronomical Roengen Telescope- X-ray Concentrator (ART?XC) instrument on board the Spectrum?Roentgen?Gamma Mission. ART?XC will consist of seven co?aligned x?ray mirror modules with seven corresponding CdTe focal plane detectors. Each module provides an effective area of 65 cm2 at 8 keV, response out to 30 keV, and an angular resolution of 45 arcsec or better HPD. We will present a status of the ART x?ray module development at MSFC.

8861-20, Session 5

X-ray optics developments at ESA

Marcos Bavdaz, Eric Wille, Kotska Wallace, Brian Shortt, Sebastiaan Fransen, Nicola Rando, European Space Research and Technology Ctr. (Netherlands); Maximilien Collon, Marcelo D. Ackermann, Giuseppe Vacanti, Ramses Guenther, cosine Research B.V. (Netherlands); Jeroen Haneveld, Mark Olde Riekering, Arenda Koelewijn, Micronit Microfluidics B.V. (Netherlands); Coen van Baren, SRON Netherlands Institute for Space Research (Netherlands); Dirk Kampf, Kayer-Threde GmbH (Germany); Karl-Heinz Zuknik, Arnd Reutlinger, Kayser-Threde GmbH (Germany); Finn E. Christensen, Desiree Della Monica Ferreira, Anders C. Jakobsen, DTU Space (Denmark); Michael Krumrey, Physikalisch-Technische Bundesanstalt (Germany); Peter Müller, Physikalisch-Technische Bundesanstalt (PTB) (Germany); Vadim Burwitz, Max-Planck-Institut für Extraterrestrische Physik (Germany); Giovanni Pareschi, Mauro Ghigo, Marta M. Civitani, Laura Proserpio, INAF - Osservatorio Astronomico di Brera (Italy); Daniele Gallieni, A.D.S. International S.r.l. (Italy); Matteo Tintori, Pierluigi Fumi, ADS International (Italy); Francesco Martelli, Giancarlo Parodi, BCV Progetti S.r.l. (Italy); Ivan Ferrario, Media Lario Technologies (Italy)

Future high energy astrophysics missions will require high performance novel X-ray optics to explore the Universe beyond the limits of the currently operating Chandra and Newton observatories. Innovative optics technologies are therefore being developed and matured by ESA in collaboration with research institutions and industry, enabling leading-edge future science missions.

Silicon Pore Optics (SPO) and Slumped Glass Optics (SGO) are lightweight high performance X-ray optics technologies being developed in Europe, driven by applications in observatory class high energy astrophysics missions, aiming at angular resolutions of 5" and providing effective areas of one or more square meters at a few keV.

This paper will report on the development activities led by ESA, and the status of the SPO and SGO technologies, including progress on high performance multilayer reflective coatings. In addition, the progress with the X-ray test facilities and associated beamlines will be reported.

8861-21, Session 5

Aberration-free silicon pore x-ray optics

Maximilien Collon, Marcelo D. Ackermann, Ramses Guenther, Giuseppe Vacanti, Marco W. Beijersbergen, cosine Research B.V. (Netherlands); Marcos Bavdaz, Eric Wille, Kotska Wallace, European Space Research and Technology Ctr. (Netherlands); Jeroen Haneveld, Mark Olde Riekerink, Arenda Koelewijn, Micronit Microfluidics B.V. (Netherlands); Coen van Baren, SRON Netherlands Institute for Space Research (Netherlands); Peter Müller, Michael Krumrey, Physikalisch-Technische Bundesanstalt (Germany); Vadim Burwitz, Max-Planck-Institut für Extraterrestrische Physik (Germany)

Silicon Pore Optics is an enabling technology for future L- and M-class astrophysics X-ray missions that require high angular resolution (~5 arc seconds) and large effective area (1 to-2 m? at a few keV). The technology exploits the high-quality of super-polished 300 mm silicon wafers and the associated industrial mass production processes, which are readily available in the semiconductor industry. The plan-parallel wafers have a surface roughness better than 0.1 nm rms and are diced, structured, wedged, coated, bent and stacked to form modular Silicon Pore Optics lenses, which can be grouped into a larger optic. The lenses are assembled from silicon alone, with all the mechanical advantages, and form an intrinsically stiff pore structure.

The optics design was initially based on long (25 to 50 m) focal length X-ray telescopes, which could achieve several arc second angular resolution by curving the silicon mirror in only one direction (conical approximation).

Recently shorter focal length missions (10 to 20 m) have been discussed, for which we started to develop Silicon Pore Optics having a secondary curvature in the mirror that will allow producing Wolter-I type optics, which are on axis aberration-free.

In this paper we will present the new manufacturing process, the results achieved and the lessons learned.

8861-22, Session 5

High resolution and high throughput x-ray optics for future astronomical missions

William W. Zhang, NASA Goddard Space Flight Ctr. (United States)

In this paper we will report on the status of the Next Generation X-ray

Optics work that is going on at NASA Goddard Space Flight Center and NASA Marshall Space Flight Center. This works has two objectives. In the near term, one to three years, we intend to make ready a technology that is capable of matching XMM-Newton's angular resolution (~10") while reducing its mass by an order or magnitude from ~3,000 to ~300 kg/m2. Put it another way, this technology will match Suzaku telescopes mass while improving its angular resolution by more than an order of magnitude from ~120" to ~10". In the long term, three to ten years, we intend to develop a process that is capable of making x-ray telescopes comparable to Chandra in angular resolution while reducing its mass per unit area by a factor of 50, thereby enabling a multi-square-meter collection area on a similar platform. We use slumped glass mirror segments to realize the near term goal, and polished silicon mirrors the long term goal. We are developing a comprehensive process of aligning, bonding, and testing of these extremely lightweight mirror segments and modules.

8861-23, Session 5

Design, construction, and testing of lightweight x-ray mirror modules

Ryan S. McClelland, SGT, Inc. (United States); William W. Zhang, NASA Goddard Space Flight Ctr. (United States); Michael P. Biskach, SGT, Inc. (United States)

The segmented slumped glass X-ray mirror technology being developed at NASA Goddard Space Flight Center (GSFC) has reached sufficient maturity to begin design, construction, and testing of flight-like mirror modules. Launching the mirror modules with integrated thin glass segments while maintaining mirror figure and alignment at ~10 arc-sec angular resolution presents unique design challenges. Issues such as high frequency vibro-acoustic response of the glass mirror segments, strength of the bonds attaching the mirrors to the module structure, and horizontal self-weight deformation of the module are especially challenging. Technology Development Modules (TDMs), holding six mirror segments each, which demonstrate the modules meet generic flight requirements have been designed, constructed, and tested. Successful environmental tests including thermal vacuum, random vibration, acoustic, and shock loading have demonstrated the performance of the TDMs in space flight environments. Results indicate that an X-ray mirror module with ~10 arc-sec angular resolution can be ready for mission implementation in the near future. TDMs holding dozens of mirror segments which will further demonstrate the flight readiness of this technology are currently being designed and analyzed.

8861-24, Session 5

Development of four-stage x-ray telescope (FXT) for DIOS mission

Satoshi Sugita, Yuzuru Tawara, Ikuya Sakurai, Nagoya Univ. (Japan)

FXT (Four Stage X-ray Telescope) has been developed as the best fit optics for DIOS which is a small satellite mission for mapping observation of the warm-hot intergalactic medium.Based on the small diameter demonstration model in last year, we developed a fabrication process of large diameter (over 500 mm) foil mirror.

And then we made a new housing which was full-size of 600 mm diameter and holded mirrors by four stage integrated alignment plates.

In this talk we report a production of the large diameter mirrors and a performance measurement of the new quadrant housing.

8861-25, Session 6

Light-weight glass mirror systems for future x-ray telescopes

Anita Winter, Peter Friedrich, Elias Breunig, Max-Planck-Institut für Extraterrestrische Physik (Germany)

We present our latest results of the glass slumping activities at MPE. We have investigated methods for mounting and integration of the glasses and have further improved our measurement methods. Furthermore we look into new possible materials for future slumping moulds. Three highly polished glass sheets have been slumped on our best slumping mould to date, therefore omitting influence of thickness variations on the slumped glass. These glass segments can be said to represent the best possible glass mirror qualities with the current slumping method at MPE. The results of the X-ray test of these glasses and future outlook are presented.

8861-26, Session 6

Non-touch thermal air-bearing shaping of x-ray telescope optics

Edward Sung, Brandon Chalifoux, Mark L. Schattenburg, Massachusetts Institute of Technology (United States); Ralf Heilmann, MIT Kavli Institute for Astrophysics and Space Research (United States)

Traditional methods for thermal shaping of thin glass x-ray mirrors use a solid mandrel, to which a thin sheet conforms at high temperature. This method results in mid-spatial frequency errors and requires a very slow thermal cycling process lasting on the order of days. This paper reports on progress in the development of a non-contact slumping technique that could solve both drawbacks. As an initial step, we focus on achieving flat surfaces instead of the curvature required for x-ray optics. The thin glass is placed between two precision ground horizontal porous ceramic air bearings and is pushed flat due to air pressure as it is thermally cycled. To keep the glass centered, a closed control loop is used, which consists of custom high temperature fiber optic position sensors and bearing tilt actuation. A previously reported actuation method of using fluid shear force on the surface of the glass via bearing-to-bearing angle has been abandoned in favor of tilting the device to use gravity to control the position of the glass. The thermal cycling time required is ten hours or less. The air bearing technique can produce optical surface shapes quickly and with repeatability, allowing for faster production of high quality x-ray optics.

8861-27, Session 6

Evaluation of the surface strength of glass plates shaped by hot slumping process

Laura Proserpio, Giuseppe Crimi, Bianca Salmaso, Mauro Ghigo, INAF - Osservatorio Astronomico di Brera (Italy); Alberto D'Este, Roberto Dall'Igna, Mirko Silvestri, Stazione Sperimentale del Vetro (Italy); Giancarlo Parodi, Francesco Martelli, BCV Progetti S.r.l. (Italy)

The Hot Slumping Technology is under development by several research groups in the world for the realization of X-ray segmented mirrors: thin glass foils are shaped over a mandrel above their transformation temperature. The performed thermal cycle and related operations might affect the glass strength, both on its surfaces or edges, with possible consequences on the structural design of the whole telescope. No reference technical literature exists since the strength of glass is not an intrinsic property of the material depending only on its composition and fabrication process rather it depends on several parameters, e.g. distribution of surface flaws or residual internal stresses from production

process, connected to any of the manufacturing steps. It is therefore extremely important to test the mechanical strength of the glass after it underwent the slumping process, to obtain reliable data to be employed in the structural analyses. The Astronomical Observatory of Brera (INAF-OAB) conducted a deep analysis at this regards, with the collaboration of Stazione Sperimentale del Vetro (SSV) and BCV Progetti. The entire study have been realized on glass D263 by Schott, currently considered for the realization of next-generation IXO-like X-ray telescopes. More than 200 slumped samples of dimension 100mmx100mm and thickness 0.4mm, both flat and curved, have been produced following the same manufacturing and handling processes effectively envisaged on real segments; they have been tested with double ring tests and the collected empirical data have been treated with Weibull statistics. The paper describes the entire activity and presents the results obtained.

8861-28, Session 6

High-precision shaping of x-ray telescope optics using ion implantation

Brandon Chalifoux, Edward Sung, Massachusetts Institute of Technology (United States); Ralf Heilmann, MIT Kavli Institute for Astrophysics and Space Research (United States); Mark L. Schattenburg, Massachusetts Institute of Technology (United States)

Achieving both high resolution and large collection area in the next generation of x-ray telescopes requires highly accurate shaping of thin mirrors, which is not achievable with current technology. Ion implantation offers a promising method of modifying the shape of mirrors by imparting internal stresses in a substrate, which are a function of the ion species and dose. This technique has the potential for highly deterministic substrate shape correction using a rapid, low cost process. Wafers of silicon and glass (D-263 and BK-7) have been implanted with Si+ ions at 150 keV, and the changes in shape have been measured using a Shack-Hartmann metrology system. We show that a uniform dose over the surface repeatably changes the spherical curvature of the substrates, and we show correction of spherical curvature in wafers. Modeling based on experiments with spherical curvature correction shows that ion implantation could be used to eliminate higher-order shape errors, such as astigmatism and coma, by using a spatially-varying implant dose. We will report on progress in modelling and experimental tests to eliminate higher-order shape errors. In addition, the results of experiments to determine the thermal and temporal stability of implanted substrates will be reported.

8861-29, Session 6

Development of light weight replicated x-ray optics

Suzanne E. Romaine, Ricardo Bruni, Harvard-Smithsonian Ctr. for Astrophysics (United States); Brian Choi, ReliaCoat Technologies, LLC (United States); Paul Gorenstein, Harvard-Smithsonian Ctr. for Astrophysics (United States); Christopher Jensen, ReliaCoat Technologies, LLC (United States); Brian Ramsey, NASA Marshall Space Flight Ctr. (United States); Richard Rosati, Harvard-Smithsonian Ctr. for Astrophysics (United States); Sanjay Sampath, Stony Brook Univ. (United States)

X-ray astronomy grazing incidence telescopes use the principle of nested shells to maximize the collecting area. Some missions, such as XMM-Newton, and the upcoming Spectrum-Röntgen-Gamma mission use an electroformed nickel replication (ENR) process to fabricate the nested shell grazing incidence X-ray telescope mirror shells. We are developing a process to fabricate metal-ceramic replicated optics which will be lighter weight and potentially much stiffer than current ENR mirror shells.

Recent results on fabrication and testing of these optics is presented.

8861-63, Session 6

Very-high-imaging resolution and large-throughput x-ray telescopes based on monolithic thin shells

Oberto Citterio, Marta M. Civitani, Stefano Basso, Paolo Conconi, Mauro Ghigo, Enrico Mattaini, Alberto Moretti, Giovanni Pareschi, INAF - Osservatorio Astronomico di Brera (Italy); Giancarlo Parodi, BCV Progetti S.r.l. (Italy); Gianpiero Tagliaferri, INAF - Osservatorio Astronomico di Brera (Italy)

The implementation of a X-ray mission with high imaging capabilities, similar to those achieved with Chandra (< 1 arcsec Half Energy Width, HEW), but with a much larger throughput is a very attractive perspective, even if challenging. For such a mission the scientific opportunities, in particular for the study of the early Universe, would remain at the state of the art for the next decades. At the beginning of the new millennium the XEUS mission has been proposed, with an effective area of several m2 and an angular resolution better than 2 arcsec HEW. Unfortunately, after the initial study this mission was not implemented, mainly due to the costs and lack of technology readiness. Currently the most advanced proposal for such a kind of mission is the SMART-X project, led by CfA and involving several other US Institutes. This project is based on adjustable segments of thin foil mirrors with piezo-electric actuators, aiming to achieve an effective area > 2 m2 at 1 keV and an angular resolution better than 1 arcsec HEW. Another attractive technology to realize a X-ray telescope with similar characteristics is being developed at NASA/Goddard. In this case the mirrors are based on Si substrates that are super-polished and figured starting from a bulky Si ingot, from which they are properly cut. Here we propose an alternative method based on precise direct grinding, figuring and polishing of thin (a few mm) glass shells with innovative deterministic polishing methods, as e.g. the bonnet polishing. This is followed by a final correction via ion figuring to obtain the desired accuracy in order to achieve the 1 arc sec HEW requirement. For this purpose, a temporary stiffening structure is used to support the shell from the polishing operations up to its integration in the telescope supporting structure. We will present the technological process under development, the results achieved so far and some mission scenarios based on this kind of optics, aiming to achieve an effective area of 1 m2 and an angular resolution of 1 arcsec HEW.

8861-30, Session 7

Coating and bonding thin mirror segments for lightweight x-ray optics

Kai-Wing Chan, NASA Goddard Space Flight Ctr. (United States)

Next generation's lightweight, high resolution, high throughput optics for x-ray astronomy requires integration of very thin mirror segments with extremely large aspect ratio into a lightweight telescope housing without distortion. Thin glass and silicon substrates with aspect ratio as large as 500 – 1000 can now be fabricated with precision. Subsequent implementation requires distortion-free deposition of reflective metallic films and mounting of these mirrors. We will present the result of thin-film coating with magnetron sputtering and atomic layer deposition, the bonding of these segments into their experimental strongbacks, the metrology and qualification of the remaining uncertainties.

8861-31, Session 7

Alignment measurement and permanent mounting of thin lightweight x-ray mirror segments

Michael P. Biskach, Mark Schofield, SGT, Inc. (United States); William W. Zhang, NASA Goddard Space Flight Ctr. (United

States); Kai-Wing Chan, Univ. of Maryland, Baltimore County (United States); Timo Saha, NASA Goddard Space Flight Ctr. (United States); Ryan S. McClelland, James Mazzarella, SGT, Inc. (United States)

Next generation X-ray optics requires precision alignment and permanent mounting of glass mirror segments. Permanent mounting of each segment must meet optical precision, mechanical strength, as well as long term stability requirements of a multiyear mission. Technology Development Modules (TDM's) containing three aligned and permanently mounted glass segment pairs have been constructed and tested by the (Next Generation X-ray Optics) NGXO team at NASA's Goddard Space Flight Center to demonstrate segment alignment and permanent mounting procedures meet initial performance goals as well as survivability requirements. Improvements to the mirror segment alignment and mounting process in the past 12 months are presented along with associated TDM X-ray test results. Objectives for future work are outlined as the near term effort to produce a fully populated module that meets mission requirements continues.

8861-32, Session 7

Shape control of modular x-ray optics during integration and alignment

Elias Breunig, Peter Friedrich, Anita Winter, Max-Planck-Institut für Extraterrestrische Physik (Germany)

MPE is involved in the development of slumped glass mirrors since many years. We use an indirect slumping method wwhich produce a complete parabola-hyperbola segment in a single piece. Recent advances in mirror quality have raised the need for a better understanding and design of the integration and alignment process.The two key issues are the handling of a mirror segment during assembly where gravity distortion is of concern, and the technology to structurally integrate the mirror segments with the mirror module. This integration has to be dimensionally stable and also robust enough to sustain launch loads.

Both steps can introduce significant shape error to the mirror. Since we pursue a design philosophy that ultimately aims for a zero stress assembly, our approach is based on the application of isostatic mounting principles and gravity compliance to minimize distortion effects. We have conducted FEM Analysis and experimental investigations to show that a vertical suspension mount can serve as a good basis for our mirrors. Especially in conjunction with a isostatic interface to the module structure. However, since such an isostatic mount can not fully support the mirror during launch, additional elements ('launch locks') may have to be introduced into the system. We have conducted numerical analsis of the bonding of the mirror segement to the supporting structure to better optimize the detailed design of the interfaces and we are currently working on an experimental quantification / calibration of those results. We are also investigating the possibility of a adhesive free integration which would have the advantage of being faster and less complicated with respect to the special properties of common adhesives like shrinkage and outgasing.

8861-33, Session 7

Direct hot slumping and accurate integration process to manufacture prototypal x-ray optical units made of glass

Marta M. Civitani, Stefano Basso, Mauro Ghigo, Laura Proserpio, Daniele Spiga, Bianca Salmaso, Giovanni Pareschi, Gianpiero Tagliaferri, INAF - Osservatorio Astronomico di Brera (Italy); Marcos Bavdaz, Eric Wille, European Space Research and Technology Ctr. (Netherlands)

X-ray telescopes with large collecting area, like the proposed International X-ray Observatory (IXO) with around 3m^2 @ 1 keV), need to be composed of a large number high quality mirror segments, aiming at achieving a global spatial resolution better than 5 arcsec (HEW). A possible technology to realize the modular elements that will compose the whole optics, named X-ray Optical Units (XOUs), consists in stacking in Wolter-I configuration several layers of thin foils of borosilicate glass, previously formed by hot slumping. The XOUs are subsequently assembled to form complete multi-shell optics with Wolter-I geometry. The achievable global angular resolution of the optic relies on the required surface shape accuracy of slumped foils, on the smoothness of the mirror surfaces and on the correct integration and co-alignment of the mirror segments. Since few years, the Brera Astronomical Observatory (INAF-OAB), with the support by ESA, is leading a study concerning the production of the mirror segments trought the direct hot slumping of thin glass foils. Moreover an innovative assembly concept making use of Wolter-I counter-forms and glass reinforcing ribs is under developement. The ribs connect pairs of consecutive foils in an XOU stack, playing a structural and a functional role. Infact, as the ribs constrain the foil profile to the correct shape during the bonding , they allow the dump of the low-frequency profile errors still present on the foil after slumping. A dedicated semirobotic Integration MAchine (IMA) has been realized and used to build the first integrated prototypes made of several layers of slumped plates. In this paper we will give an overview of the project and a status report of the results achieved, in particular regarding the development of representative breadboards, based on several confocal shells, calibrated at Panter/MPE

8861-34, Session 8

Updated coating design for ATHENA

Desiree Della Monica Ferreira, Finn E. Christensen, Anders C. Jakobsen, DTU Space (Denmark); Brian Shortt, European Space Research and Technology Ctr. (Netherlands); Niels Jørgen S. Westergaard, DTU Space (Denmark)

The ATHENA mission concept continues to be refined to address important questions in modern astrophysics. Previous studies have established that the requirement for effective area can be achieved using a combination of bi-layer coatings and/or simple graded multilayers. We find that further coating developments can improve on the baseline specifications and present here the updated results on the optimization of coating design for the ATHENA mission. The performances of several material combinations are investigated with the goal of maximizing the telescope effective area within the energy envelope of the mission and simulation of mirror performance is carried out including realistic effects of scatter and coating non-uniformities both on- and off-axis.

8861-35, Session 8

Optimal coating design for x-ray optic in CERN Axion Solar Telescope

Anders C. Jakobsen, DTU Space (Denmark); Michael J. Pivovaroff, Lawrence Livermore National Lab. (United States); Finn E. Christensen, DTU Space (Denmark)

In this paper, a computer model has been developed to optimize a Wolter I X-ray telescope to be installed at the CERN Axion Solar Telescope (CAST). The geometric configuration was calculated to give maximum throughput with only a 1.5 m focal length. Optical coatings for X-ray reflectivity was optimized with respect to detector quantum efficiency (QE) and axion spectrum. Coatings considered were multilayers and single bilayers of W/Si, W/B4C, Pt/C, Pt/B4C, Ni/B4C and Ni/C as well as single layers of Pt, W, Ni and Ir. A comparison between the optimal coating of each material combination is presented.

8861-36, Session 8

Design scheme and fabrication of the supermirror with broad bandwidth and flattop response for hard x-ray telescopes

Youwei Yao, Hideyo Kunieda, Nagoya Univ. (Japan)

We present our design and fabrication scheme of supermirror with broad bandwidth and flat-top response for hard X-ray telescopes. A Platinum-Carbon Non-periodic multilayer of 123 layer pairs with a varying d-space of 2-6nm were designed and successfully fabricated to enhance the reflectivity in the energy band from 11 to 55keV with flat top of 20% at grazing angle of 0.28deg. It is applicable for hard X-ray optics in general. The structure of this mirror was obtained by a conventional design process, i.e. the combination of an initial multilayer structure and a local optimization process. An evaluation process which consists of 3 steps has been used to check the validity of the designed structure for our application. First, the robustness of the grazing angle has been checked to demonstrate the consistent off-axis response of the designed structure. Second, the concept of “equivalent layer number” has been defined to evaluate the efficiency of the optimization process. Third, the fabrication difficulty has been carefully considered in the practical point of view. Then, a fabrication process has been established and the designed structure was deposited on a float glass by our DC magnetron sputtering system. The energy response has been measured by our X-ray beam line. The measurement result suggests a convincible reflectivity profile which is about 20% with little oscillation in the entire target band.

8861-37, Session 8

High reflectivity multilayers for hard x-ray and soft gamma-ray applications

Michael J. Pivovaroff, Jennifer Alameda, Sherry L. Baker, Nicolai F. Brejnholt, Marie-Anne Descalle, Monica Fernandez-Perea, Thomas J. McCarville, Paul B. Mirkarimi, Regina Soufli, Julia K. Vogel, Lawrence Livermore National Lab. (United States); Finn E. Christensen, Desiree Della Monica Ferreira, Anders C. Jakobsen, Niels Jørgen S. Westergaard, DTU Space (Denmark); Mark J. Harrison, Donald E. Hornback, Klaus P. Ziock, Oak Ridge National Lab. (United States); Viejo Honkimäki, Eric Ziegler, European Synchrotron Radiation Facility (France); Zhong Zhong, Brookhaven National Lab. (United Kingdom); Ricardo Bruni, Suzanne E. Romaine, Harvard-Smithsonian Ctr. for Astrophysics (United States)

Advances in x-ray reflective optics, including innovations in designs, manufacturing, and reflecting coatings, have traditionally come from the astrophysics and x-ray light source communities. The success of observatories like Chandra and XMM-Newton and the number of researchers who use synchrotron (and increasingly free electron lasers) has enabled the use of x-ray optics in a broad range of disciplines, including diagnostics for laser-plasma facilities, biomedical research and national security missions. Here, we report on measurements of WC/SiC multilayers at energies ranging from 8 to 400 keV that were performed as part of a research program for nuclear Safeguards. Fitting to the experimental data indicate that a single model, derived from low energy data, can consistently predict performance across the entire energy band. Reflectivity exceeding 50% was achieved at 386 keV. Above 100 keV, we show that is extremely important to include incoherent scattering effects when interpreting data. These effects are not included in the classical wave treatment typically used to calculate multilayer performance and must be calculated using appropriate Monte Carlo particle transport codes. We describe the WC/SiC systems we have developed, the experimental results and discuss the limits of multilayer performance we think achievable for future astrophysics missions. A companion paper in this conference uses these results to derive point-designs for various high-energy astrophysics missions.

Part of this work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

8861-38, Session 8

Hard x-ray/soft gamma ray telescope designs for future astrophysics missions

Desiree Della Monica Ferreira, Finn E. Christensen, Niels Jørgen S. Westergaard, Anders C. Jakobsen, DTU Space (Denmark); Michael J. Pivovaroff, Marie-Anne Descalle, Regina Soufli, Monica Fernandez-Perea, Nicolai Brejnholt, Julia K. Vogel, Lawrence Livermore National Lab. (United States)

We present several strawman designs of hard X-ray/soft Gamma ray focusing telescopes for future astrophysics missions. The designs are based on depth graded multilayer coatings. These have been successfully employed on the NuSTAR mission for energies up to 80 keV. Recent advancement in demonstrating theoretical reflectivity for multilayer material combinations up to 400 keV, including effects of incoherent scatter, has given the experimental base for extending multilayer designs to the soft Gamma ray range (see also companion paper at this conference) . At the same time, the calibration of the in-flight performance of the NuSTAR mission allows for a solid understanding and modeling of all relevant effects influencing the performance, including optical constants, roughness, scatter, non-uniformities and figure error. Those permit a realistic extension of the predictions for designs going to much higher energies. Similarly, both thin slumped glass and silicon pore optics substrates have been developed to a prototype stage which promises imaging resolution in the sub 10 arcsec range. We present designs based on both types of substrates, taking into consideration all the developments listed above.

8861-39, Session 8

Exploring the near absorption-edge optical constants for enhanced and sensitive grazing incident reflectvity

Mewael G. Sertsu, Piergergio Nicolosi, Univ. degli Studi di Padova (Italy)

Generally speaking, reflectiity of EUV and X-ray radiations is very low. Reflectivity gets even lowest for perpendicular incidences. The thin film multilayers came into picture to resove this problem. By now, the EUV multilayers are well known both in academia and companies for applications in EUV lithography, high resolution imaging, solar corona imaging, attpsecond radation manuplaton, etc..

For a well designed multilayers of atleast two different materials, there is a region of wavelength where the refractive index contrast is higher . Those region of spectrum are actually near the absorption edges of either of the constituent elements. Thus, an EUV mulitlayer designed by taking into considaration such greater index contrast near the absorption edge gives better reflectivity and sensitivity to small parameter fluctuations on the surface and buried layers of few nanometer depth.

Theoretical and numerical studies of reflectvity near Si-L edge for multilayers with Si as one of the multilayer materials are performed here. Multilayers of Si/Mo , Ir/Si and Si/ZrSiO4 are numerically studied. The reflectivity is calculated by adopting the recursive Parrate’s method. Two design models are used for multilayers. The statstical mode(two-layer-model) and the Interlayer model(four-layer-mode) are coded in Matlab. Both of them could fit well to the experimentally measured reflectivity by varying structural and optical parameters of the multilayers. However, the interlayer model have additional advantage in that one can study the phases of the interlayer compounds formed at the interfaces and thier thicknesses. This technique gives encouraging sensitivity to the phases of interlayer formation and thicknesses. In otherwords, it could be instrumental in studying the optical and structreral properties of buried interfaces with better sensitivity level. Its analogy to the XANES but in reflectivity not in absorption.

8861-40, Session 9

Development of lightweight blazed transmission gratings and large-area soft x-ray spectrographs

Ralf Heilmann, MIT Kavli Institute for Astrophysics and Space Research (United States); Alexander R. Bruccoleri, Dong Guan, Mark L. Schattenburg, Massachusetts Institute of Technology (United States)

Large area, high resolving power spectroscopy in the soft x-ray band can only be achieved with a state-of-the-art diffraction grating spectrometer. Recently developed critical-angle transmission (CAT) gratings combine the advantages of transmission gratings (low mass, relaxed figure and alignment tolerances) and blazed reflection gratings (high broad band diffraction efficiency, utilization of higher diffraction orders). Several recently developed mission concepts containing CAT grating based spectrometers (AEGIS, AXSIO, SMART-X) promise to deliver unprecedented order-of-magnitude improvements in soft x-ray spectroscopy figures of merit. The CAT grating principle has previously been demonstrated with x rays using small wet-etched samples. The latest gratings are fabricated from silicon-on-insulator wafers using advanced lithography and a never-before demonstrated combination of highly anisotropic dry and wet etching techniques. We designed and built a setup for the measurement of spectral resolving power of an adjustable CAT grating array, and we shall report on the latest progress in the fabrication and x-ray testing of lightweight, large area gratings with a scalable hierarchy of low-obstruction support structures.

8861-41, Session 9

Nanofabrication advances for high efficiency critical-angle transmission gratings

Alexander R. Bruccoleri, Dong Guan, Massachusetts Institute of Technology (United States); Steve Vargo, SPTS Technologies Ltd. (United States); Frank DiPiazza, Silicon Resources LLC (United States); Ralf Heilmann, MIT Kavli Institute for Astrophysics and Space Research (United States); Mark L. Schattenburg, Massachusetts Institute of Technology (United States)

We report several break-though nanofabrication developments enabling high efficiency and high resolving power spectrometers in the soft x-ray band. The device is the critical-angle transmission (CAT) grating, which combines the low mass and relaxed alignment tolerances of a transmission grating with the high broad-band efficiency and high diffraction orders of a blazed reflection grating. Past work successfully demonstrated the CAT grating concept; however, the open-area fraction was often less than 20 % whilst more than 50% is desired. This presents numerous nanofabrication challenges including a requirement for a free-standing silicon membrane of ultra high-aspect ratio bars at a period of 200 nanometers with minimal cross support blockage. Furthermore, the sidewalls must be smooth to a few nanometers to efficiently reflect soft x-rays. We have developed a complete nanofabrication process for creating free-standing CAT gratings via plasma-etching silicon wafers with a buried layer of SiO_2. This removable buried layer enables combining a record-performance plasma etch for the CAT grating with a millimeter-scale honeycomb structural support to create a free-standing membrane. We have also developed the first reported process for polishing sidewalls of plasma-etched ultra-high aspect ratio nanoscale silicon structures via KOH. This process utilizes the anisotropic etch nature of single crystal silicon in KOH. We developed a novel alignment technique to align the CAT grating bars to the <111> planes of silicon within 0.2 degrees, which enables KOH to etch away sidewall roughness without destroying the structure, since the <111> planes etch approximately 100 times slower than the non-<111> planes.

8861-42, Session 9

Revamping off-plane x-ray gratings

Randall L. McEntaffer, The Univ. of Iowa (United States)

X-ray reflection gratings have significant flight heritage from suborbital rockets to XMM-Newton. The off-plane mount is a configuration capable of obtaining the high throughput, high spectral resolving power requirements necessary for achieving key science goals in future NASA Explorer missions and Observatories. We detail the current state of off-plane gratings and highlight recent results in performance testing. We discuss the major difficulties involved with spectrometer development and plans on dealing with these issues. Finally, we present our future plans and a roadmap for technology development.

8861-43, Session 9

Pushing the boundaries of x-ray grating spectroscopy in a suborbital rocket

Randall L. McEntaffer, Casey DeRoo, Ted Schultz, The Univ. of Iowa (United States); William W. Zhang, NASA Goddard Space Flight Ctr. (United States); Neil J. Murray, e2v Ctr. for Electronic Imaging at The Open Univ. (United Kingdom); Stephen L. O'Dell, NASA Marshall Space Flight Ctr. (United States); Webster Cash, Univ. of Colorado at Boulder (United States)

Developments in grating spectroscopy are paramount for meeting the soft X-ray science goals of future NASA X-ray Observatories. While developments in the laboratory setting have verified the technical feasibility of using off-plane reflection gratings to reach this goal, flight heritage is a key step in the development process toward large missions. To this end we have developed a design for a suborbital rocket payload employing an Off-Plane X-ray Grating Spectrometer. This spectrometer utilizes slumped glass Wolter-1 optics, an array of gratings, and a CCD camera. We discuss the unique capabilities of this design, the expected performance, the science return, and the perceived impact to future missions.

8861-44, Session 9

Alignment tolerances for off-plane reflection grating spectrometry: theoretical calculations and laboratory techniques

Ryan Allured, Randall L. McEntaffer, The Univ. of Iowa (United States)

Future NASA X-ray Observatories will shed light on a variety of high-energy astrophysical phenomena. Off-plane reflection gratings can be used to provide high throughput and spectral resolution in the 0.3-2.0 keV band, allowing for unprecedented diagnostics of energetic astrophysical processes. A grating spectrometer consists of multiple aligned gratings intersecting the converging beam of a Wolter-I telescope. Each grating will be aligned such that the diffracted spectra overlap at the focal plane. Misalignments will degrade both spectral resolution and effective area. In this paper we present an analytical formulation of alignment tolerances that define grating orientations in all six degrees of freedom. We verify our analytical results with raytrace simulations to fully explore the alignment parameter space. Finally, we report on the status of laboratory techniques to achieve these tolerances for flight-like optics.

8861-45, Session 9

Progress toward a soft X-ray polarimeter

Herman L. Marshall, Norbert S. Schulz, Massachusetts Institute of Technology (United States)

We are developing instrumentation for an telescope design capable of measuring linear X-ray polarization over a broad-band using conventional spectroscopic optics. Multilayer-coated mirrors are key to this approach, being used as Bragg reflectors at the Brewster angle. By laterally grading the multilayer mirrors and matching to the dispersion of a spectrometer, one may take advantage of high multilayer reflectivities and achieve modulation factors over 50% over the entire 0.2-0.8 keV band. We present progress on laboratory work to demonstrate the capabilities of an existing laterally graded multilayer coated mirror pair. We also present plans for a suborbital rocket experiment designed to detect a polarization level of 10% for an active galactic nucleus in the 0.1-1.0 keV band.

8861-46, Session 10

Straylight baffling and environmental qualification of silicon pore optics

Eric Wille, Marcos Bavdaz, Sebastiaan Fransen, European Space Research and Technology Ctr. (Netherlands); Maximilien Collon, Marcelo D. Ackermann, Ramses Guenther, Giuseppe Vacanti, cosine Research B.V. (Netherlands); Coen van Baren, SRON Netherlands Institute for Space Research (Netherlands); Jeroen Haneveld, Mark Olde Riekerink, Arenda Koelewijn, Micronit Microfluidics B.V. (Netherlands); Dirk Kampf, Karl-Heinz Zuknik, Arnd Reutlinger, Kayser-Threde GmbH (Germany)

Silicon Pore Optics (SPO) provide a high angular resolution with a low areal density as required for future X-ray telescopes for high energy astrophysics. We present progress in two areas of ESA's SPO development activities. Straylight baffling and environmental qualification.

Residual straylight originating from off-axis sources or the sky background can be blocked by placing suitable baffles in front of the mirror modules. We developed two different mechanical implementations. The first uses longer, tapered mirror plates which improve the straylight rejection without the need of mounting additional parts to the modules or the telescope. The second method is based on placing a sieve plate in front of the optics. We compare both methods in terms of baffling performance using raytracing simulations and present test results of prototype mirror modules.

Any optics for space telescopes needs to be compliant with the harsh conditions of the launch and in-orbit operation. We present new efforts in improving the mechanical and thermal ruggedness of SPO mirror modules and show recent results of qualification level tests, including tests of modules with externally mounted sieve plate baffles.

8861-47, Session 10

Point spread function derivation of grazing-incidence x-ray mirrors from near-field x-ray full imaging

Daniele Spiga, Stefano Basso, INAF - Osservatorio Astronomico di Brera (Italy); Marcos Bavdaz, European Space Research and Technology Ctr. (Netherlands); Bernd Budau, Vadim Burwitz, Max-Planck-Institut für extraterrestrische Physik (Germany); Marta M. Civitani, Oberto Citterio, Mauro Ghigo, INAF - Osservatorio Astronomico di Brera (Italy); Gisela Hartner, Benedikt Menz, Max-Planck-Institut für extraterrestrische Physik (Germany); Giovanni Pareschi, Laura Proserpio, Bianca Salmaso, Gianpiero Tagliaferri, INAF - Osservatorio Astronomico di Brera (Italy); Eric Wille, European Space Research and Technology Ctr. (Netherlands)

The optics of a number of future X-ray telescopes will have very long focal lengths (10 - 20 m), and will consist of a number of nested/stacked thin, grazing-incidence mirror. The optical quality characterization of a real mirror can be obtained via profile metrology, and the Point Spread Function of the mirror can be derived via a standard ray-tracing routine. However, in practical cases it can be difficult to access the optical surfaces of densely stacked mirror shells after they have been assembled, using the widespread metrological tools. For this reason, the assessment of the imaging resolution of a system of mirrors is better obtained via a direct, full-illumination test in X-rays. If the focus cannot be reached, an intra-focus test can be performed, and the image can be compared with the ray tracing based on the metrology, if available. However, until today no quantitative information was extracted from a full-illumination, intra-focal exposure. In this work we show that, if the detector is located close enough to the mirror, the intensity variations of the intra-focal, full-illumination image in single reflection can be used to reconstruct the profile of the mirror surface, without scanning the surface and without the need of a wavefront sensor. The Point Spread Function can be subsequently computed by tracing the rays from the reconstructed mirror shape. We show the application of this method to an intra-focal (8 m distance) test performed at PANTER on an optical module prototype made of hot-slumped glass foils with a 20 m focal length, from which we could derive an expected imaging quality of 16 arcsec HEW.

8861-48, Session 10

Opto-mechanical analyses for performance optimization of lightweight grazing-incidence mirrors

Jacqueline M. Roche, Jeffrey J. Kolodziejczak, Stephen L. O'Dell, Ronald F. Elsner, Martin C. Weisskopf, Brian Ramsey, Mikhail V. Gubarev, NASA Marshall Space Flight Ctr. (United States)

New technology in grazing-incidence mirror fabrication and assembly is necessary to achieve sub-arcsecond optics for large-area x-ray telescopes. In order to define specifications, an understanding of performance sensitivity to design parameters is crucial. MSFC is undertaking a systematic study to specify a mounting approach, mirror substrate, and testing method. Because the lightweight mirrors are typically flimsy, they are susceptible to significant distortion due to mounting and gravitational forces. Material properties of the mirror substrate along with its thickness and dimensions significantly affect the distortions caused by mounting and gravity. A parametric study of these properties and their relationship to mounting and testing schemes will indicate specifications for the design of the next generation of lightweight grazing-incidence mirrors. Initial results will be reported.

8861-49, Session 11

Hartmann testing of x-ray telescopes

Timo Saha, William W. Zhang, NASA Goddard Space Flight Ctr. (United States); Michael P. Biskach, SGT, Inc. (United States)

Optical Hartmann testing of x-ray telescopes is a simple test method to retrieve and analyze alignment errors and low order circumferential errors of x-ray telescopes and its components. A narrow slit is scanned along the circumference of the telescope in front of the primary mirror. The centroids of the images are calculated. From the centroid data, alignment errors, radius variation errors, and cone angle variation errors can be calculated. Mean cone angle, mean radial height (average radius), and the focal length of the telescope can also easily be estimated if the centroid data is measured at multiple focal plane locations.

In this paper we present the basic equations that can be used in the analysis process. These equations can be applied to full-circumference or

segmented x-ray telescopes. We use the Optical Surface Analysis Code (OSAC) to model a segmented x-ray telescope and show that the derived equations and accompanying analysis retrieves the alignment errors and low order circumferential errors accurately.

8861-50, Session 11

Alignment of eROSITA mirrors at the PANTER X-ray test facility

Benedikt Menz, Max-Planck-Institut für Wissenschaftsgeschichte (Germany); Heinrich Braeuninger, Wolfgang Burkert, Vadim Burwitz, Gisela Hartner, Peter Friedrich, Max-Planck-Institut für Extraterrestrische Physik (Germany)

The development and calibration of eROSITA mirror modules is accompanied by continuous measurements at the X-ray Test Facility PANTER.

To obtain comparable measurement results after each new integration robust alignment procedures are needed to place the mirror module on the optical axis.

Here we present the different methods that we use to align eROSITA like mirror modules. One method uses the symmetry of single reflection images, another one is based on a symmetry of intensity distribution, and the last one on the symmetry of the HEW (half energy width).

8861-51, Session 11

In focus measurements of IXO type optics using the new PANTER x-ray test facility extension

Vadim Burwitz, Max-Planck-Institut für Extraterrestrische Physik (Germany); Marcos Bavdaz, European Space Research and Technology Ctr. (Netherlands); Giovanni Paresci, INAF - Osservatorio Astronomico di Brera (Italy); Maximilien Collon, cosine Research B.V. (Netherlands); Wolfgang Burkert, Max-Planck-Institut für Extraterrestrische Physik (Germany); Marcelo D. Ackermann, cosine Research B.V. (Netherlands); Gisela Hartner, Max-Planck-Institut für Extraterrestrische Physik (Germany); Daniele Spiga, Marta M. Civitani, INAF - Osservatorio Astronomico di Brera (Italy); Benedikt Menz, Max-Planck-Institut für Extraterrestrische Physik (Germany)

Future large X-ray observatories in space will require mirrors with large effective areas and long focal lengths. European Space Agency ESA programs for developing light weight optics based on modules of silicon pore optics (SPO) and slumped glas optics (SGO) where put in place for the IXO mission (mirror focal length 20 m and radii 0.74 and 1.00 m). In order to test such optics the MPE PANTER X-ray test facility has been upgraded/extended to accomodate in-focus measurements of such optics modules. We will describe the details of the extension to PANTER as well as the first results obtained from measuring such SPO and SGO modules during the comissioning phase.

8861-52, Session 11

X-ray pencil beam characterization of silicon pore optics

Giuseppe Vacanti, Marcelo D. Ackermann, Maximilien Collon, Ramses Guenther, cosine Research B.V. (Netherlands); Chris Kelly, cosine Science & Computing B.V. (Netherlands); Levent Cibik, Michael Krumrey, Peter Müller, Physikalisch-Technische Bundesanstalt (Germany)

The characterization of large aperture (> 2 meters), long focal length (> 10 meters) X-ray mirrors for X-ray astronomy with synchrotron radiation poses significant problems related to the available space at synchrotron radiation facilities. Intra-focal pencil beam characterization of part of the optics is advantageous if its results can be shown to have predictive capabilities with respect to the full system.

In this paper we present the routine characterization of silicon pore optics at the PTB X-ray Pencil Beam Facility (XPBF), located at the synchrotron radiation facility BESSY II. In particular we show how measurements taken in the standard XPBF configuration (detector at 5 meter from the optics) can effectively be used to predict the optical performance of the optics at their design focal length. We compare data taken on 20-meter focal length SPO unit in the 20-meter XPBF configuration (available only a few weeks every year) with extrapolated 5-meter measurements. The issue of how to deal with the direct beam contribution to the optical performance of the optics is also addressed.

8861-53, Session 11

Characterising x-ray optics with a collimated x-ray beam: the zone plate approach

Benedikt Menz, Max-Planck-Institut für Wissenschaftsgeschichte (Germany); Christoph Braig, Friedrich-Schiller-Univ. Jena (Germany); Heinrich Braeuninger, Vadim Burwitz, Gisela Hartner, Max-Planck-Institut für Extraterrestrische Physik (Germany); Ernst-Bernhard Kley, Friedrich-Schiller-Univ. Jena (Germany); Peter Predehl, Max-Planck-Institut für Extraterrestrische Physik (Germany)

An open question in the measurment of X-ray optics for satellite experiments is what the PSF looks like in orbit and the focal length for an infinite source distance.

In order to measure such a PSF (point spread function) a collimated X-ray beam with a diameter of several centimeters to meters is needed.

For this purpose we have started a study of how to collimate the X-rays using a zone plate.

We present the results of our studies with a zone plate of 122 m focal length at Al-K and a diameter of 5 cm.

We present our configuration study to use such a collimator for measuring long focal length segmented optics for future ATHENA-type X-ray missions.

8861-54, Session 12

Silicon optics for wide field x-ray imaging

Richard Willingale, Univ. of Leicester (United Kingdom); Marcelo D. Ackermann, Maximilien Collon, cosine Research B.V. (Netherlands)

Silicon pore optics (SPO) were originally designed to provide very large collecting areas combined with good angular resolution in narrow field X-ray telescopes. We describe modifications and changes to the geometry and manufacture of SPO to facilitate wide field X-ray imaging applications. Modest changes can greatly improve the vignetting function of SPO in the Wolter I geometry. Reconfiguring SPO to the form Kirkpatrick-Baez stacks in the Schmidt geometry cnd provide very large fields of view with high angular resolution and large collecting area.

8861-55, Session 12

Adjustable x-ray optics and Kirkpatrick-Baez telescopes

Paul Gorenstein, Harvard-Smithsonian Ctr. for Astrophysics (United States)

The long term goal of the SMART-X program is the development of a segmented Wolter 1 X-ray telescope whose angular resolution and effective area are superior to the Chandra X-Ray Observatory. SMART-X's methodology consists of applying piezoelectric coatings to the rear of a mirror substrate that has been thermally slumped to the approximate figure. The figure is optimized during ground calibration by adjusting the voltages to the piezoelectric backings, with the capability to optimize imaging performance further on-orbit by viewing a suitably bright point-like object. A similar procedure should be very effective with Kirkpatrick-Baez (KB) telescopes. This author believes it can be performed much more rapidly during ground calibration. The complete line image from a single mirror can be isolated by a moveable slit of variable width, and optimized under computer control. The slit then proceeds to the next mirror and adjusts its width as needed. The two sections can be tuned independently and joined subsequently with rather lenient tolerances. Because of theoretical limitations on its angular resolution a KB telescope cannot replace the Wolter 1 as the ultimate goal of SMART-X but we do suggest that shorter term projects with more modest angular resolution goals, such as a dispersive spectroscopy mission, should consider it. Dispersing the spectrum along the 45 degree direction between the two axes minimizes the effect of scattering similar to what is accomplished by using only part of the azimuth of a Wolter mirror.

8861-56, Session 12

Development status of adjustable grazing incidence optics for 0.5 arcsec x-ray imaging

Paul B. Reid, Thomas L. Aldcroft, Vincenzo Cotroneo, Harvard-Smithsonian Ctr. for Astrophysics (United States); Raegan L. Johnson-Wilke, The Pennsylvania State Univ. (United States); Stuart McMuldroch, Daniel A. Schwartz, Harvard-Smithsonian Ctr. for Astrophysics (United States); Susan E. Trolier-McKinstry, The Pennsylvania State Univ. (United States); Alexey Vikhlinin, Harvard-Smithsonian Ctr. for Astrophysics (United States); Rudeger H. T. Wilke, The Pennsylvania State Univ. (United States)

We describe progress in the development of adjustable grazing incidence X-ray optics for 0.5 arcsec resolution cosmic X-ray imaging. To date, no optics technology is available to blend high resolution imaging like the Chandra X-ray Observatory, with square meter collecting area. Our approach to achieve these goals simultaneously is to directly deposit thin film piezoelectric actuators on the back surface of thin, lightweight Wolter-I or Wolter-Schwarschild mirror segments. The actuators are used to correct mirror figure errors due to fabrication, mounting and alignment, using calibration and a one-time figure adjustment on the ground. If necessary, it will also be possible to correct for residual gravity release and thermal effects on-orbit.

In this paper we discuss our most recent results in operating multiple adjusters, and extending the process from flat test mirrors to cylindrical and conical test mirror segments. A comparison of modeled and measured influence functions is shown. We also present simulation results showing the process is consistent with the achievement of half arcsec imaging.

8861-57, Session 12

Update to an application using magnetic smart materials to modify the shape of a x-ray telescope mirror

Melville P. Ulmer, Xiaoli Wang, Jian Cao, Michael E. Graham, Semyon Vaynman, Bridget Bellavia, Liutian Chen, Peter M. Knapp, Thomas Defrancisco, Northwestern Univ. (United States)

We describe a technique of shape modification that can be applied to thin walled (~ 100-400 micron thickness) electroformed replicated optics or glass optics to improve the near net shape of the mirror as well as the mid-frequency (~ 2-10 mm length scales) ripple. The process involves sputter deposition of a magnetic smart material (MSM) film onto a magnetically hard material (i.e., one that retains a magnetic field, e.g. the material in hard disk drives). Since the previous report, we have made extensive measurements of the deflection versus magnetic field strength and direction. Here we report those results along with detailed finite element analysis modeling.

8861-58, Session 12

A slatted mirror for an x-ray interferometer manufactured in silicon

Richard Willingale, Gillian I. Butcher, Univ. of Leicester (United Kingdom); Marcelo D. Ackermann, Ramses Guenther, Maximilien Collon, cosine Research B.V. (Netherlands)

A slatted mirror is a unique and crucial component in a particular design for an astronomical X-ray interferometer (Willingale SPIE 2004).

The slats must be thin, <300 microns, flat and co-planar to a very high precision. We describe the manufacture and characterisation of a prototype slatted mirror using an modified form of Silicon pore optics technology.

8862-1, Session 1

Scatter studies for the roughness specifications of the primary mirror of visible emission line coronagraph (VELC) on board ADITYA-1

Suresh N. Venkata, B. Raghavendra Prasad, N. Raj Kumar, Jagdev Singh, Indian Institute of Astrophysics (India)

Visible Emission Line Coronagraph (VELC) on board ADITYA-1 is an internally occulted mirror coronagraph to perform simultaneous narrow-band imaging of solar corona in emission lines centered at 5303 Å (Fe XIV) and 6374 Å (Fe X) over a Field Of View (FOV) of 3 Ro (Ro - Solar Radii) and broad band imaging centered at 5800 Å over a FOV of 6 Ro. To achieve the scientific goals of the mission, instrument background have to be kept minimal (<= 5ppm). One of the major contributions of the instrument background is scatter due to the RMS micro-roughness of the Primary Mirror (M1). Hence, a detailed study of scatter through simulations is carried out in order to arrive at the polishing specifications of M1. Defining an appropriate Bidirectional Scatter Distribution Function (BSDF) plays a crucial role in scatter simulations. For current simulations, we used a three parameter Harvey BSDF defined by bo, S and l. Harvey BSDF holds good for optical surfaces with RMS roughness < 10 Å. Also estimation of RMS roughness correction factor due to finite band width of the profilometer is very important while specifying the RMS roughness of M1. From our simulations we estimate that to maintain 5 ppm scatter level over the FOV, RMS micro-roughness of M1 should be <1.5 Å over the spatial periods from 25 microns to ~ 2 mm at 5000 Å. Simulations are carried out using Advanced System Analysis Program (ASAP), developed by Breault Research Organisation (BRO).

8862-2, Session 1

Effect of field of view and wavelength on scatter distribution at prime focus of visible emission line coronagraph (VELC) on board ADITYA-1

Suresh N. Venkata, B. Raghavendra Prasad, N. Raj Kumar, Jagdev Singh, Indian Institute of Astrophysics (India)

Aditya-1 is India's first space mission for solar coronal observations. It carries Visible Emission Line Coronagraph (VELC) which is an internally occulted mirror coronagraph to low earth orbital. VELC performs simultaneous narrow-band imaging of solar corona in emission lines centered at 5303 Å (Fe XIV) and 6374 Å (Fe X) over a Field Of View (FOV) of 3 Ro (Ro - Solar Radii) and broad band imaging centered at 5800 Å over a FOV of 6 Ro. To achieve the scientific goals of the mission, instrument background have to be kept minimal (<= 5ppm). One of the major contributions of the instrument background is scatter due to the RMS micro roughness of the Primary Mirror (M1). In general, in scatter studies rms micro roughness and surface topography are always in limelight and the effect of other parameters are not given that importance. But in case of VELC, where the source is an extended source (angular size ±16arcmin) and the instrument back ground is to be of the order of few ppm. Hence, a detailed study on the effect of FOV and Wavelength on scatter distribution at the prime focus of VELC was carried out through simulations. In this paper we describe in detail about the results obtained from simulations. Simulations are carried out using Advanced System Analysis Program (ASAP), developed by Breault Research Organization (BRO).

8862-3, Session 1

Improved stray light suppression performance for the solar orbiter/METIS inverted external occulter

Federico Landini, INAF - Osservatorio Astrofisico di Arcetri (Italy); Sébastien Vivès, Lab. d'Astrophysique de Marseille (France); Marco Romoli, Univ. degli Studi di Firenze (Italy); Silvano Fineschi, INAF - Osservatorio Astronomico di Torino (Italy); Christophe Guillon, Observatoire Astronomique de Marseille-Provence (France); Gerardo Capobianco, Giuseppe Massone, INAF - Osservatorio Astronomico di Torino (Italy); Clément Escolle, Lab. d'Astrophysique de Marseille (France); Enzo Turchi, Univ. degli Studi di Firenze (Italy); Maurizio Pancrazzi, INAF - Osservatorio Astrofisico di Arcetri (Italy); Giuseppe Crescenzio, INAF - Osservatorio Astronomico di Torino (Italy); Mauro Focardi, INAF - Osservatorio Astrofisico di Arcetri (Italy)

The Solar Orbiter/METIS visible and UV coronagraph introduces the concept of occulter inversion in solar coronagraphy. Classical externally occulted coronagraphs usually have a disk in front of the telescope entrance pupil. According to the mission requirements, in order to reduce the amount of power entering the instrument and to limit the instrument dimensions, METIS is equipped with an inverted external occulter (IEO). The IEO consists of a circular aperture on the Solar Orbiter thermal shield that acts as coronagraph entrance pupil. A spherical mirror (M0), located ~800mm behind the IEO, rejects back the disk-light through the IEO itself. A light-tight boom connects the IEO to the M0 through the thermal shield.

In order to achieve high performance in stray light suppression, the IEO design needs optimization. Due to the novelty of the concept we can only use the heritage of past space-borne coronagraph occulters as a starting point to design a dedicated occulter optimization shape.

A 1.5 years long, accurate test campaign has been carried out to evaluate the best optimization configuration for the IEO. Two prototypes were manufactured to take into account the impact of the boom geometry on the stray light suppression performance. Two optimization concepts were compared: the inverted cone (that derives from the conic optimization of classical occulting disks) and the serrated edge, of which several samples were manufactured, with different geometrical parameters, surface roughnesses and coatings. This work summarizes the activity we have been carrying on to define the flight specifications for the METIS occulter.

8862-4, Session 1

Optimization of baffle configuration for stray light reduction

Maurizio Pancrazzi, Observatoire Astronomique de Marseille-Provence (France) and Univ. degli Studi di Firenze (Italy); Sébastien Vivès, Christophe Guillon, Clément Escolle, Observatoire Astronomique de Marseille-Provence (France); José Garcia, Lab. d'Astrophysique de Marseille (France); Federico Landini, Univ. degli Studi di Firenze (Italy)

Reducing the stray light level is one of the issues that astronomical instruments have to face. In particular, the design of baffles requires special attention in order to minimize the light scattered and diffracted by the edges of the baffle's vanes. The choice of the materials and the treatments used to manufacture these edges can significantly increase the performance of stray light suppression. This is particularly critical for instruments in which the science target is close to a much brighter object

e.g. the solar corona around the Sun disk.

In the framework of the phase B for the solar coronagraph METIS (onboard Solar Orbiter, ESA), we designed a dedicated set-up allowing to evaluate how edge geometry is impacted by black coatings and to identify the possible configurations for SOLO/METIS vanes edges.

In this paper, we compare several edge geometries and finishing in a fast and comprehensive approach.

8862-5, Session 2

HEROES: high-energy replicated optics to explore the sun

Steven D. Christe, NASA Goddard Space Flight Ctr. (United States); Jessica A. Gaskin, NASA Marshall Space Flight Ctr. (United States); Albert Y. M. Shih, NASA Goddard Space Flight Ctr. (United States); Colleen Wilson-Hodge, Leigh Smith, Katherine Stevenson Chavis, NASA Marshall Space Flight Ctr. (United States); Marcello Rodriguez, Alexander Cramer, Melissa Edgerton, NASA Goddard Space Flight Ctr. (United States); Brian O'Connor, Alex R. Sobey, Jonathan Pryor, Miguel Rodriguez Otero, Brian Ramsey, NASA Marshall Space Flight Ctr. (United States)

Set to fly in the Fall of 2013 from Ft. Sumner, NM, the High Energy Replicated Optics to Explore the Sun (HEROES) mission is a collaborative effort between the NASA Marshall Space Flight Center and the Goddard Space Flight Center to upgrade an existing payload, the High Energy Replicated Optics (HERO) balloon-borne telescope, to make unique scientific measurements of the Sun and astrophysical targets during the same flight. The HEROES science payload consists of 8 mirror modules, housing a total of 109 grazing- incidence optics. These modules are mounted on a carbon-fiber - and Aluminum optical bench 6 m from a matching array of high pressure xenon gas scintillation proportional counters, which serve as the focal-plane detectors. The HERO gondola utilizes a differential GPS system (backed by a magnetometer) for coarse pointing in the azimuth and a shaft angle encoder plus inclinometer provides the coarse elevation. The HEROES payload will incorporate a new solar aspect system to supplement the existing star camera, for fine pointing during both the day and night. The overall payload will be discussed as well as the new solar aspect system. This mission is funded by the NASA HOPE (Hands On Project Experience) Training Opportunity awarded by the NASA Academy of Program/Project and Engineering Leadership, in partnership with NASA's Science Mission Directorate, Office of the Chief Engineer and Office of the Chief Technologist.

8862-6, Session 2

Solar alpha particles damage effects on UV and EUV optical coatings

Vanessa Polito, Sara Zuccon, Marco Nardello, Alain Jody Corso, Paola Zuppella, IFN-CNR LUXOR Lab. (Italy); Piergiorgio Nicolosi, Univ. degli Studi di Padova (Italy); Silvano Fineschi, Ester Antonucci, INAF - Osservatorio Astronomico di Torino (Italy); Maria Guglielmina Pelizzo, IFN-CNR LUXOR Lab. (Italy); Giampiero Naletto, Univ. degli Studi di Padova (Italy)

Low energy particles from solar wind plasma contribute to the damage of optical materials, with severe effects on space instruments performance. In the present work the degradation of UV and EUV optical coatings under irradiation by solar alpha particles has been experimentally investigated. A dedicated experiment was realized at the Forschungszentrum Dresden-Rossendorf. The estimation of the total irradiated dose was based on the trajectory that will be kept by the Solar Orbiter satellite, and was varied to represent a total He+ exposure of 1 to 4 years mission. The tested samples include novel multilayer structures based on periodic Mo/Si couples with Ir/Si and Ir/Mo capping layers, designed to enhance the peak of reflectivity at 30.4 nm. Moreover, the experiment was performed on different prototype metallic coatings which were deposited at CNR-IFN U.O.S. Padova for application in the UV-VIS spectral range. The reflectance performance of the samples has been compared prior and after the experiment.

The throughputs from the outlined research contributed to the validation of the proposed structures for potential application to the METIS coronagraph on board the Solar Orbiter spacecraft and future solar instruments.

8862-33, Session 2

Test of a multilayer-coated EUV grating for I-IV order spectroscopic measurements of the solar corona

Luca Poletto, Fabio Frassetto, IFN-CNR LUXOR Lab. (Italy); Angelo Giglia, Istituto Officina dei Materiali CNR (Italy); Stefano Nannarone, Univ. degli Studi di Modena e Reggio Emilia (Italy); Paolo Miotti, Maria-Guglielmina Pelizzo, Paola Zuppella, IFN-CNR LUXOR Lab. (Italy); Silvano Fineschi, Ester Antonucci, INAF - Osservatorio Astronomico di Torino (Italy); Giampiero Naletto, Piergiorgio Nicolosi, Univ. degli Studi di Padova (Italy); Marco Romoli, Univ. degli Studi di Firenze (Italy)

METIS, the "Multi Element Telescope for Imaging and Spectroscopy", is a coronagraph selected by the European Space Agency to be part of the payload of the Solar Orbiter mission to be launched in 2017. The original METIS proposal included four optical paths: 1) linearly polarized visible-light (590-650 nm), 2) narrow-band ultraviolet HI Lyman-? (121.6 nm), 3) narrow-band extreme-ultraviolet HeII Lyman-? (30.4 nm), 4) spectrographic observations of HI Lyman-? and He II Lyman-??in corona. The development and test activities of the grating for the spectroscopic path are here described. It is optimized to work at near normal incidence and to diffract the 121.6 nm radiation at the first order and the 30.4 nm at its 4th order, consequently the two spectroscopic channels are overlapped on the focal plane. The grating is spherical with variable-line-spaced rulings, 1800 gr/mm central density. The selection of the spectroscopic channel to be acquired, either the 121.6 nm or the 30.4 nm, is made by a suitable filter wheel. The grating is multilayer-coated, to have high efficiency in both the spectral channels. A test prototype has been characterized at the BEAR beamline at the ELETTRA synchrotron in Trieste (Italy). The grating was initially coated by Au and successively by a Mo-Si multilayer optimized at 30.4 nm. The efficiencies at the diffracted orders up to the 4th (i.e., intervals centered at 121.6, 60.8, 40.5 and 30.4 nm) have been measured before and after the multilayer deposition. The quality of the multilayer deposition has been tested by AFM measurements on the grating surface and by reflectivity measurements performed on a test reference mirror. Comparisons between the experimental data and numerical simulations are also shown.

8862-34, Session 2

Recent developments of ASPIICS: a giant solar coronagraph for the ESA/PROBA-3 formation flying mission

Sébastien Vives, Lab. d'Astrophysique de Marseille (France); Jean-Yves D. Plesseria, Univ. de Liège (Belgium); Patrick Levacher, Lab. d'Astrophysique de Marseille (France); Werner Curdt, Max-Planck-Institut für Sonnensystemforschung (Germany); Christophe Guillon, Lab. d'Astrophysique de Marseille (France)

PROBA-3 is a technology mission of the European Space Agency (ESA), devoted to the in-orbit demonstration of formation flying techniques

and technologies. Presently in phase B, PROBA-3 will implement a coronagraph (called ASPIICS, "Association de Satellites Pour l'Imagerie et l'Interferometrie de la Couronne Solaire") that will both demonstrate and exploit the capabilities and performance of formation flying.

ASPIICS is distributed on two spacecrafts separated by 140m with the external occulting disk hosted by one spacecraft and the telescope (optical camera included) on the other one. ASPIICS will perform high spatial resolution imaging of the solar corona from the coronal base (1.04 solar radii) out to 3 solar radii.

ASPIICS is developed by a large consortium of European Institutes and Industries from Belgium, Czech Republic, France, Germany, Greece, Italy, Luxembourg and Russia. The design studies concern the external occulter mounted on one satellite and the telescope on the other one but also the additional metrology tools that will help checking the formation and ensure that the flight configuration is optimal for observations.

PROBA-3/ASPIICS successfully passed the Preliminary Design Review (PDR) in April 2013 and is currently in the implementation phase C/D. The present paper will provide the current status of PROBA-3/ASPIICS, a description of the instrument and its expected performance.

8862-35, Session 2

Development of multilayer coatings for solar orbiter EUV imaging telescopes

Franck Delmotte, Evgueni Meltchakov, Sébastien de Rossi, Françoise Bridou, Arnaud Jérôme, Raymond F. Mercier, Lab. Charles Fabry (France); Frédéric Auchère, Xueyan Zhang, Bruno Borgo, Institut d'Astrophysique Spatiale (France); Marc Roulliay, Institut des Sciences Moléculaires d'Orsay (France)

Since more than 20 years, Laboratoire Charles Fabry and Institut d'Astrophysique Spatiale are involved in development of the EUV multilayer coating for solar imaging. Previous instruments, such as the SOHO EIT and STEREO EUVI telescopes, employed the Mo/Si multilayer coatings, which offered at that time the best efficiency and stability. We present here recent results of the development of highly efficient EUV multilayers coatings at 17.4 nm and 30.4 nm for the Solar Orbiter mission. New multilayer structures, based on a combination of three materials including aluminum, have been optimized both theoretically and experimentally. We have succeeded to reduce interfacial roughness of Al-based multilayers down to 0.5 nm via optimization of the multilayer design and the deposition process. The EUV peak reflectance of Al/Mo/SiC and Al/Mo/B4C multilayer coatings reaches 56% at 17.4 nm, the highest value reported up to now for this wavelength. For instance, the Mo/Si coating of the STEREO EUVI telescopes reflects only about 40% at the same wavelength. We have also optimized specific bi-periodic structures that possess two reflection bands in the EUV range with high spectral selectivity. The EUV reflectivity and spectral purity of single and dual-band coatings studied with synchrotron radiation will be discussed. Since the stability of reflecting multilayer coating is an important issue for space missions, we have also studied the temporal and thermal stability (including thermal cycling) as well as the resistivity of the coatings to high-energy and highdose proton irradiation. Experimental results confirm that Al/Mo/SiC multilayer coatings are good candidates for the Solar Orbiter EUV imaging telescopes.

8862-7, Session 3

Solar chromosphere flare spectrograph

Debi Prasad Choudhary, California State Univ., Northridge (United States); Vasyl Yurchyshyn, Big Bear Solar Observatory (United States); Sanjay Gosain, National Solar Observatory (United States); Damian Christian, California State Univ., Northridge (United States)

This paper describes the optical design of a two channel echelle spectrograph to observe the optical spectra at the locations of flares and explosive events on the Sun. This Solar Chromosphere Flare Spectrograph (SCFS) will record flare spectra in two channels in the wavelength range of 350-890 nm, which has several chromospheric spectral lines. The SCFS have a multi-fiber based slit capable of observing at 100 locations of the active region magnetic field polarity inversion lines. The field of view of SCFS will be 80 x 80 arc sec with spatial resolution of 8 arc sec. The spectral resolution of 60,000 will be adequate for measuring Doppler velocities of about 5 km/s. The instrument is designed using off-the-shelves optical and mechanical parts with minimum fabrication at an in-house machine shop. The SCFS will be integrated with the full-disk Halpha telescope at the Big Bear Solar Observatory that is operating semi-automatically a round the year except for weather interruptions.

8862-8, Session 3

An off-limb solar adaptive optics system: design and testing

Gregory E. Taylor, New Mexico State Univ. (United States); Thomas R. Rimmele, National Solar Observatory (United States)

Prominences are complex magnetic structures observed near the limb of the sun. Prominences can erupt and cause coronal mass ejections that drive space weather. Long-exposure spectroscopy and spectro-polarimetry at near-infrared wavelengths is one of the preferred tools deployed to measure the physical properties of prominences, including the prominence magnetic field. However, the required long-exposure diffraction limited observations of prominences are lacking since solar adaptive optics systems currently are not able to lock onto the faint, low contrast prominence structure. We are developing a prototype adaptive optics system capable of locking-on to H-alpha off-limb prominence structure. A correlating Shack-Hartmann wavefront sensor approach is used. In contrast to solar AO systems operated on-disk the low photon flux of off-limb structure is one of the main performance limiting factors. In this presentation, I will detail the design and system analysis of the prototype limb AO system.

8862-9, Session 3

The advanced technology solar telescope (ATST) project: a construction update *(Invited Paper)*

Mark Warner, Thomas R. Rimmele, Joseph P. McMullin, National Solar Observatory (United States)

The 4m Advance Technology Solar Telescope (ATST) will be the most powerful solar telescope and the world's leading ground-based resource for studying solar magnetism that controls the solar wind, flares, coronal mass ejections and variability in the Sun's output. The project has entered its construction phase. Major subsystems have been contracted, designs are complete, and fabrication has started. As its highest priority science driver ATST shall provide high resolution and high sensitivity observations of the dynamic solar magnetic fields throughout the solar atmosphere, including the corona at infrared wavelengths. A high order adaptive optics system delivers a corrected beam to the initial set of state-of-the-art, facility class instrumentation located in the Coudé laboratory facility. The initial set of first generation instruments consists of five facility class instruments, including imagers and spectro-polarimeters. Development and construction of a four-meter solar telescope presents many technical challenges, including thermal control of the enclosure, telescope structure and optics and wavefront control. A brief overview of the science goals and observational requirements of the ATST will be given, followed by a summary of the design status of the telescope and its instrumentation, including design status of major subsystems, such as the telescope mount assembly, enclosure, mirror assemblies, and wavefront correction.

8862-10, Session 4

Solar orbiter: exploring the sun-heliosphere connection *(Invited Paper)*

Daniel Mueller, Richard G. Marsden, European Space Agency (Netherlands); Orville C. St. Cyr, NASA Goddard Space Flight Ctr. (United States)

Solar Orbiter, the first mission of ESA's Cosmic Vision 2015-2025 programme, promises to deliver groundbreaking science with previously unavailable observational capabilities provided by a suite of in-situ and remote-sensing instruments in a unique orbit. The mission will address the central question of heliophysics: How does the Sun create and control the heliosphere? The heliosphere represents a uniquely accessible domain of space, where fundamental physical processes common to solar, astrophysical and laboratory plasmas can be studied under conditions impossible to reproduce on Earth and unfeasible to observe from astronomical distances. In this talk, we highlight the scientific goals of Solar Orbiter, address the synergy between this joint ESA/NASA mission and other new space- and ground-based observatories, and present the mission's development status.

8862-11, Session 4

Spice EUV spectrometer for solar orbiter mission *(Invited Paper)*

Andrzej Fludra, Douglas K. Griffin, Martin E. Caldwell, Paul Eccleston, Nick R. Waltham, Rutherford Appleton Lab. (United Kingdom); Anne Philippon, Institut d'Astrophysique Spatiale (France); Udo H. Schühle, Max-Planck-Institut für Sonnensystemforschung (Germany); Manfred Gyo, Physikalisch-Meteorologisches Observatorium Davos (Switzerland); Joseph M. Davila, NASA Goddard Space Flight Ctr. (United States); B. Walls, Donald M. Hassler, Southwest Research Institute (United States); Grant J. Munro, ESR Technology Ltd. (United Kingdom)

SPICE is a high resolution imaging spectrometer operating at extreme ultraviolet wavelengths, 70.4 – 79.0 nm and 97.3 - 104.9 nm. It is a facility instrument on the Solar Orbiter mission. SPICE addresses the key science goals of Solar Orbiter by providing the quantitative knowledge of the physical state and composition of the plasmas in the solar atmosphere, in particular investigating the source regions of outflows and ejection processes which link the solar surface and corona to the heliosphere. By observing the intensities of selected lines and line profiles, SPICE will derive temperature, density, flow and composition information for the plasmas in the temperature range from 10,000 K to 10MK. The instrument optics consists of a single-mirror telescope (off-axis paraboloid operating at near-normal incidence), feeding an imaging spectrometer. The spectrometer is also using just one optical element, a Toroidal Variable Line Space grating, which images the entrance slit from the telescope focal plane onto a pair of detector arrays, with a magnification of approximately x5. Each detector consists of a photocathode coated microchannel plate image intensifier, coupled to active-pixel-sensor (APS). Particular features of the instrument needed due to proximity to the Sun include: use of dichroic coating on the mirror to reject the majority of the solar spectrum, particle-deflector to protect the optics from the solar wind, and use of data compression due to telemetry limitations. The current status of the instrument design will be presented.

8862-12, Session 4

Novel space coronagraphs: flexible optical design for multiwavelength imaging and spectroscopy

Silvano Fineschi, Gerardo Capobianco, Giuseppe Crescenzio, INAF - Osservatorio Astronomico di Torino (Italy); Vania Da Deppo, Consiglio Nazionale delle Ricerche (Italy); Mauro Focardi, Fedrico Landini, INAF - Osservatorio Astrofisico di Arcetri (Italy); Giuseppe Massone, INAF - Osservatorio Astronomico di Torino (Italy); John D. Moses, U.S. Naval Research Lab. (United States); Giampiero Naletto, Univ. degli Studi di Padova (Italy); Gianalfredo Nicolini, INAF - Osservatorio Astronomico di Torino (Italy); Maurizio Pancrazzi, INAF - Osservatorio Astrofisico di Arcetri (Italy); Maria Guglielmina Pelizzo, Luca Poletto, IFN-CNR LUXOR Lab. (Italy); Marco Romoli, Univ. degli Studi di Firenze (Italy)

The classical optical design for visible-light, solar coronagraphs is based on the traditional optical scheme by Lyot who introduced the stop blocking the light diffraction off the entrance pupil. In the ultraviolet (UV: 10-100 nm), the sun-to-corona intensity ratio is order of magnitudes lower than that in the visible-light. The resulting diffraction off the entrance pupil is therefore negligible. For this reason, UV solar coronagraphs do not require Lyot-stops, but need to be all-reflective

This presentation outlines a general optical scheme for coronagraphs working in both the visible-light (VL) and UV wavelength ranges combining the use of reflective optics with Lyot stops. This scheme has been successfully applied to a sub-orbital coronagraph. Another version of this novel design for visible-light/EUV coronagraphs uses an inverted-occultation scheme in order to minimize the solar flux entering the instrument. This scheme has been adopted for the coronagraph on board the ESA Solar Orbital mission.

The innovative inverted-occultation concept is flexible enough that it could also accommodate a EUV spectrograph using the same basic optical layout. The presentation also describes the potential capabilities of the inverted-occulter coronagraph as a VL/UV imager and EUV spectrograph for future solar missions.

8862-13, Session 4

The solar and heliospheric imager (SoloHI) instrument for the solar orbiter mission *(Invited Paper)*

Russell A. Howard, Angelos Vourlidas, Clarence M. Korendyke, Simon P. Plunkett, Michael T. Carter, Dennis Wang, Nathan Rich, U.S. Naval Research Lab. (United States); Donald R. McMullin, Space Systems Research Corp. (United States); Sean P. Lynch, U.S. Naval Research Lab. (United States); Gregory E. Clifford, Silver Engineering, Inc. (United States); Dennis G. Socker, U.S. Naval Research Lab. (United States); Arnaud F. R. Thernisien, George Mason Univ. (United States); Damien Chua, Mark G. Linton, U.S. Naval Research Lab. (United States); David Keller, James R. Janesick, John R. Tower, SRI International Sarnoff (United States); Paulett C. Liewer, Marco Velli, Eric M. DeJong, Jet Propulsion Lab. (United States); Zoran Miki?, Predictive Science Inc. (United States); Volker Bothmer, Univ. Göttingen (Germany); Pierre L. P. M. Rochus, Jean-Philippe A. Halain, Univ. de Liège (Belgium); Philippe L. Lamy, Lab. d'Astrophysique de Marseille (France)

The SoloHI instrument for the ESA/NASA Solar Orbiter mission will track density fluctuations in the inner heliosphere, by observing visible sunlight scattered by electrons in the solar wind. Fluctuations are associated

with dynamic events such as coronal mass ejections, but also with the "quiescent" solar wind. SoloHI will provide the crucial link between the low corona observations from the Solar Orbiter instruments and the in-situ measurements on Solar Orbiter and the Solar Probe Plus missions. The instrument is a visible-light telescope, based on the SECCHI/Heliospheric Imager (HI) currently flying on the STEREO mission. In this instrument concept, a series of baffles reduce the scattered light from the solar disk and reflections from the spacecraft to levels below the scene brightness, typically by a factor of 1012. The fluctuations are imposed against a much brighter signal produced by light scattered by dust particles (the zodiacal light/F-corona). Multiple images are obtained over a period of several minutes and are summed on-board to increase the signal-to-noise ratio and to reduce the telemetry load. SoloHI is a single telescope with a 40? field of view beginning at 5? from the Sun center. Through a series of Venus gravity assists, the minimum perihelia for Solar Orbiter will be reduced to about 60 Rsun (0.28 AU), and the inclination of the orbital plane will be increased to a maximum of 35? after the 7 year mission. The CMOS/APS detector is a mosaic of four 2048 x 1920 pixel arrays, each 2-side buttable with 11 µm pixels.

8862-14, Session 5

Seeing the corona with the solar probe plus mission: the wide-field imager for solar probe+ (WISPR)

Angelos Vourlidas, Russell A. Howard, Simon P. Plunkett, Clarence M. Korendyke, Michael T. Carter, U.S. Naval Research Lab. (United States); Arnaud F. R. Thernisien, George Mason Univ. (United States); Damien Chua, Dennis G. Socker, Mark G. Linton, U.S. Naval Research Lab. (United States); Paulett C. Liewer, Jeffrey R. Hall, Jet Propulsion Lab. (United States); Jeff S. Morrill, U.S. Naval Research Lab. (United States); Eric M. DeJong, Jet Propulsion Lab. (United States); Zoran Miki?, Predictive Science Inc. (United States); Pierre L. P. M. Rochus, Univ. de Liège (Belgium); Volker Bothmer, Jens Rodman, Georg-August-Univ. Göttingen (Germany); Philippe L. Lamy, Lab. d'Astrophysique de Marseille (France)

The Solar Probe Plus (SPP) scheduled for launch in 2018, will orbit between the Sun and Venus with diminishing perihelia reaching as close as 7 million km (9.5 solar radii). Besides a suite of in-situ probes for the magnetic field, plasma, and energetic particles, SPP will be equipped with an imager. The Wide-field Imager for the Solar PRobe+ (WISPR), with a 90 deg radial by 55 deg transverse field of view, will image the fine-scale coronal structure of the corona, derive the 3D structure of the large-scale corona, and determine whether a dust-free zone exists near the Sun. Given the tight mass constrains of the mission, WISPR incorporates an efficient design of two wide-field telescopes and their associated focal plane arrays based on novel large-format (4kx4k) APS CMOs detectors into the smallest heliospheric imaging package to date. The flexible control electronics allow WISPR to collect individual images at cadences up to 1 second at perihelion or sum several of them to increase the signal-to-noise during the outbound part of the orbit. The use of two telescopes minimizes the risk of dust damage which may be considerable close to the Sun. The dependency of the Thomson scattering emission of the corona on the imaging geometry dictates that WISPR will be very sensitive to the emission from plasma close to the spacecraft in contrast to the situation for imaging from Earth orbit. WISPR will be the first 'local' imager providing a crucial link between the large scale corona and the in-situ measurements.

8862-15, Session 5

Development and test of an active pixel sensor detector for heliospheric imager on solar orbiter and solar probe plus

Clarence M. Korendyke, Angelos Vourlidas, Simon P. Plunkett, Russell A. Howard, Dennis Wang, U.S. Naval Research Lab. (United States); Cheryl J. Marshall, NASA Goddard Space Flight Ctr. (United States); James R. Janesick, SRI International Sarnoff (United States); Samuel Tun, U.S. Naval Research Lab. (United States); John R. Tower, David Keller, SRI International Sarnoff (United States); Gregory E. Clifford, Silver Engineering, Inc. (United States)

The Naval Research Laboratory is developing next generation CMOS imaging arrays for the Solar Orbiter and Solar Probe Plus missions. The device development is nearly complete with delivery scheduled for summer of 2013. The 4Kx4K mosaic array with 10micron pixels is well suited to the panoramic imaging required for the Solar Orbiter mission. The devices have adjustable gain. In high gain, a read noise of 2-3 electrons with a full well of ~30,000 electrons has been measured. In low gain, a read noise of ~20 electrons with a full well of >200,000 electrons has been measured. The devices are robust (>100krad) and exhibit minimal performance degradation with respect to radiation. The device development program will be presented. The device performance characteristics will be described.

8862-16, Session 5

Technology development for the Solar Probe Plus Faraday cup

Mark D. Freeman, Jay A. Bookbinder, Anthony W. Case, Peter S. Daigneau, Thomas M. Gauron, Justin C. Kasper, Harvard-Smithsonian Ctr. for Astrophysics (United States)

The upcoming Solar Probe Plus (SPP) mission requires novel approaches for in-situ plasma instrument design. SPP's Solar Probe Cup (SPC) instrument will, as part of the Solar Wind Electrons, Alphas, and Protons (SWEAP) instrument suite, operate over an enormous range of temperatures, yet must still accurately measure femto-amp currents, and with modest power requirements.

This paper discusses some of the key technology development aspects of the SPC, a Faraday Cup and one of the few instruments on SPP that is directly exposed to the solar disk, where at closest approach to the sun (9.5 solar radii) the intensity is greater than 500 earth-suns. These challenges range from materials characterization at temperatures in excess of 1000C to thermal modeling of the behavior of the materials and their interactions at these temperatures. We discuss the trades that have resulted in the material selection for the current design of the Faraday Cup. Specific challenges include the material selection and mechanical design of insulators, particularly for the high-voltage (up to 8 kV) grid and coaxial supply line, and thermo-optical techniques to minimize temperatures in the SPC, with the specific intent of demonstrating Technology Readiness Level 6 by the end of 2013.

8862-17, Session 5

Mechanical design of the solar probe cup instrument on solar probe plus

Peter S. Daigneau, David Caldwell, Henry W. Bergner, Anthony W. Case, Justin C. Kasper, Mark D. Freeman, Harvard-Smithsonian Ctr. for Astrophysics (United States)

The Solar Probe Cup (SPC) instrument is a sun-facing Faraday Cup slated for launch aboard the Solar Probe Plus (SPP) spacecraft in 2018.

The SPC is the only SPP plasma instrument which will not be shielded behind the SPP Thermal Protection System (TPS). The 7-year SPP mission will take SPC on 24 solar pass-bys at perihelia ranging from 35 Rs to 9.5 Rs. At 9.5 Rs, SPC's Sun-facing surface temperatures could approach 1500 degrees C. This paper details the derived mechanical and structural requirements on the primary SPC mechanical assemblies including its shield, sensor and strut. The SPC requirements derivation flows from the SPP environment and interface definition as of the mid-Phase B or preliminary design/technology development program. SPC instrument performance compliance to date will be covered along with results of developmental testing.

8862-18, Session 5

The design, development, and implementation of a solar environmental simulator (SES) for the SAO faraday cup on solar probe plus

Peter N. Cheimets, Jay A. Bookbinder, Mark D. Freeman, Richard Gates, Thomas M. Gauron, Giora Guth, Justin C. Kasper, Kenneth McCracken, William A. Podgorski, Harvard-Smithsonian Ctr. for Astrophysics (United States)

This paper describes the implementation of a solar simulator ,the Solar Environment Simulator (SES), that can simulate solar optical and IR flux levels up to those encountered at 9.5 solar radii. The paper outlines the design, and the challenges of realizing the SES. It also describes its initial uses for proving out the design of the Solar Wind Electron, Alphas, and Protons (SWEAP) Faraday cup.

The upcoming Solar Probe Plus (SPP) mission requires that its in-situ plasma instrument (the Faraday Cup) survive and operate over an unprecedented range of temperatures. One of the key risk mitigation activities in the current Phase B has been to develop and implement an environmental simulator that will enable thermal testing of the Faraday Cup under-flight like conditions.

The SES has proven to be a workhorse in the process of helping to predict the in-flight performance of the SWEAP Faraday Cup. With continuously variable power control above lamp ignition threshold, the SES has been used to determine the system response to a wide range of incoming flux, thereby making it possible to correlate detailed thermal models to a high degree of certainty.

The SES consists of a set of re-purposed, and slightly re-designed standard movie projectors. The projectors have proven to be an economical and effective means to safely hold and control the xenon short-arc lamps that are the basis of the SES. This paper outlines the key challenges controlling the extremely high flux levels (>70w/cm^2) necessary to make the SES a useful testing facility.

8862-19, Session 6

Space weather measurements with the RAD instrument on the Mars Science Laboratory *(Invited Paper)*

Donald M. Hassler, Southwest Research Institute (United States); Robert F. Wimmer-Schweingruber, Christian-Albrechts-Univ. zu Kiel (Germany); Cary Zeitlin, MSL RAD Science Team, Southwest Research Institute (United States)

The Radiation Assessment Detector (RAD) is a compact, lightweight energetic particle analyzer currently operating on the surface of Mars as part of the Mars Science Laboratory (MSL) Mission. These are the first measurements of the radiation environment on the surface of another planet.

This presentation will provide an overview of the RAD investigation and present the early measurements of the radiation environment during cruise and on the surface of Mars and discuss the importance of providing broad heliospheric coverage and situational awareness of space weather as we plan to send humans out into deep space and to Mars.

RAD is supported by NASA (HEOMD) under JPL subcontract #1273039 to SwRI, and by DLR in Germany under contract with Christian-Albrechts-Universitat (CAU).

8862-20, Session 6

10 years of degradation trends of the SORCE SIM instrument

Stéphane Béland, Thomas N. Woods, Jerald W. Harder, Univ. of Colorado at Boulder (United States)

The Solar Radiation and Climate Experiment (SORCE) is a NASA-sponsored satellite mission providing measurements of incoming x-ray, ultraviolet, visible, near-infrared, and total solar radiation. SORCE is currently in its 10th year of operation.

The Spectral Irradiance Monitor (SIM) instrument has been providing daily solar spectrum covering the wavelength range from 240 to 2400 nm at a resolution between 0.25-33 nm using a single optical element. SIM was designed to provide an absolute accuracy of < 2% over the wavelength coverage and a goal of long term accuracy of 0.03% per year.

The exposure of the optics, detectors and electronics to the harsh space environment causes changes in their properties. With the very high accuracy goals, it is critical to keep track of these changes as precisely as possible throughout the lifetime of the mission.

We will be reviewing the methods used to track and correct for SIM instrumental degradation of the optics and the detectors since the start of the mission.

We will also discuss lessons learned in the design of long lived solar observing missions and how they were applied to the SIM instrument on the coming Total Solar Irradiance Sensor (TSIS) mission.

8862-21, Session 7

Solar sounding rocket instrument development at NASA MSFC/Univ. of Alabama in Huntsville *(Invited Paper)*

Ken Kobayashi, The Univ. of Alabama in Huntsville (United States); Jonathan W. Cirtain, Amy R. Winebarger, NASA Marshall Space Flight Ctr. (United States); Leon Golub, Kelly E. Korreck, Harvard-Smithsonian Ctr. for Astrophysics (United States); Sergey V. Kuzin, P.N. Lebedev Physical Institute (Russian Federation); Robert W. Walsh, Univ. of Central Lancashire (United Kingdom); Craig E. DeForest, Southwest Research Institute (United States); Bart De Pontieu, Alan M. Title, Lockheed Martin Space Systems Co. (United States); William A. Podgorski, Harvard-Smithsonian Ctr. for Astrophysics (United States); Sabrina L. Savage, NASA Marshall Space Flight Ctr. (United States); Ryouhei Kano, Noriyuki Narukage, Ryoko Narukage, National Astronomical Observatory of Japan (Japan); Javier Trujillo-Bueno, Instituto de Astrofísica de Canarias (Spain)

We present an overview of solar sounding rocket instruments developed jointly by NASA Marshall Space Flight Center and the University of Alabama in Huntsville. The High Resolution Coronal Imager (Hi-C) is an EUV (19.3 nm) imaging telescope which was flown successfully in July 2012, demonstrating an unprecedented spatial resolution of 0.2 arcscond. The Chromospheric Lyman-Alpha SpectroPolarimeter (CLASP) is a Lyman Alpha (121.6 nm) spectropolarimeter developed jointly with the National Astronomical Observatory of Japan and scheduled for launch in 2015. The Marshall Grazing Incidence X-ray Spectrograph is

a soft X-ray (0.5-1.2 keV) stigmatic spectrograph designed to achieve 5 arcsecond spatial resolution along the slit.

8862-22, Session 7

Effect of surface scatter upon the MTF of the solar ultra violet imager (SUVI) telescope *(Invited Paper)*

James E. Harvey, Scott Ellis, Richard N. Pfisterer, Photon Engineering LLC (United States)

The solar UV imager (SUVI) is an extreme ultraviolet instrument that will fly on the Geostationary Operational Environmental Satellite (GOES)-R and-S platforms, as part of NOAA's space weather monitoring fleet. It will provide important information on solar activity and the effects of the Sun on the earth and the near-earth environment. This instrument will image the full solar disc in 6 EUV wavebands between 304.8 Å and 93.9 Å. A generalized Cassegrain telescope configuration is employed where six mirror sectors utilize multilayer coatings optimized for the six wavelengths of interest. An aperture shutter is used to select the appropriate sector for observations at a particular wavelength. A thinned, back-illuminated CCD sensor with 21mm (2.5 arcsec) pixels resides in the telescope focal plane. The modulation transfer function (MTF) is usually considered to be the image quality criterion of choice for applications where fine detail in extended images needs to be specified or evaluated. However, the contractual image quality requirement was specified in terms of fractional ensquared energy for a variety of different wavelengths and square sizes. In this paper we will calculate and present MTF plots (as degraded by diffraction, geometrical aberrations and surface scatter effects) for each of the SUVI wavelengths of interest. At the shortest wavelengths of interest, image degradation from surface scatter effects due to residual optical fabrication errors will dominate the effects of both diffraction and geometrical aberrations.

8862-23, Session 7

Results from the first flight of the focusing optics x-ray solar imager (FOXSI) sounding rocket

Lindsay Glesener, Univ. of California, Berkeley (United States); Steven D. Christe, NASA Goddard Space Flight Ctr. (United States); Shin-nosuke Ishikawa, National Astronomical Observatory of Japan (Japan); Brian Ramsey, NASA Marshall Space Flight Ctr. (United States); Tadayuki Takahashi, Shinya Saito, Japan Aerospace Exploration Agency (Japan) and The Univ. of Tokyo (Japan); Robert P. Lin, Univ. of California, Berkeley (United States); Säm Krucker, Univ. of Applied Sciences Northwestern Switzerland (Switzerland) and Univ. of California, Berkeley (United States)

Understanding electron acceleration in solar flares requires X-ray studies with greater sensitivity and dynamic range than are available with current solar hard X-ray observers (i.e. the RHESSI spacecraft). RHESSI employs an indirect Fourier imaging method that is intrinsically limited in dynamic range and therefore can rarely image faint coronal flare sources in the presence of bright footpoints. With greater sensitivity and dynamic range, electron acceleration sites in the corona could be studied in great detail. Both these capabilities can be advanced by the use of direct focusing optics. The recently flown Focusing Optics X-ray Solar Imager (FOXSI) sounding rocket payload demonstrates the feasibility and usefulness of focusing optics for observation of solar hard X-rays. FOXSI features grazing-incidence replicated nickel optics made by the NASA Marshall Space Flight Center and fine-pitch silicon strip detectors developed by the Astro-H team at JAXA/ISAS. FOXSI flew successfully on November 2, 2012, producing images and spectra of a microflare and performing a search for nonthermal emission (4-15 keV) from nanoflares occurring outside of active regions (in the "quiet" Sun). Nanoflares are a candidate for providing the required energy to heat the solar corona to its high temperature of a few million degrees. A future satellite version of FOXSI, featuring similar optics and detectors, could make detailed observations of hard X-rays from flare-accelerated electrons, identifying and characterizing particle acceleration sites and mapping out paths of energetic electrons as they leave these sites and propagate throughout the solar corona.

8862-24, Session 7

Design progress of the solar UV-VIS-IR telescope (SUVIT) aboard SOLAR-C

Yukio Katsukawa, National Astronomical Observatory of Japan (Japan); Kiyoshi Ichimoto, Kyoto Univ. Hida Observatory (Japan); Yoshinori Suematsu, Hirohisa Hara, Ryouhei Kano, National Astronomical Observatory of Japan (Japan); Toshifumi Shimizu, Keiichi Matsuzaki, Japan Aerospace Exploration Agency (Japan)

We present a design progress of the Solar UV-Vis-IR Telescope (SUVIT) aboard the next Japanese solar mission SOLAR-C. SUVIT has an aperture diameter of ~1.5 m for achieving spectro-polarimetric observations with spatial and temporal resolution exceeding Hinode SOT. We have studied structural and thermal designs of the optical telescope as well as the optical interface between the telescope and the focal plane instruments. The focal plane instruments are installed into two packages, filtergraph and spectrograph packages. The spectro-polarimeter is the instrument dedicated to accurate polarimetry in the three spectrum windows at 525 nm, 854 nm, and 1083 nm for observing magnetic fields at both the photospheric and chromospheric layers. We made optical design of the spectrograph accommodating the classical slit spectrograph and the integral field unit (IFU) for two-dimensional coverage with the spectro-polarimetric observation. We are running feasibility study of IFU using fiber bundles consisting of rectangular cores as well as the IR camera system for high-sensitivity observations of the He I 1083 nm line.

8862-25, Session 7

The soft x-ray photon-counting spectroscopic imager for the sun

Taro Sakao, Noriyuki Narukage, Kyoko Watanabe, Japan Aerospace Exploration Agency (Japan); Shin-nosuke Ishikawa, National Astronomical Observatory of Japan (Japan); Shinsuke Imada, Nagoya Univ. (Japan)

We report development activities as well as science with the soft X-ray photon-counting spectroscopic imager for the solar corona that we conceive as a possible scientific payload for the Japanese Solar-C mission whose projected launch around 2019.

The imager employs a grazing-incidence sector mirror of Wolter-I type with which images of the corona are to be taken in a wide temperature range (1 MK to beyond 10 MK) with the highest-ever angular resolution (0.5"/pixel for a focal length of 4 m) as an X-ray telescope for the Sun. Moreover, by employing a back-thinned CMOS image sensor as the focal-plane device, we attempmt to implement photon-counting capability with which imaging-spectroscopy of the X-ray corona will be performed for the first time, in the energy range from ~0.5 keV up to 10 keV. The imaging-spectroscopic observations will provide totally-new information on mechanism(s) for the generation of hot coronal plasmas (heated beyond a few MK) which may be responsible for the formation of the hot cores of solar active regions, those for magnetic reconnection, and even generation of supra-thermal electrons associated with flares.

An overview of instrument outline and science of the soft X-ray imager will be presented. Also, ongoing development activities in Japan towards soft X-ray photon-counting observations, including sub-arcsecond-resolution grazing-incidence mirror, high-speed X-ray CMOS detector,

and possible considerations on NASA sounding rocket experiment as a verification flight, will be reported and their perspective discussed.

8862-26, Session PMon

Recent advances in electronics and software for the METIS coronagraph aboard solar orbiter

Mauro Focardi, Maurizio Pancrazzi, INAF - Osservatorio Astrofisico di Arcetri (Italy); Gianalfredo Nicolini, INAF - Osservatorio Astronomico di Torino (Italy); Michela C. Uslenghi, INAF - IASF Milano (Italy); Enrico Magli, Marco Ricci, Politecnico di Torino (Italy); Marco Romoli, Univ. degli Studi di Firenze (Italy); Vincenzo Andretta, INAF - Osservatorio Astronomico di Capodimonte (Italy); Federico Landini, INAF - Osservatorio Astrofisico di Arcetri (Italy); Ester Antonucci, Silvano Fineschi, INAF - Osservatorio Astronomico di Torino (Italy); Giampiero Naletto, Piergiorgio Nicolosi, Univ. degli Studi di Padova (Italy); Daniele Spadaro, INAF - Osservatorio Astrofisico di Catania (Italy); Walter Errico, Franco Bigongiari, Lorenzo Fontani, Marco Orlandi, Annamaria Colonna, Sitael S.p.a. (Italy)

METIS is a visible and UV externally inversely occulted coronagraph selected to fly aboard the Solar Orbiter space mission. Thanks to its own capabilities and exploiting the peculiar opportunities offered by the SO mission profile, the instrument will address some of the still open issues in understanding the physics driving the observed processes in the corona and characterizing the slow and fast components of the solar wind.

Recently the METIS design went thorough a significant revision involving the overall electronics configuration and software functionalities, comprehensive of descoping of some features but also aiming at the improvement of the instrument reliability. As a result the electronics architecture has been simplified enabling a potential cold-strapped redundancy scheme of some subsystems, while the preliminary SW database was defined as well.

We also identified the scientific processing algorithms implementing the instrument functionalities and the image compression capabilities able to match the selected HW resources providing an optimal compromise between complexity and compression ratio.

This paper will describe the revised electronics and software design developed in order to maximise the overall scientific returns with the updated instrument configuration.

8862-27, Session PMon

Charged particle data from the combined x-ray and dosimeter instrument aboard GPS satellites

Richard C. Schirato, Los Alamos National Lab. (United States)

Abstract to come: waiting on export control approval

8862-28, Session PMon

Imaging and detector systems of the gamma-ray imager/polarimeter for solar flares (GRIPS) instrument

Nicole Duncan, Univ. of California, Berkeley (United States); Albert Y. M. Shih, NASA Goddard Space Flight Ctr. (United States); Gordon J. Hurford, Pascal Saint-Hilaire, Andreas Zoglauer, Hazel M. Bain, Univ. of California, Berkeley (United States); Mark S. Amman, Lawrence Berkeley National Lab. (United States); Steven E. Boggs, Robert P. Lin, Univ. of California, Berkeley (United States)

Hard X-ray and gamma-ray emission during solar flares encode information about electron/ion dynamics and provide a proxy to deduce solar atmospheric parameters. Enhanced imaging, spectroscopy and polarimetry of gamma/HXR flare emissions over 20 keV to >~10MeV is needed to study particle transport; the Gamma-Ray Imager/Polarimeter for Solar Flares (GRIPS) instrument is designed to meet these goals. GRIPS' key technological improvements over the current solar state of the art in HXR/gamma-ray energies (RHESSI) include 3D position-sensitive germanium detectors (3D-GeDs) and a single-grid modulation collimator, the Multi-Pitch Rotating Modulator (MPRM). The 3D-GeDs allow GRIPS to reconstruct Compton-scatter tracks of energy deposition within the crystal, providing enhanced background reduction and polarization measurements. Each of GRIPS' sixteen detectors has 250 electrode strips with dedicated ASIC/FPGA electronics. In GRIPS' energy range, indirect Fourier imaging provides higher resolution than focusing optics or Compton imaging techniques. The MPRM grid-imaging system has a single-grid design which provides 2x the throughput of a bigrid imaging system like RHESSI. Quasi-continuous resolution from 12.5 – 162 arcsecs is achieved by varying the grid pitch between 1 - 13mm. This spatial resolution will be capable of imaging the separate footpoints in a variety of flare sizes. In comparison, RHESSI's minimum 35arcsec resolution at the same energy makes footpoints resolvable in only the largest flares. We discuss GRIPS science goals, the instrument overall and recent developments in GRIPS' imaging and detector systems. GRIPS is scheduled for an engineering flight from Fort Sumner in September 2013, followed by two long-duration balloon flights from Antarctica.

8862-29, Session PMon

Preliminary tolererance analysis of the coronagraphic instrument METIS for the solar orbiter ESA mission

Vania Da Deppo, Consiglio Nazionale delle Ricerche (Italy); Giuseppe Crescenzio, INAF - Osservatorio Astronomico di Torino (Italy); Giampiero Naletto, Univ. degli Studi di Padova (Italy); Silvano Fineschi, Ester Antonucci, INAF - Osservatorio Astronomico di Torino (Italy)

METIS, the Multi Element Telescope for Imaging and Spectroscopy, is the solar coronagraph foreseen for the ESA Solar Orbiter mission. METIS is conceived to image the solar corona from a near-Sun orbit in two different spectral bands: in the HI UV narrow band at 121.6 nm, and in the polarized visible light band (590 – 650 nm).

METIS is an externally occulted coronagraph which adopts an "inverted occulted" configuration. The inverted external occulter (IEO) is a small circular aperture after which a small spherical mirror M0 rejects back the disk-light through the IEO, then an annular mirror collects the signal coming from the corona and redirects it toward the telescope secondary mirror.

This paper presents the error budget analysis for this new-concept coronagraph configuration, which incorporates two different sub-channels: the UV imaging and the polarimetric VIS one. The two sub-channels are sharing the telescope optics, then an interference filter transmits the UV light towards the UV detector, while the VIS light is reflected towards the polarimetric unit.

The tolerance analysis is rather complex, in fact not only the optical performance for the two sub-channels has to be maintained simultaneously, but also the positions of the M0 and the occulters (IEO, internal occulter and Lyot stop), which assure the optimal disk light suppression, have to be taken into account as tolerancing parameters.

To guarantee the scientific requirements are optimally fulfilled for the two sub-channels, the preliminary results of manufacturing, alignment and

stability tolerance analysis for the whole instrument will be described and discussed.

8862-30, Session PMon

Characterization of linear polarizers in the wavelength range 100-150 nm (VUV) for solar physics applications

Gerardo Capobianco, INAF - Osservatorio Astronomico di Torino (Italy); A. Marco Malvezzi, Univ. degli Studi di Pavia (Italy); Silvano Fineschi, INAF - Osservatorio Astronomico di Torino (Italy); Juan I. Larruquert, Consejo Superior de Investigaciones Científicas (Spain); Giuseppe Crescenzio, Giuseppe Massone, INAF - Osservatorio Astronomico di Torino (Italy); José A. Aznárez Candao, José A. Méndez, Luis Rodríguez-De Marcos, Consejo Superior de Investigaciones Científicas (Spain); Angelo Giglia, Sincrotrone Trieste S.C.p.A. (Italy) and Consiglio Nazionale delle Ricerche (Italy); Stefano Nannarone, Sincrotrone Trieste S.C.p.A. (Italy) and Consiglio Nazionale delle Ricerche (Italy) and Univ. degli Studi di Modena e Reggio Emilia (Italy); Fabio Frassetto, Univ. degli Studi di Padova (Italy)

VUV polarimetry has been recognized as one of the most powerful diagnostic tools for remote sensing of the solar corona, with the potential of providing accurate space resolved information on magnetic activity through observation of resonance lines of the most abundant species. In an on-going collaboration between our groups from Spain and Italy, a program to design, build and characterize optical components for the VUV region has been activated. In particular, using the beamline BEAR at the synchrotron facility Elettra in Trieste (Italy) we have characterized some thin film reflecting linear polarizers, designed and optimized for the study of polarimetric properties of the HI Ly-alpha at 121.6 nm. The characterizations are performed in wavelengths (from 100 to 150 nm) at different angles of incidence (40 – 80 deg). Some polarizers have shown excellent performances with a reflectivity $R \approx 34\%$ and a modulation factor exceeding 95%. The calibration of several samples is reported and aging effects on some old samples is discussed. One of the calibrated sample will be used for the evaluation of the performances of a new fast calibration set-up facility for VUV.

8862-31, Session PMon

In-flight calibration and astronomical polarimetry in the V-band with solar orbiter/ METIS instrument

Gerardo Capobianco, Giuseppe Crescenzio, Silvano Fineschi, Giuseppe Massone, Alessandro Bemporad, INAF - Osservatorio Astronomico di Torino (Italy)

METIS (Multi Element Telescope for Imaging and Spectroscopy) is one of the remote sensing instruments on board the ESA- Solar Orbiter mission, who will be launched in 2017. The Visible Light channel of the instrument is composed by an achromatic LC-based polarimeter for the study of the linearly polarized solar K-corona in visible light (bandpass: 580-640nm). The in-flight calibration of the channel requires the use of some well knows linearly polarized stars in the FoV of the instrument. The check and the selection of the stars and the use of other astronomical targets (i.e. planets, comets,…) are here discussed. The possibility of measure the degree of linear polarization of some astronomical objects (i.e. Earth, comets,…) is also object of this paper.

8862-32, Session PMon

The visible light source for METIS stray-light tests: preliminary design

Massimiliano Tordi, Space Technologies Srl (Italy); Silvano Fineschi, Giuseppe Crescenzio, INAF - Osservatorio Astronomico di Torino (Italy)

METIS is the UV/VIS coronagraph of the ESA mission Solar Orbiter. One of the main technical drivers of the instrument is the detailed stray-light control, as close to the disk edge the VIS coronal emission is six to about seven order of magnitudes lower than the disk one. The instrument testing procedure must then include a measurement of its stray-light rejection capability, which is a fundamental step in the whole instrument calibration / acceptance process. A preliminary optical design of the optical light source for stray-light test is presented. The main requirements are discussed and two possible solutions are outlined.

8863-2, Session 1

Raytheon low temperature RSP2 cryocooler flight program

Brian R. Schaefer, Raytheon Space & Airborne Systems (United States)

The Low-Temperature Raytheon Stirling / Pulse Tube 2-stage ("LT-RSP2") hybrid cryocooler is a long-life, robust machine designed to operate efficiently at a first stage temperature of 55K and a capacity of 5W and a second stage temperature of 10 K and a capacity of 250mW. While some aspects of the expander warm-end mechanical design are carryovers from the existing High Capacity RSP2, the compressor module and expander cold head have been substantially optimized for increased efficiency and capacity at low cryogenic temperatures. The LT-RSP2 design was finalized in mid-2009, with piece-part fabrication taking place in late 2009 and early 2010. Assembly and initial testing in an ambient benchtop configuration occurred in 2010/2011. The flight program was executed in 2011 and 2012. Major aspects of the mechanical and thermodynamic design will be presented in this paper, including information regarding the final operating point, performance, and packaging details. Results from the fabrication, assembly, and testing will be discussed, as will observations regarding the achieved system performance. Future testing and design enhancement plans will be discussed as well.

8863-3, Session 1

Advanced regenerator testing in the Raytheon dual-use cryocooler

Brian R. Schaefer, Raytheon Space & Airborne Systems (United States)

Significant progress has been made on the Raytheon low cost space cryocooler called the Dual Use Cryocooler (DUC), most notably; the DUC has been integrated and tested with an advanced regenerator. The advanced regenerator is a drop in replacement for stainless steel screens and has shown significant thermodynamic performance improvements. This paper will compare the performance of two different regenerators and explain the benefits of the advanced regenerator.

8863-4, Session 1

Raytheon's next generation compact in-line cryocooler architecture

Brian R. Schaefer, Raytheon Space & Airborne Systems (United States)

Since the 1970s, Raytheon has developed, built, tested and integrated high performance space cryocoolers. Our versatile designs for single- and multi-stage cryocoolers provide reliable operation for temperatures from 10 to 200 Kelvin with power levels ranging from 50 W to nearly 600 W. These advanced cryocoolers incorporate clearance seals, flexure suspensions, hermetic housings and dynamic balancing to provide long service life and reliable operation in ground, air and space environments.

Today, sensors face a multitude of cryocooler integration challenges such as exported disturbance, efficiency, scalability, maturity, and cost. As a result, cryocooler selection is application dependent, oftentimes requiring extensive trade studies to determine the most suitable architecture. To optimally meet the needs of next generation passive IR sensors, the Compact Inline Raytheon Stirling 1-Stage (CI-RS1), Compact Inline Raytheon Single Stage Pulse Tube (CI-RP1) and Compact Inline Raytheon Hybrid Stirling/Pulse Tube 2-Stage (CI-RSP2) cryocoolers are being developed to satisfy this suite of requirements. This lightweight, compact, efficient, low vibration cryocooler combines proven 1-stage (RS1 or RP1) and 2-stage (RSP2) cold-head architectures with an inventive set of warm-end mechanisms into a single cooler module, allowing the moving mechanisms for the compressor and the Stirling displacer to be consolidated onto a common axis and in a common working volume. The CI cryocooler is a significant departure from the current Stirling cryocoolers in which the compressor mechanisms are remote from the Stirling displacer mechanism.

Placing all of the mechanisms in a single volume and on a single axis provides benefits in terms of package size (30% reduction), mass (30% reduction), thermodynamic efficiency (>20% improvement) and exported vibration performance (≤25 mN peak in all three orthogonal axes at frequencies from 1 to 500 Hz). The main benefit of axial symmetry is that proven balancing techniques and hardware can be utilized to null all motion along the common axis. Low vibration translates to better sensor performance resulting in simpler, more direct mechanical mounting configurations, eliminating the need for convoluted, expensive, massive, long lead damping hardware.

8863-5, Session 1

Cryomechanism: a cryogenic rotating actuator

Jean-Christophe Barriere, Michel Berthe, Michael Carty, Jean Fontignie, Didier Leboeuf, Jérome Martignac, Christophe Cara, Patrice Charon, Gilles A. Durand, Damien Bachet, Commissariat à l'Énergie Atomique (France); Bruno Duboué, CEA (France)

Fifteen years ago, CEA started the development of cryogenic rotating actuators for VISIR, an astronomy IR camera mounted on the Very Large Telescope. At Visir first light in 2004, 10 cryogenic rotating actuators, also known as "cryomechanisms", were integrated in the instrument. As VISIR is still operating, cryomechnisms are operated several times a day, without any reported failure.

The cryomechanism has been designed to operate from room temperature to cryogenic environment (down to 4 Kelvin) with the same level of performances. Based on a stepper motor and a gear clutch system, the cryomechanism enables any discrete position to be reached(360 positions a turn for VISIR model) with a very good repeatability: below 100µrad peak to peak. Due to the clutch mechanism, there is no power consumption once the actuation has stopped.

After the VISIR project, CEA undertook the task of performing space qualification tests with the aim of making the cryomechanism compatible with space missions. Relying on test results, a smaller model of the mechanism (200 positions a turn) has been built and cryo-tested.

Today, cryomechanisms are selected for the EUCLID space project. Qualification program will run throughout 2014.

The proposed paper will first describe the baseline requirements, the design and operation principles. Then, the qualification plan will be shown as well as the environment test results with respect to vibrations, thermal cycling and life testing campaigns carried out on a Qualification Model. The synthesis of cryomechanisms capabilities will be presented and design improvements for the EUCLID project will be addressed in the last part.

8863-6, Session 1

Cryogenic optical position encoders for mechanisms in the JWST optical telescope element simulator (OSIM)

Douglas B. Leviton, NASA Goddard Space Flight Ctr. (United States); Thomas Anderjaska, Northrop Grumman Technical Services (United States); James Badger, Ball Aerospace & Technologies Corp. (United States); Thomas Capon, NASA Goddard Space Flight Ctr. (United States); Clinton Davis, Orbital

Sciences Corp. (United States); Brent Dicks, Ball Aerospace & Technologies Corp. (United States); William L. Eichhorn, NASA Goddard Space Flight Ctr. (United States); Mario S. Garza, Orbital Sciences Corp. (United States); Shadan Haghani, Northrop Grumman Technical Services (United States); Claef F. Hakun, Paul G. Haney, NASA Goddard Space Flight Ctr. (United States); David Happs, Ball Aerospace & Technologies Corp. (United States); Lars Hovmand, Northrop Grumman Corp. (United States); Madhu Kadari, Jackson & Tull Inc. (United States); Jeffrey Kirk, Orbital Sciences Corp. (United States); Corina Koca, NASA Goddard Space Flight Ctr. (United States); Richard Nyquist, Ball Aerospace & Technologies Corp. (United States); Frederick D. Robinson, Global Science and Tech Inc. (United States); Joseph F. Sullivan, Ball Aerospace & Technologies Corp. (United States); Erin M. Wilson, Genesis Engineering Solutions, Inc. (United States)

The James Webb Space Telescope (JWST) Optical Telescope Element Simulator (OSIM) is a massive, configurable, cryogenic, optical stimulus for JWST's flight instrument complement – called the Integrated Science Instrument Module (ISIM) – and allows high fidelity ground characterization and calibration of the instruments. Using a collection of remotely operated point sources, a single spherical primary mirror, and several ultra-precise, cryogenic mechanisms, OSIM projects images of those sources to ISIM as if they were stars in the sky according to the same optical prescription as the flight telescope would. A large, X-Y-Z-tip-tilt mechanism known as the Beam Image Analyzer (BIA) carries a point-diffraction interferometer, phase retrieval camera, and radiometer assembly – tools that allow OSIM to be configured to establish the correct optical prescription for each field point and chief ray angle. The BIA surveys the telescope's focal surface, calibrating OSIM for all required ground observations with ISIM. OSIM itself contains two X-Y-Z stages (the Source Plate Mechanism and Pupil Translation Mechanism), two rotary pupil selection wheels (Pupil Select Mechanism), and a two-axis gimbal (for Fold Mirror 3). Each mechanism in OSIM and the BIA navigate according to redundant, cryogenic, absolute, optical encoders – 32 in all operating at temperatures at or below 100 K. This paper discusses OSIM's optical encoder subsystem, the engineering challenges that were met in its development, and the sub-micron and sub-arcsecond performance of OSIM's absolute linear (and Cartesian) and angular encoders, respectively.

8863-7, Session 2

Temperature-dependent refractive index of Cleartran® ZnS to cryogenic temperatures

Douglas B. Leviton, Bradley J. Frey, NASA Goddard Space Flight Ctr. (United States)

In order to enable high quality lens designs using Cleartran® ZnS at cryogenic temperatures, we have measured the absolute refractive index of a Cleartran® ZnS prism as a function of both wavelength and temperature using the Cryogenic, High-Accuracy Refraction Measuring System (CHARMS) at NASA's Goddard Space Flight Center. Cleartran® ZnS is a water clear form of CVD ZnS, and while we have not measured "regular" ZnS, literature values indicate that its refractive index does differ from that of Cleartran® ZnS by 0.001-0.002 depending on wavelength at room temperature. For our Cleartran® measurements, we report absolute refractive index and thermo-optic coefficient (dn/dT) at temperatures ranging from 25 to 300 K at wavelengths from 0.50 to 5.6 microns. We compare our measurements with others in the literature and provide temperature-dependent Sellmeier coefficients based on our data to allow accurate interpolation of index to other wavelengths and temperatures. We generally find good agreement at room temperature between our measured values and those provided by the material's manufacturer.

8863-8, Session 2

Temperature-dependent refractive index measurements of S-FPL51, S-FTM16, and S-TIM28 to cryogenic temperatures

Douglas B. Leviton, Bradley J. Frey, Ross M. Henry, NASA Goddard Space Flight Ctr. (United States)

Using the Cryogenic High Accuracy Refraction Measuring System (CHARMS) at NASA's Goddard Space Flight Center, we measured absolute refractive indices at temperatures from 30 to 300 K at wavelengths from 0.50 to 2.6 microns for three infrared materials in support of lens designs for instruments for two of the world's largest astronomical observatories – the present W.M. Keck Observatory and the future Giant Magellan Telescope (GMT). MOSFIRE – a near-infrared multi-object spectrograph and wide-field camera for the Cassegrain focus of Keck 1 – achieves diffraction limited performance at 120 K owing in part to the accuracy of our measurements of S-FPL51 and S-FTM16 prisms provided by University of California Observatories/Lick Observatory. MOSFIRE's lens design was also based in part on previously published CHARMS measurements of its four other infrared lens materials – ZnSe, CaF2, BaF2, and Infrasil 301. NIRMOS – a near infrared multiple object imager/spectrograph proposed for the GMT – uses S-TIM28 in addition to CaF2 and Infrasil in its multi-element imaging lens design. One S-TIM28 prism fabricated for a previous measurement study was provided by the Harvard College Observatory. We report absolute refractive index and thermo-optic coefficient (dn/dT) for these materials and compare our measurements with others in the literature. We provide temperature-dependent Sellmeier coefficients based on our data to allow accurate interpolation of index to other wavelengths and temperatures. Our uncertainty in absolute index for all samples in this study is limited to about 3 x 10-5 for all wavelengths and temperatures measured.

8863-9, Session 2

Cryogenic refractive index and coefficient of thermal expansion of S-TiH1 glass

Manuel A. Quijada, NASA Goddard Space Flight Ctr. (United States)

The top level science requirements for the Wide Field Infrared Survey Telescope (WFIRST) mission are: • Complete the statistical census of Galactic planetary systems using microlensing; • Determine the nature of the dark energy that is driving the current accelerating expansion of the universe; • Produce a deep map survey of the sky at NIR wavelengths, enabling new and fundamental discoveries ranging from mapping the Galactic plane to probing the reionization epoch by finding bright quasars at z>10. A refractive optical system design has been proposed to accomplish the galaxy redshift survey (GRS) on the WFIRST mission. S-TIH1 type glass is a current candidate for the refractive elements. This instrument is expected to operate in a space environment at temperatures as low as 150K. This paper reports on cryogenic optical property studies performed on S-TIH1 glass samples in order to enable progress toward an optical design that will be valid at the 150K operating temperature. Tests results to be reported include coefficient of thermal expansion (CTE) and cryogenic refractive index data obtained with the Cryogenic High Accuracy Refraction Measuring System (CHARMS) facility at the Goddard Space Flight Center.

8863-11, Session 3

Consequences of cathodoluminescence for cryogenic applications of SiO2-based space observatory optics and coating

Amberly Evans, J.R. Dennison, Gregory Wilson, Justin Dekany, Utah State Univ. (United States); Charles W. Bowers, Robert Meloy, NASA Goddard Space Flight Ctr. (United States); James

B. Heaney, SGT, Inc. (United States)

Disordered thin-film fused silica samples undergoing electron-beam bombardment exhibit cathodoluminescence, showing increased intensity and red-shift at lower temperatures. Such light emission from SiO2/SiOx optical elements or coatings can produce deleterious stray background light in cryogenic space-based astronomical observatories exposed to high-energy electron fluxes from space plasmas. Measurements of radiance of cathodoluminescence on irradiation time, incident flux and energy, sample thickness, and temperature are presented along with a simple disordered band theory model. Calculations are presented of absolute spectral radiances for flux profiles over incident electron energies typical of space environments; these allow prediction of luminescence for specific space applications.

8863-12, Session 3

Diverse electron-induced optical emissions from space observatory materials at low temperatures

J.R. Dennison, Amberly Evans, Justin Dekany, Gregory Wilson, Utah State Univ. (United States); Charles W. Bowers, Robert Meloy, NASA Goddard Space Flight Ctr. (United States)

8863-14, Session 4

The development and analysis of cryogenic optical systems for the rapid infrared imager/spectrometer

John I. Capone, Univ. of Maryland, College Park (United States); David A. Content, NASA Goddard Space Flight Ctr. (United States); Ori D Fox, NASA Goddard Space Flight Ctr (United States) and Univ. of California, Berkeley (United States); Neil A. Gehrels, Alexander S. Kutyrev, Gennadiy N. Lotkin, Samuel H. Moseley, Frederick D. Robinson, NASA Goddard Space Flight Ctr. (United States); Vicki L. Toy, Sylvain Veilleux, Stuart N. Vogel, Univ. of Maryland, College Park (United States)

The observational cosmology lab at NASA's Goddard Space Flight Center (GSFC), in collaboration with the University of Maryland, is building the Rapid Infrared Imager/Spectrometer (RIMAS) for the new 4.3 meter Discovery Channel Telescope (DCT). The instrument is designed to observe gamma-ray burst (GRB) afterglows following their initial detection by the Swift satellite. RIMAS will operate in the near infrared (0.9 – 2.4 microns) with all of its optics cooled to ~60 K. The primary optical design includes a collimator lens assembly, a dichroic dividing the wavelength coverage into the "YJ band" and "HK band" optical arms, and camera lens assemblies for each arm. Additionally, filters and dispersive elements are attached to wheels positioned prior to each arm's camera, allowing the instrument to quickly change from its imaging modes to spectroscopic modes. Optics have also been designed to image the sky surrounding spectroscopic slits to help observers pass light from target sources through these slits. Because the optical systems are entirely cryogenic, it was necessary to model the effects of thermal contraction. One result of this work is a lens mount design that keeps lenses centered on the optical axis as the system is cooled. Efforts to design, tolerance and assemble these cryogenic optical systems are presented.

8863-15, Session 4

NIRCam filter wheel assembly design

Béla I. Privári, Lockheed Martin Space Systems Co. (United States)

The Filter Wheel Assembly (FWA) is an integral and important sub-system of the Near Infra-Red Camera (NIRCam) instrument on the James Webb Space Telescope. The FWA mechanism provides the capability to position one of twelve different filters in the optical path of the camera, and also positions one of twelve different pupil optics in the same path. The FWA is therefore comprised of two separate wheel assemblies that can be positioned independently to provide the desired configuration of optical elements for imaging. Along with the rest of the instrument, the FWA operates at cryogenic temperatures and is used for both short and long wavelength imaging . Also contained within the FWA is a calibration light source assembly used for confirming detector performance throughout the mission and assists alignment of the telescope primary mirror segments . This paper will review significant elements of the mechanical design of the FWA mechanism.

8863-16, Session 4

JWST NIRCam pick-off mirror grounding

Paul V. Mammini, Howard P. Demroff, James Mathieson, Brian B. Jones, Michael Jacoby, Yalan Mao, Lockheed Martin Space Systems Co. (United States)

The optics train of the Near Infrared Camera (NIRCam) instrument for NASA's James Webb Space Telescope (JWST) includes a Pick Off Mirror (POM) with a view of the L2 space environment. A technique to ground the mirror and remove accumulated charge has been qualified and implemented on the Mod A and B POM. This paper will provide an overview of the qualification process including cryogenic resistance and surface error measurements as well as vibration testing. To measure the efficiency of this technique, a POM engineering model was exposed to representative Mission electron fluence and results with the POM grounded and ungrounded will be presented.

8863-18, Session 4

The GAIA basic angle monitoring system: cryogenic aspects

Ben C. Braam, Wim L. Gielesen, Dick de Bruijn, Teun C. van den Dool, Fred Kamphues, Ellart A. Meijer, TNO (Netherlands)

The GAIA mission will create an extraordinarily precise three-dimensional map of more than one billion stars in our Galaxy. The GAIA spacecraft, built by EADS Astrium, is part of ESA's Cosmic Vision programme and scheduled for launch in 2013. GAIA measures the position, distance and motion of stars with an accuracy of 24 micro-arcsec using two telescopes at a fixed mutual angle of 106.5°, named the 'Basic Angle', at 100 K operational temperature. This accuracy requires ultra-high stability, which can only be achieved by using Silicon Carbide for both the optical bench and the telescopes. TNO has developed, built and space qualified the Silicon carbide Basic Angle Monitoring (BAM) on-board metrology system for this mission. The BAM measures the relative motion of GAIA's telescopes with accuracies in the range of 0.5 micro-arcsec. This is achieved by a system of two laser interferometers able to measure Optical Path Differences (OPD) as small as 1.5 picometer rms. Following a general introduction to the GAIA mission, the Payload Module (PLM) and the use of Silicon Carbide as base material, this presentation will address an overview of the challenges towards the key requirements, cryo-design, integration and (cryo)-testing (including space-level qualification) of GAIA BAM.

8864-50, Session PMon

Survey of experimental results in high-contrast imaging for future exoplanet missions

Peter R. Lawson, Jet Propulsion Lab. (United States); Ruslan Belikov, NASA Ames Research Ctr. (United States); Webster Cash, Univ. of Colorado at Boulder (United States); Mark Clampin, NASA Goddard Space Flight Ctr. (United States); Tiffany Glassman, Northrop Grumman Aerospace Systems (United States); Olivier Guyon, The Univ. of Arizona (United States); N. Jeremy Kasdin, Princeton Univ. (United States); Brian D. Kern, Jet Propulsion Lab. (United States); Richard Lyon, NASA Goddard Space Flight Ctr. (United States); Eugene Serabyn, Jet Propulsion Lab. (United States); Dan Sirbu, Princeton Univ. (United States); John T. Trauger, Jet Propulsion Lab. (United States)

We present and compare experimental results in high contrast imaging representing the state of the art in coronagraph and starshade technology. These experiments have been undertaken with the goal of demonstrating the capability of detecting Earth-like planets around nearby Sun-like stars. The contrast of an Earth seen in reflected light around a Sun-like star would be about 1.2 x 10^-10. Several of the current candidate technologies now yield raw contrasts of 1.0 x 10^-9 or better, and so should enable the detection of Earths, assuming a gain in sensitivity in post-processing of a factor of 10. We present results of coronagraph and starshade experiments conducted at visible and infrared wavelengths. Cross-sections of dark fields are directly compared as a function of field angle and bandwidth. The strength and differences of the techniques are compared.

8864-51, Session PMon

Achromatic focal plane mask for exoplanet imaging coronagraphy

Kevin E. Newman, The Univ. of Arizona (United States); Ruslan Belikov, NASA Ames Research Ctr. (United States); Olivier Guyon, Subaru Telescope, National Astronomical Observatory of Japan (United States); Kunjithapatham Balasubramanian, Daniel Wilson, Jet Propulsion Lab. (United States)

Recent advances in coronagraph technologies for exoplanet imaging have achieved contrasts close to 1e-10 at 4 ?/D and 1e-9 at 2 ?/D in monochromatic light. A remaining technological challenge is to achieve high contrast in broadband light; a challenge that is largely limited by chromaticity of the focal plane mask. The size of a star image scales linearly with wavelength. Focal plane masks are typically the same size at all wavelengths, and must be sized for the longest wavelength in the observational band to avoid starlight leakage. However, this oversized mask blocks useful discovery space from the shorter wavelengths.

We present here the design, development, and testing of an achromatic focal plane mask based on the concept of optical filtering by a diffractive optical element (DOE). The mask consists of an array of DOE cells, the combination of which functions as a wavelength filter with any desired amplitude and phase transmission. The effective size of the mask scales nearly linearly with wavelength, and allows significant improvement in the inner working angle of the coronagraph at shorter wavelengths. The design is applicable to almost any coronagraph configuration, and enables operation in a wider band of wavelengths than would otherwise be possible. We include initial results from a laboratory demonstration of the mask with the Phase Induced Amplitude Apodization coronagraph.

8864-52, Session PMon

Pressure and temperature stabilization of an existing Echelle

Anna Brucalassi, Max-Planck-Institut für extraterrestrische Physik (Germany) and Univ.-Sternwarte München (Germany); Frank U. Grupp, Univ.-Sternwarte München (Germany); Liang Wang, Max-Planck-Institut für extraterrestrische Physik (Germany) and Univ.-Sternwarte München (Germany) and National Astronomical Observatories (China); Ralf Bender, Max-Planck-Institut für extraterrestrische Physik (Germany) and Univ.-Sternwarte München (Germany)

FOCES the stabilized Echelle spectrograph of the Wendelstein observatory of Munich University Observatory is intended to be equipped with a frequency comb for highly accurate and precise radial velocity measurements. In this paper of the series we investigate the influence of the CCD camera system thermal control on the stability of the instrument.

8864-53, Session PMon

An advanced fiber link for the test of highly stable frequency comb-spectrograph coupling

Frank U. Grupp, Max-Planck-Institut für extraterrestrische Physik (Germany) and Univ.-Sternwarte München (Germany); Ronald Holzwarth, Menlo Systems GmbH (Germany) and Max-Planck-Institut für Quantenoptik (Germany); Ralf Bender, Max-Planck-Institut für extraterrestrische Physik (Germany) and Univ.-Sternwarte München (Germany)

FOCES the stabilized Echelle spectrograph of the Wendelstein observatory of Munich University Observatory is intended to be equipped with a frequency comb for highly accurate and precise radial velocity measurements. The design of a prototype fiber link allowing stability check and variations of the simultaneous calibration idea is presented with this paper.

8864-54, Session PMon

Precision near-infrared radial velocity instrumentation I: absorption gas cells

Peter P. Plavchan, NASA Exoplanet Science Institute (United States); Guillem Anglada-Escude, Univ. Göttingen (Germany); Russel White, Georgia State Univ. (United States); Peter Gao, California Institute of Technology (United States); Cassy Davison, Georgia State Univ. (United States); Sean Mills, The Univ. of Chicago (United States); Charles Beichman, California Institute of Technology (United States); Carolyn Brinkworth, Caltech/NASA Exoplanet Science Institute (United States); John A. Johnson, Michael Bottom, California Institute of Technology (United States); David Ciardi, Kent K. Wallace, Bertrand Mennesson, Jet Propulsion Lab. (United States); Kaspar von Braun, California Institute of Technology (United States); Gautam Vasisht, Jet Propulsion Lab. (United States); Lisa Prato, Lowell Observatory (United States); Stephen Kane, California Institute of Technology (United States); Angelle Tanner, Mississippi State Univ. (United

States); Bernie Walp, Gemini Observatory (United States); Samuel L. Crawford, Jet Propulsion Lab. (United States); Sean Lin, California Institute of Technology (United States)

We have built and commissioned gas absorption cells for precision spectroscopic radial velocity measurements in the near-infrared in the H and K bands. We describe the construction and installation of three such cells filled with 13CH4, 12CH3D, and 14NH3 for the CSHELL spectrograph at the NASA Infrared Telescope Facility (IRTF). We have obtained their high-resolution laboratory Fourier Transform spectra, which can have other practical uses. We summarize the practical details involved in the construction of the three cells, and the thermal and mechanical control. In all cases, the construction of the cells is very affordable. We are carrying out a pilot survey with the 13CH4 methane gas cell on the CSHELL spectrograph at the IRTF to detect exoplanets around low mass and young stars. We discuss the current status of our survey, with the aim of photon-noise limited radial velocity precision. For adequately bright targets, we are able to probe a noise floor of ~7 m/s with the gas cell with CSHELL at cassegrain focus. Our results demonstrate the feasibility of using a gas cell on the next generation of near-infrared spectrographs such as iSHELL on IRTF and an upgraded NIRSPEC at Keck.

High-contrast imaging testbed design for future space telescopes with segmented apertures

Mamadou N'Diaye, Rémi Soummer, Space Telescope Science Institute (United States); Laurent A. Pueyo, Space Telescope Science Institute (United States) and Johns Hopkins Univ. (United States); Erin Elliot, Elodie Choquet, Space Telescope Science Institute (United States); Matthew Scheckells, Johns Hopkins Univ. (United States) and Space Telescope Science Institute (United States); Marshall D. Perrin, Anand Sivaramakrishnan, Space Telescope Science Institute (United States); Stuart Shaklan, Jet Propulsion Lab. (United States); Bruce Macintosh, Lawrence Livermore National Lab. (United States); N. Jeremy Kasdin, Princeton Univ. (United States)

Searching for nearby habitable worlds with direct imaging and spectroscopy will require a telescope large enough to provide angular resolution and sensitivity to planets around a significant sample of stars. Segmented telescopes are a compelling option to obtain such large apertures. However, these designs have a complex geometry (central obstruction, support structures, segmentation) that makes high contrast imaging challenging. We are developing a new high-contrast imaging testbed at STScI to provide an integrated solution for wavefront control and starlight suppression on complex aperture geometries. To study these questions and understand the ultimate contrast capabilities, we present our approach to minimize the impact of bench optics, in particular with amplitude-induced errors from the propagation of out-of-pupil surfaces. In addition to classical optical design optimization, the approach includes an analytical model based on Talbot propagation and numerical simulations combining Fresnel propagation with wavefront control (e.g. Electric Field Conjugation / Stroke Minimization).

8864-56, Session PMon

Flat field errors and intrapixel sensitivities for nonredundant aperture mask interferometry (AMI) on JWST-NIRISS

Alexandra Z. Greenbaum, Johns Hopkins Univ. (United States)

The James Webb Space Telescope (JWST) is equipped with a 7-hole non-redundant mask on the Near IR Imager and Slitless Spectrograph (NIRISS). Flat field error is likely to limit the contrast of this imaging mode. This can be mitigated by placing calibrator and target on the same pixel. Image plane modeling, using measured sub-pixel sensitivities, enables us to determine the target and calibrator placements to a fraction of a pixel. This is helpful given the barely Nyquist pixel scale on NIRISS and non-uniform sensitivity within the pixel.

8864-57, Session PMon

Could Giovanni Domenico Cassini see the famous division in Saturn's rings?

Julien Lozi, The Univ. of Arizona (United States) and CNES (France) and ONERA (France); Jean-Michel Reess, Alain Semery, Emilie Lhomé, Sophie Jacquinod, Michel Combes, Pernelle Bernardi, Rémi Andretta, Maxime Motisi, LESIA - Observatoire de Paris (France); Laurence Bobis, Emilie Kaftan, Observatoire de Paris (France)

Nowadays, astronomers want to observe gaps in exozodiacal disks to confirm the presence of exoplanets, or even make actual images of these companions. Four hundred and fifty years ago, Giovanni Domenico Cassini did a similar study on a closer object: Saturn. After joining the newly created Observatoire de Paris in 1671, he discovered 4 of Saturn's satellites (Iapetus, Rhea, Tethys and Dione), and also the gap in its rings. He made these discoveries observing through the best optics at the time, made in Italy by famous opticians like Giuseppe Campani or Eustachio Divini. But was he really able to observe this black line in Saturn's rings? That is what a team of optical scientists from Observatoire de Paris - LESIA with the help of Onera and Institut d'Optique tried to find out, analyzing the lenses used by Cassini, and still preserved in the collection of the observatory. The main difficulty was that even if the lenses have diameters between 84 and 239 mm, the focal lengths are between 6 and 50 m, more than the focal lengths of the primary mirrors of future ELTs. The analysis shows that the lenses have an exceptionally good quality, with a wavefront error of approximately 50 nm rms and 200 nm peak-to-valley, leading to Strehl ratios higher than 0.8. Taking into account the chromaticity of the glass, the wavefront quality and atmospheric turbulence, reconstructions of his observations tend to show that he was actually able to see the division named after him.

The optical design of CHARIS: an exoplanet IFS for the Subaru telescope

Mary A. Peters, Tyler D. Groff, N. Jeremy Kasdin, Princeton Univ. (United States); Michael W. McElwain, NASA Goddard Space Flight Ctr. (United States); Michael Galvin, Michael A. Carr, Robert Lupton, Gillian Knapp, Timothy Brandt, Markus Janson, James E. Gunn, Princeton Univ. (United States); Olivier Guyon, Frantz Martinache, Nemanja Jovanovic, Masahiko Hayashi, Naruhisa Takato, Subaru Telescope, National Astronomical Observatory of Japan (United States)

High-contrast imaging instrumentation is now capable of imaging and taking spectra of young planets around nearby stars. We present the optical design of the Coronagraphic High Angular Resolution Imaging Spectrograph (CHARIS), a lenslet-based, cryogenic integral field spectrograph (IFS) for imaging exoplanets on the Subaru telescope. The IFS will provide spectral information for 140x140 spatial elements over a 1.75 arcsecs x 1.75 arcsecs field of view (FOV). CHARIS will operate in the near infrared (0.9-2.5 microns) and provide two separate low (R ~ 15) and high (R ~ 60) spectral resolution observing modes. Taking advantage of the adaptive optics systems and advanced coronagraphs (AO188 and SCExAO) on the Subaru telescope, CHARIS will provide sufficient contrast to obtain spectra of young self-luminous Jupiter-mass exoplanets. In this paper we will focus specifically on the details of the

CHARIS optical design and layout. We include a discussion of the design trades and methods for calculating first order IFS design parameters. The paper will contain the CHARIS Zemax layout and an explanation of the components and design choices. We also quantify the noise sources and noise reduction methods. Finally, we draw conclusions concerning the general optimization of the optical design of exoplanet-purposed integral field spectrographs.

PISCES: an integral field spectrograph to advance high contrast imaging technologies

Michael W. McElwain, Qian Gong, Karl R. Stapelfeldt, NASA Goddard Space Flight Ctr. (United States); Marshall D. Perrin, Space Telescope Science Institute (United States); Bruce E. Woodgate, Sara R. Heap, George M. Hilton, NASA Goddard Space Flight Ctr. (United States)

We present a novel optical integral field spectrograph (IFS) concept called the Prototype Imaging Spectrograph for Coronagraphic Exoplanet Studies (PISCES). PISCES is a prototype IFS to be used as a facility class instrument within the NASA Exoplanet Exploration Program's High Contrast Imaging Testbed at the Jet Propulsion Laboratory. Integral field spectroscopy is ideal for high contrast imaging because it enables spectral characterization of exoplanet atmospheres and can enhance achieved image contrast by providing multi-wavelength measurements of the target star's chromatic point spread function. PISCES would be the first IFS to demonstrate the challenging performance requirements of a direct imaging of Earth-like exoplanets mission.

We will present the instrument requirements, a baseline design for PISCES, a simulation of its performance, a solution to mitigate spectral crosstalk, experimental verification of our simulator, and the vacuum compatible opto-mechanical design. PISCES would be assembled and tested at the Goddard Space Flight Center (GSFC), and subsequently delivered and integrated into the HCIT facility. The HCIT will be used to verify the PISCES instrument performance, which will validate the PISCES model, and thereby advance the technological readiness of this system. After demonstrating the performance, PISCES will be used to advance other critical high contrast technologies inside the HCIT.

8864-60, Session PMon

Optimal apodizers for the vector vortex coronagraph with on-axis telescopes

Alexis Carlotti, Princeton Univ. (United States); Dimitri Mawet, European Southern Observatory (Chile); Laurent A. Pueyo, Space Telescope Science Institute (United States)

Phase mask coronagraphs such as the vector vortex coronagraph (VVC) are meant to be used with the circular clear aperture of off-axis telescopes, and their performance is greatly reduced when used with on-axis telescopes. A possible solution to that problem consists in apodizing the entrance pupil plane of the coronagraph. Apodizers can be computed by solving a quadratic optimization problem in which the transmission of the apodizer is maximized under the constraint that the intensity of the electric field in the Lyot plane is less than an extremum value that is chosen to be small enough to sufficiently attenuate the starlight in the subsequent image plane. The transmission of the apodizer and the throughput of the system depends on the characteristics of the aperture and of the Lyot stop. We present apodizers optimally designed for the apertures of the Palomar telescope, the VLT, the E-ELT and the AFTA telescope, and for vortex phase masks with a topological charge of 4. Transmissions of 30 to 50% are found for mean contrast of 1e-8. To relax the manufacturing specifications of the vortex phase mask, we also attempt at taking into account the presence of a small Lyot mask in its center.

8864-61, Session PMon

Hybrid coronagraphic design: optimization of complex apodizers

Alexis Carlotti, N. Jeremy Kasdin, Robert J. Vanderbei, A. J. Eldorado Riggs, Princeton Univ. (United States); Laurent A. Pueyo, Space Telescope Science Institute (United States); Tyler D. Groff, Princeton Univ. (United States)

To spectrally characterize Earth-like planets around nearby stars with a coronagraph, an extreme adaptive optics (ExAO) system is mandatory. The correction of the amplitude and phase aberrations in the wavefront on both sides of the image plane and in sufficiently large bandwidths can be done with two deformable mirrors (DM) in a pupil mapping configuration. While this system is primarily intended to correct for aberrations, it can potentially be used to improve the contrast beyond the nominal value set by the coronagraph; the two DMs can be seen as a complex apodizer. In this paper we compute this complex apodization by solving a numerical optimization problem where the amplitude of the real and the imaginary parts of the electric field in the pupil plane are maximized while the intensity of the electric field in chosen regions of the the subsequent image plane is constrained to be less that a chosen extremum. A phase and an amplitude are then associated to the complex transmission of the apodizer. We add a smoothness constraint to the problem so that a single DM can be used to induce this phase. The amplitude of the apodization can be induced by an upstream mirror, as in a PIAA, or with a transmissive apodizer. Its transmission is not binary, however, and this can be a problem in term of manufacturing. A second optimization problem is solved that finds a high-transmission binary equivalent.

Techniques for producing pupil-plane and image-plane coronagraph masks

Kunjithapatham Balasubramanian, Stuart Shaklan, Daniel Wilson, Victor White, Richard Muller, Ronald Ruiz, Brian D. Kern, Eric J. Cady, Jet Propulsion Lab. (United States); Olivier Guyon, The Univ. of Arizona (United States); Ruslan Belikov, NASA Ames Research Ctr. (United States)

Masks for high contrast internal and external coronagraphic imaging require various fabrication technologies to address a wide range of needs including gradient amplitude transmission, tunable phase profiles, ultra-low reflectivity, precise small scale features, and low-chromaticity. We present the approaches employed at JPL to produce pupil plane and image plane coronagraph masks, and lab-scale external occulter type masks by combining electron beam, ion beam, deep reactive ion etching, and black silicon technologies with illustrative examples of each.

8864-63, Session PMon

HOMES holographic optical method for exoplanet spectroscopy

Thomas D. Ditto, 3DeWitt LLC (United States)

A novel telescope architecture is proposed specifically for the purpose of taking spectra of exoplanets orbiting stars within 10 pc ("the neighborhood"). The primary objective and the secondary spectrograph are holographic optical elements (HOEs) formed on flat membrane substrates of low areal mass that can be transported on cylinder rolls that are compatible with the payload geometry of delivery vehicles. Ribbon-shaped HOEs of up to 100 x 10 meters are contemplated. Computer models are presented with these dimensions. The models predict resolving power better than 10 mas. Because the primary separates wavelengths, we consider coronagraphs that use the divide and conquer strategy of one wavelength at a time. After delivery at the second Lagrange point, the stowed membranes are unfurled into flat holographic optics positioned in a four part formation spanning 1 km of open space.

8864-66, Session PMon

Wavelength calibration for the Gemini planet imager ifs using its non-redundant mask

Alexandra Z. Greenbaum, Johns Hopkins Univ. (United States)

The Gemini Planet Imager (GPI) Extreme Adaptive Optics Coronagraph (ExAOC) possesses a non-redundant mask (NRM) in its pupil plane. GPI uses an integral field unit spectrograph (IFS) operating at Y, J, H, and K. IFS data is arranged into wavelength slices. Accurate knowledge of the wavelength of each slice of data in this hyperspectral cube is essential. We show that NRM data provide a reliable independent and precise check on the assumed wavelength calibration of the cubes. This data also provides a reliable measure of pupil geometry, which can feed advanced coronagraphic data analysis techniques.

8864-67, Session PMon

Aqueye+: a wavefront sensorless adaptive optics system for narrowfield coronagraph

Enrico Verroi, Univ. degli Studi di Padova (Italy); Tommaso Occhipinti, Ivan Capraro, Adaptica S.r.l. (Italy); Giampiero Naletto, Cesare Barbieri, Univ. degli Studi di Padova (Italy)

We designed and developed Aqueye+, an instrument for the Copernico 182cm Asiago Telescope, with two observations channels. The first allows the use of a ultrafast photometer based on four single photon avalanche photodiodes (SPADs), the second is a channel for stellar coronagraphy based on innovative optical vortices coronagraph system OVC.

The OVC makes use of a phase mask designed to cut out the light of a on-axis target and to let the light from off-axis sources entering the sensor. The target need to be pointed on the center of the phase mask, extreme pointing precision and image stability, as well as the correction of the wavefront deformation induced by atmospheric effects is therefore required. Since the reduction of asymmetries in the target image is critical for the success for faint objects around the central target direct observations, we implemented an adaptive optics (AO) system with a deformable mirror using 32 actuators. The peculiarity of this AO system is that in Aqueye+ there is no wavefront sensors, but the feedback for the deformable mirror is instead given by the photometric channel (PC). The light flux from telescope is split by a dichroic plate, a narrow band around 633nm is reflected towards the OVC while the rest of the light continues through the PC where a pyramid mirror split the beam in 4arms, with a SPAD each.

The adaptive optics system that allows the stabilization of the image and the use of the OVCis described in this paper

Laboratory test of a night-time adaptive optics optimized for exoplanet imaging

Xi Zhang, Nanjing Institute of Astronomical Optics & Technology (China); Deqing Ren, California State Univ., Northridge (United States); Jiangpei Dou, Gang Zhao, Yongtian Zhu, Feng Yang, Rong Li, Nanjing Institute of Astronomical Optics & Technology (China)

The conception of Extreme AO is proposed for exoplanet direct imaging, and the current Extreme AO plans are mainly designed for large telescopes. Here we propose a night-time AO, which is optimized for 2~4-meter telescopes. With our methods of non-common-path error correction and speckle noise nulling, the goal of this night-time AO is to reach Strehl Ratio > 0.8 at near-infrared K band, which enables direct imaging for brown dwarfs and young-hot Jupiters by using a follow-up coronagraph. The night-time AO uses LabVIEW's parallel programming based on a high-performance workstation computer with multi-core CPUs. In this paper, we report the latest results of laboratory testing for the night-time AO and evaluate its performance based on specified sites and telescopes.

Holographic spectrograph for space telescope

Thomas D. Ditto, 3DeWitt LLC (United States)

A spectrograph is described which is made with dual Holographic Optical Elements (HOEs) which are identical and parallel to each other. Both optics are collimating transmission HOEs with focal points that are at equal and opposite distances from each other. The identical HOEs are formed by the interference of a plane wave parallel to the grating plane with an off-axis spherical wave originating in the near-field. In playback, a spectrum can be formed from a point source radiator placed at the position of the recording spherical wave. If played back at an arbitrary wavelength other than the recording wavelength, the image exhibits coma. However, the spectrograph can be configured to play back different wavelengths without coma, if sources are adjusted to optimal locations relative to the first HOE. This spectrograph is intended for an unusual configuration where many nearly monochromatic sources of known wavelengths are separately positioned relative to the first HOE. The special application is in a space telescope capable of resolving spectra from habitable planets within 10 pc. HOEs of this type could be fabricated on membrane substrates with a low areal mass and stowable on rolls for insertion into the second Lagrange point. The intended application is for a 50 x 10 meter class primary objective holographic space telescope with 100 x 10 m HOEs in the spectrograph. We present a computer model of the spectrograph and a preliminary experiment that is a proof-of-principle. Experimental results include variations in efficiency and coma over changes in proximity and parallelism between the two HOEs. Experimental results are compared with predictions from theory.

Comparison of simulated contrast performance of different phase induced amplitude apodization (PIAA) coronagraph configurations

Erkin Sidick, Brian Kern, Andreas Kuhnert, Stuart Shaklan, Jet Propulsion Lab. (United States)

One of the High Contrast Imaging Testbed (HCIT) setups at the Jet Propulsion Laboratory (JPL) is a Phase Induced Amplitude Apodization (PIAA) coronagraph. It employs a deformable mirror and a broadband wavefront estimation and control algorithm called Electric Field Conjugation (EFC) to create a "dark hole" in the final focal plane where exoplanets to be found. So far a mean intensity of 5x10-10 has been achieved experimentally in a dark hole in the monochromatic

point-spread function (PSF) with an inner working angle of 2f?/Dsky using a PIAA coronagraph configuration in which the DM was placed downstream of the front end PIAA set. Placing the DM upstream of the front end PIAA sub-system enables the correction of high spatial frequencies before the PIAA remapping carries that information to frequencies higher than Nyquist, allowing a larger outer working angle. Also, using an inverse-PIAA set at the back end enables one to recover a sharp diffraction-limited image over a useful field of view. We have investigated the broadband-contrast performance of several PIAA coronagraph configurations. The structural design of the optical system as well as the parameters of various optical elements used in the analysis are drawn from those of the PIAA/HCIT system that have been implemented with one DM. In this paper, we present the results of these studies.

8864-71, Session PMon

Spectral flattening of supercontinua with a spatial light modulator

Rafael A. Probst, Max-Planck-Institut für Quantenoptik (Germany); Tilo Steinmetz, Max-Planck-Institut für Quantenoptik (Germany) and Menlo Systems GmbH (Germany); Tobias Wilken, Max-Planck-Institut für Quantenoptik (Germany); Gordon K. L. Wong, Max-Planck-Institut für die Physik des Lichts (Germany); Holger Hundertmark, Menlo Systems GmbH (Germany); Sebastian P. Stark, Philip St.J. Russell, Max-Planck-Institut für die Physik des Lichts (Germany); Theodor W. Hänsch, Max-Planck Institut für Quantenoptik (Germany); Ronald Holzwarth, Max-Planck Institut für Quantenoptik (Germany) and Menlo Systems GmbH (Germany); Thomas Udem, Max-Planck-Institut für Quantenoptik (Germany)

We demonstrate the generation of broad spectra with a flat intensity distribution from originally highly structured supercontinua, obtained with femtosecond pulses in a photonic crystal fiber. This is accomplished by truncating the spectra at a constant level using a liquid crystal based spatial light modulator. The technique is useful for astronomical spectrograph calibration using frequency combs, where it allows to equalize the optical power of the calibration lines. This enables an increased calibration accuracy by maximizing each line's signal-to-noise ratio.

8864-1, Session 1

Patterns of planet occurrence from Doppler and Kepler *(Invited Paper)*

Andrew W. Howard, Univ. of Hawai'i (United States)

The currently observed architectures of extrasolar planetary systems trace the processes of planetary formation and evolution. Until recently, Jovian-size planets provided nearly all of the observational constraints. From Doppler studies, we detect a steeply rising planet mass distribution down to at least 3 Earth-masses for planets orbiting inside of 0.25 AU. The planet size distribution from Kepler also shows a steep rise with decreasing size, but with a plateau in the occurrence rate for 1-2.8 times Earth size. Analyses of the Kepler data support the bottom-up picture of planet formation by core accretion, but also raise new questions about the mechanisms of planet migration, the timing of protoplanetary gas depletion, and the effect of stellar mass on small planet formation. My talk will focus on these occurrence measurements and their interpretation in the context of small planet formation and migration.

8864-2, Session 1

Space mission design for exoplanet imaging *(Invited Paper)*

Dmitry Savransky, Lawrence Livermore National Lab. (United States)

In the next few years, Kepler will constrain the occurrence rates of Earth-radius planets , multiple ground-based exoplanet imagers will begin to provide spectra of self-luminous giant planets and a large number of transit photometry, doppler spectroscopy, microlensing and direct imaging surveys will continuously add to the pool of known exoplanets. We can now look forward to the next step in exoplanet science: direct imaging from space. Over the last decade, there have been a large number of mission concept studies covering a variety of spacecraft architectures, scales and starlight suppression systems. In this paper, I present systematic methods for predicting the expected science yield of different instrument designs, allowing for the direct comparison of different mission concepts. These methods include the selection of target lists, setting of observation rules, and end-to-end simulations of entire surveys. The effects of the assumed planetary distributions are particularly important and I present results consistent with known distributions of physical and orbital parameters, extrapolated from the results of Kepler and multiple radial velocity surveys. I discuss the trades between using internal and external starlight suppression systems (coronagraphs vs. starshades), as well the benefits of including both in one mission. I present the dependence of science yield on telescope scale, focusing in particular on the 2.4 m aperture provided by the Astrophysics Focused Telescope Asset (AFTA). Finally, I discuss how to select specific rules to optimize different classes of surveys, including followups of known planets and searches for Earth-like planets in the habitable zone.

8864-3, Session 1

Implications for future missions of a possible low value of ETA Earth

Alain M. Léger, Institut d'Astrophysique Spatiale (France); Fabien Malbet, Institut de Planétologie et d'Astrophysique de Grenoble (France)

The main question addressed by the Kepler mission is: "What is the mean number of exo-earths and super-earths located in the Habitable Zone (HZ) of solar-like stars?", ?_earth.

The Kepler mission has not yet given its final estimate, but there is already a clear tendency pointing to a low value, possibly between 3 and 10%, but definitely not 100% or so.

We think that such a possible value for ?_earth will necessarily imply the need for an exhaustive census of the Earth-like planets that are actually present around the 300 nearest F,G,K stars, and the characterization of their orbits. If not, the spectroscopic missions would require a very long detection phase that we estimate to ? 93%, to be for nothing. This census can be achieved by a combination of a 20-yr Radial Velocity survey at a 1 m/s accuracy with an astrometric mission of 5 yrs at an extreme accuracy (0.2 ?as).

We will give an estimate of the number of planets that can be studied spectroscopically by missions (i) in the visible (TPF-C, NWO...), and (ii) in the thermal IR (Darwin, TPF-I...). We will also discuss the consequences of descoping these two classes of missions.

8864-4, Session 1

New worlds airship

Webster Cash, Anthony Harness, Ann Shipley, Univ. of Colorado at Boulder (United States); Tiffany Glassman, Steven Warwick, Northrop Grumman Aerospace Systems (United States)

We review the progress on the New Worlds Airship project, which has the goal of suborbitally mapping the Alpha Centauri planetary system into the Habitable Zone in the next few years. We have completed ground tests of starshades on dry lake beds and have shown excellent contrast. We are now attempting to use starshades on hilltops to occult stars and perform high contrast imaging of outer planetary systems like Fomalhaut. We built a precision line of sight position indicator and flew it on a Zeppelin in October (2013). Since the airship provider went out of business we have been redesigning the project to use UAVs instead. We will report on the latest plans at the meeting.

8864-5, Session 1

MESSI: an efficient broadband high contrast high resolution simultaneous multispectral exoplanetary system imager

Brian A. Hicks, Supriya Chakrabarti, TImothy A. Cook, Univ. of Massachusetts Lowell (United States); Christopher B. Mendillo, Boston Univ. (United States); Nikole Lewis, Massachusetts Institute of Technology (United States); Paul A. Bierden, Boston Micromachines Corp. (United States); Jason Martel, Univ. of Massachusetts Lowell (United States)

We present the Monolithic Exoplanetary System Spectral Imager (MESSI) for simultaneous high-contrast visible multispectral direct imaging of exo-Jupiters. MESSI will enable future discovery and eight color characterization of Jupiter-like exoplanets around stars within 10 parsecs. Technological highlights of this program include: 1. Diffraction limited resolution at 350~nm through active optical aberration correction and greater than million-to-one contrast at narrow star separation using interferometry and post-processing techniques; 2. Demonstrating extreme interferometric stability through the use of monolithic optical assemblies in a controlled environment 3. Optimizing multispectral optical throughput beyond the state of the art while minimizing components. The instrument consists of a monolithic nulling interferometer, tip/tilt mounted deformable mirror, wavefront sensor, and pointing/aberration sensor. The MESSI target field of view is simultaneously broken up into eight colors spanning 350-950 nm using an optically contacted, coated set of longpass filters. Following filtering, all bands are relayed to a single detector using two monolithic assemblies of identical focusing mirrors. The aim is to develop a capable instrument with an eye for simplicity and robustness. The program will be focused on designing for operation on a sounding rocket, a unique platform for establishing heritage for high contrast spectral imaging systems that will be used in future satellites.

8864-6, Session 1

Completion of the echo phase 0/A study

Ludovic Puig, Kate Isaak, Martin Linder, Isabel Escudero Sanz, Pierre-Elie Crouzet, Roger Walker, European Space Research and Technology Ctr. (Netherlands)

The Exoplanet Characterisation Observatory (EChO) is an M-class mission candidate within the science program Cosmic Vision 2015-2025 of the European Space Agency. It was selected in February 2011 to enter an assessment phase (phase 0/A). EChO will characterise the atmospheres of a representative sample of known transiting exoplanets found around nearby stars, potentially from giant Hot Jupiters down to Super-Earths orbiting in the habitable zone of M-dwarf stars.

Following the completion of the Concurrent Design Facility study conducted by ESA in June/July 2011, two parallel industrial studies were carried out throughout 2012, and were then extended till August 2013. Similarly, two parallel instrument studies were conducted till mid-2012, following which an Announcement of Opportunity was released and concluded in February 2013 with the selection of a single instrument consortium.

This paper describes the status of EChO upon completion of the system level and instrument studies. It includes a discussion on the evolution of the science and mission requirements, the description of the final preliminary design and performance parameters, as well as programmatic estimates in terms of technology readiness and schedule.

The next step for EChO will consist of passing the Preliminary Requirements Review, followed by the down-selection of a single M3 mission, towards the end of 2013.

8864-8, Session 1

The debris disk explorer: a balloon-borne coronagraph for observing debris disks

Lewis C. Roberts Jr., Geoffrey Bryden, Wesley Traub, Stephen Unwin, John T. Trauger, John E. Krist, James K. Wallace, Jet Propulsion Lab. (United States); Karl Stapelfeldt, NASA Goddard Space Flight Ctr. (United States); Mark Wyatt, Univ. of Cambridge (United Kingdom)

The Debris Disk Explorer (DDX) is a proposed balloon-borne investigation of debris disks around nearby stars. Debris disks are analogs of the Asteroid Belt (mainly rocky) and Kuiper Belt (mainly icy) in our Solar System. DDX will measure the size, shape, brightness, and color of tens of disks. These measurements will enable us to place the Solar System in context. By imaging debris disks around nearby stars, DDX will reveal the presence of perturbing planets via their influence on disk structure, and explore the physics and history of debris disks by characterizing the size and composition of disk dust.

The DDX instrument is a 0.7-m diameter off-axis telescope and a coronagraph carried by a stratospheric balloon. DDX will take high-resolution, multi-wavelength images of the debris disks around tens of nearby stars. Two flights are planned; an overnight test flight within the United States followed by a month-long science flight launched from New Zealand. The long flight will fully explore the set of known debris disks accessible only to DDX. It will achieve a raw contrast of 10^-7, with a processed contrast of 10^-8. A technology benefit of DDX is that operation in the near-space environment will raise the Technology Readiness Level of internal coronagraphs, deformable mirrors, and wavefront sensing and control, all potentially needed for a future space-based telescope for high-contrast exoplanet imaging.

8864-46, Session 1

Exoplanet detection and characterization using combined coronagraphy and sub-UAS astrometry from space *(Invited Paper)*

Eduardo A. Bendek, NASA Ames Research Ctr. (United States); Olivier Guyon, The Univ. of Arizona (United States); Ruslan Belikov, NASA Ames Research Ctr. (United States); S. Mark Ammons, Lawrence Livermore National Lab. (United States)

Combining high-contrast imaging and astrometry in a single space mission would enable efficient detection and characterization of single- and multiple- planetary systems around nearby stars, allowing determination of planetary mass, composition, atmosphere, and system architecture. These science goals can be achieved using a 2m wide-field (>0.1deg2) class telescope equipped with two instruments: a high-performance coronagraph to perform direct imaging, and a wide field camera to achieve sub-microarcsecond astrometric accuracy. However, these measurements are only possible if there are no relative distortion changes between astrometric observations. At sub-microarcsecond

accuracy regime, even space optics suffers from dynamic distortions in the optical system and dominates the error budget. We propose to utilize a diffractive pupil, in which an array of dots on the primary mirror generates polychromatic diffraction spikes in the focal plane to calibrate the dynamic distortions of the optical system. According to simulations, this technique would allow to obtain 0.2microarcsecond single-visit precision astrometric accuracy. In this talk, we present the laboratory results that demonstrate the diffractive pupil concept on wide-field images. We also discuss simulations and experiments performed at the NASA Ames ACE test bed, demonstrating that the diffractive pupil does not affect the coronagraph performance to 2x10-7. Finally, we assess the compatibility of a diffractive pupil telescope with a general astrophysics mission, showing that the spikes do not impact wide-field observations.

8864-9, Session 2

Sphere: complete laboratory performance and prediction for on-sky first light *(Invited Paper)*

Jean-François Sauvage, ONERA (France); Jean-Luc Beuzit, Institut de Planétologie et d'Astrophysique de Grenoble (France)

Direct imaging of exoplanet is one of the most exciting field of planetology today. The light coming from exoplanet orbiting their host star witnesses for the chemical composition of the atmosphere, and the potential biomarkers for life. However, the faint flux to be imaged, very close to the huge flux of the parent star, makes this kind of observation extremely difficult to perform from the ground.

The direct imaging instruments (SPHERE, GPI) are nowaday reaching lab maturity. Such instrument imply the coordination of XAO for atmospherical turbulence real-time correction, coronagraphy for star light extinction, IR Dual band camera, IFS, and visible polarimetry. The imaging modes include single and double difference (spectral and angular).

The SPHERE project is now at the end of AIT phase. This paper presents the very last results obtained in laboratory, with realistic working conditions. These AIT results allows one to predict on-sky performance, that should come within the next weeks after re-installation at Very Large Telescope at Paranal.

8864-10, Session 2

The ZIMPOL high-contrast imaging polarimeter for sphere: system test results

Ronald Roelfsema, ASTRON (Netherlands); Daniel Gisler, ETH Zurich (Switzerland); Johan Pragt, ASTRON (Netherlands); Hans Martin Schmid, Andreas Bazzon, ETH Zurich (Switzerland); Matthew Kenworthy, Leiden Observatory (Netherlands); Carsten Dominik, Univ. van Amsterdam (Netherlands); Andrea Baruffolo, INAF - Osservatorio Astronomico di Padova (Italy); Anthony Boccaletti, Observatoire de Paris (France); Anne Costille, Jean-Luc Beuzit, Institut de Planétologie et d'Astrophysique de Grenoble (France); Kjetil Dohlen, Observatoire Astronomique de Marseille-Provence (France); Mark Downing, European Southern Observatory (Germany); Eddy Elswijk, Menno de Haan, ASTRON (Netherlands); Norbert Hubin, Markus Kasper, European Southern Observatory (Germany); Christoph Keller, Leiden Observatory (Netherlands); Jean-Louis Lizon, European Southern Observatory (Germany); Patrice Martinez, David Mouillet, Institut de Planétologie et d'Astrophysique de Grenoble (France); Alexey Pavlov, Max-Planck-Institut für Astronomie (Germany); Pascal Puget, Institut de Planétologie et d'Astrophysique de Grenoble (France); Bernardo Salasnich, INAF - Osservatorio Astronomico di Padova (Italy); Frans Snik, Leiden Observatory (Netherlands); Christian Thalmann, Univ. van Amsterdam (Netherlands); Francois Wildi, Observatory of Geneva (Switzerland)

SPHERE (Spectro-Polarimetric High Contrast Exoplanet Research) is one of the first instruments which aim for the direct detection from extra-solar planets. SPHERE commissioning is foreseen in 2013 on the VLT. ZIMPOL (Zurich Imaging Polarimeter) is the high contrast imaging polarimeter subsystem of the ESO SPHERE instrument. ZIMPOL is dedicated to detect the very faint reflected and hence polarized visible light (600-900 nm) from extrasolar planets. It is located behind an extreme AO system (SAXO) and a stellar coronagraph. For the sub-system high contrast performance testing we have build a dedicated test setup including a fiber based star-planet simulator, a switching Half Wave Plate and a coronagraph setup. We have measured the polarimetric high contrast performance of several coronagraphs: a Classical Lyot on substrate, a suspended Classical Lyot, a 4 Quadrant Phase Mask and an Apodized Phase Mask. We describe the impact of crucial system parameters (FLC differential aberrations, HWP switching, instrument polarization, detector non-linearity) on the contrast performance. We also present the high contrast results obtained for the fully integrated SPHERE-ZIMPOL system.

8864-11, Session 3

Estimation and compensation of quasistatic aberrations in high-contrast imaging systems with the coronagraphic phase diversity application to the sphere instrument

Baptiste Paul, ONERA (France) and Lab. d'Astrophysique de Marseille (France); Jean-François Sauvage, Laurent M. Mugnier, ONERA (France); Kjetil Dohlen, Observatoire Astronomique de Marseille-Provence (France); David Mouillet, Institut de Planétologie et d'Astrophysique de Grenoble (France); Thierry Fusco, ONERA (France) and Lab. d'Astrophysique de Marseille (France); Jean-Luc Beuzit, Institut de Planétologie et d'Astrophysique de Grenoble (France); Mamadou N'Diaye, Telescope Science Institute (United States); Marc Ferrari, Lab. d'Astrophysique de Marseille (France)

The final performance of current and future instruments dedicated to exoplanet detection and characterization (such as SPHERE on the VLT, GPI on Gemini North or future instruments on the E-ELT) is limited by intensity residuals in the scientific image plane, which originate in uncorrected optical aberrations. After correction of the atmospheric turbulence, the main contribution to these residuals comes from the quasi-static aberrations introduced upstream of the coronagraph.

In order to measure and compensate for these aberrations, we have proposed a dedicated focal-plane sensor called COFFEE (for COronagraphic Focal-plane wave-Front Estimation for Exoplanet detection), which consists in an extension of conventional phase diversity to a coronagraphic system: aberrations both upstream and downstream of the coronagraph are estimated using two coronagraphic focal-plane images, recorded from the scientific camera itself, without any differential aberration.

This communication gathers COFFEE's improvements: the phase estimation is now performed on a pixel-wise map, which, used with a dedicated regularization metric, allows COFFEE to estimate very high order aberrations, making possible to estimate and compensate for quasi-static aberrations with nanometric precision, leading to an optimization of the contrast on the scientific detector. Besides, COFFEE

has been modified so that it can be used with any coronagraphic focal plane mask.

Lastly, we use COFFEE to measure and correct the wavefront on the SPHERE (Spectro-Polarimetric High-contrast Exoplanet Research) instrument during its integration phase: COFFEE's estimation is used to compensate for the quasi-static aberrations upstream of the coronagraph, leading to a contrast improvement on the scientific camera.

8864-12, Session 3

ESPRESSO: an exo-Earths hunter for the VLT

Denis Mégevand, Observatory of Geneva (Switzerland); Filippo M. Zerbi, INAF - Osservatorio Astronomico di Brera (Italy); Paolo Di Marcantonio, INAF - Osservatorio Astronomico di Trieste (Italy); Alexandre Cabral Pereira, Univ. de Lisboa (Portugal); Manuel Amate, Instituto de Astrofísica de Canarias (Spain); Francesco Pepe, Observatory of Geneva (Switzerland); Stefano Cristiani, INAF - Osservatorio Astronomico di Trieste (Italy); Hans Dekker, European Southern Observatory (Germany); Rafael Rebolo Lopez, Instituto de Astrofísica de Canarias (Spain); Nuno Santos, Univ. de Porto (Portugal); Manuel Abreu, Univ. de Lisboa (Portugal); Michael Affolter, Univ. Bern (Switzerland); Matteo Aliverti, INAF - Osservatorio Astronomico di Brera (Italy); Gerardo Avila, European Southern Observatory (Germany); Veronica Baldini, INAF - Osservatorio Astronomico di Trieste (Italy); Paul Bristow, European Southern Observatory (Germany); Christopher Broeg, Univ. Bern (Switzerland); Roberto Cirami, INAF - Osservatorio Astronomico di Trieste (Italy); Joao M. Coelho, Univ. de Lisboa (Portugal); Paolo Conconi, INAF - Osservatorio Astronomico di Brera (Italy); Igor Coretti, Guido Cupani, Valentina D'Odorico, INAF - Osservatorio Astronomico di Trieste (Italy); Vincenzo De Caprio, INAF - Osservatorio Astronomico di Brera (Italy); Bernard Delabre, Reinhold Dorn, European Southern Observatory (Germany); Pedro Figueira, Univ. de Porto (Portugal); Ana Fragoso, Instituto de Astrofísica de Canarias (Spain); Samuele Galeotta, INAF - Osservatorio Astronomico di Trieste (Italy); Ludovic Genolet, ISDC Data Ctr. for Astrophysics (Switzerland); Jonay I. González Hernández, Instituto de Astrofísica de Canarias (Spain); Ricardo Gomes, Univ. de Lisboa (Portugal); Ian Hughes, Observatory of Geneva (Switzerland); Olaf Iwert, Florian Kerber, European Southern Observatory (Germany); Marco Landoni, INAF - Osservatorio Astronomico di Brera (Italy); Jean-Louis Lizon, European Southern Observatory (Germany); Christophe Lovis, Charles Maire, Observatory of Geneva (Switzerland); Marco Mannetta, INAF - Osservatorio Astronomico di Trieste (Italy); C. J. A. P. Martins, Univ. de Porto (Portugal); Paolo Molaro, INAF - Osservatorio Astronomico di Trieste (Italy); Manuel A. Monteiro, Univ. de Porto (Portugal); Antonio Oliveira, Univ. de Lisboa (Portugal); Maria-Rosa Zapatero Osorio, Ctr. de Astrobiología (Spain); Ennio Poretti, INAF - Osservatorio Astronomico di Brera (Italy); Jose-Luis Rasilla, Instituto de Astrofísica de Canarias (Spain); Marco Riva, INAF - Osservatorio Astronomico di Brera (Italy); Samuel Santana, Instituto de Astrofísica de Canarias (Spain); Paolo Santin, INAF - Osservatorio Astronomico di Trieste (Italy); Pedro Santos, Univ. de Lisboa (Portugal); Danuta Sosnowska, Observatory of Geneva (Switzerland); Sergio Sousa, Univ. de Porto (Portugal); Fabio Tenegi, Instituto de Astrofísica de Canarias (Spain); Giorgio Toso, INAF - Osservatorio Astronomico di Brera (Italy); Eros Vanzella, Matteo Viel, INAF - Osservatorio Astronomico di Trieste (Italy)

ESPRESSO is the next european exoplanets hunter. It will combine the efficiency of modern echelle spectrograph with extreme radial-velocity precision. It will be installed at Paranal's VLT in order to achieve two magnitudes gain with respect to its predecessor HARPS, and the instrumental radial-velocity precision will be improved to reach cm/s level. We have constituted a Consortium of astronomical research institutes to fund, design and build ESPRESSO on behalf of and in collaboration with ESO, the European Southern Observatory. The project has passed the final design review in May 2013. The spectrograph will be installed at the Combined Coudé Laboratory of the VLT, it will be linked to the four 8.2 meters Unit

Telescopes through four optical "Coudé trains" and will be operated either with a single telescope or with up to four UTs, enabling an additional 1.5 magnitude gain. In exchange of the financial and human effort, the Consortium will be awarded with guaranteed observing time, which will be invested in a common scientific program. Thanks to its characteristics and ability of combining incoherently the light of 4 large telescopes, ESPRESSO will offer new possibilities in many fields of astronomy. Our main scientific objectives are, however, the search and characterization of rocky exoplanets in the habitable zone of quiet, near-by G to M-dwarfs, and the analysis of the variability of fundamental physical constants. In this paper, we will present the scientific objectives, the capabilities of ESPRESSO, the status of the technical development and the project aspects of this facility.

8864-13, Session 3

ESPRESSO front end exposure meter: a chromatic approach to radial velocity correction

Marco Landoni, Marco Riva, INAF - Osservatorio Astronomico di Brera (Italy); Francesco Pepe, Observatory of Geneva (Switzerland); Paolo Conconi, Filippo M. Zerbi, INAF - Osservatorio Astronomico di Brera (Italy); Alexandre Cabral Pereira, Univ. de Lisboa (Portugal); Stefano Cristiani, INAF - Osservatorio Astronomico di Trieste (Italy); Denis Mégevand, Observatory of Geneva (Switzerland)

This paper presents the Espresso Exposure Meter (EM) implementation. ESPRESSO, the Echelle SPectrograph for Rocky Exoplanets and Stable Spectroscopic Observations, will be installed on ESO's Very Large Telescope (VLT). The light coming from the Telescope through a Coudè Focus of all the Four Telescope Units (UTs) will be collected by the Front End Unit that provides Field and Pupil stabilization and injects the beams into the Spectrograph fibers. An advanced Exposure Meter system will be used to correct Radial Velocity (RV) obtained from the scientific spectrum for the Earth relative motion.

In this work we will present the performance of an innovative concept for the Exposure Meter system based on a Charge Coupled Device (CCD) with a chromatic approach for the calculation of the Mean Time of Exposure (MTE). The MTE is a crucial quantity used for the correction of RV for the Earth relative motion during the exposure. In particular, splitting the light in 5/7 different chromatic channels on the CCD, we will probe for potential chromatic effects on the calculation of the MTE in each channel and how they could be used in order to perform the correction of RV. The paper is accompanied by a fully described numerical analysis that keeps into view a key performance evaluation for different stellar spectral types (BA to M spectral class).

8864-14, Session 3

Precision near-infrared radial velocity instrumentation II: noncircular core fiber scrambler

Peter P. Plavchan, Infrared Processing and Analysis Ctr. (United States); Michael Bottom, Peter Gao, California Institute of Technology (United States); Kent K. Wallace, Bertrand Mennesson, David Ciardi, Samuel L. Crawford, Sean Lin, Jet Propulsion Lab. (United States); Charles Beichman, Carolyn Brinkworth, John A. Johnson, California Institute of Technology (United States); Cassy Davison, Russel White, Georgia State Univ. (United States); Guillem Anglada-Escude, Univ. Göttingen (Germany); Kaspar von Braun, California Institute of Technology (United States); Guatum Vasisht, Jet Propulsion Lab. (United States); Lisa Prato, Lowell Observatory (United States); Stephen Kane, California Institute of Technology (United States); Angelle Tanner, Mississippi State Univ. (United States); Bernie Walp, Gemini Observatory (United States); Sean Mills, The Univ. of Chicago (United States)

We have built and commissioned a prototype agitated non-circular core fiber scrambler for precision spectroscopic radial velocity measurements in the near-infrared H band. We have collected the first on-sky performance and modal noise tests of these novel fibers in the near-infrared at H and K bands using the CSHELL spectrograph at the NASA InfraRed Telescope Facility (IRTF). We discuss the design behind our novel reverse injection of a red laser for co-alignment of star-light with the fiber tip via a corner cube and visible camera. We summarize the practical details involved in the construction of the fiber scrambler, and the mechanical agitation of the fiber at the telescope. We present radial velocity measurements of a bright standard star taken with and without the fiber scrambler to quantify the relative improvement in the obtainable blaze function stability, the line spread function stability, and the resulting radial velocity precision. We assess the feasibility of applying this illumination stabilization technique to the next generation of near-infrared spectrographs such as iSHELL on IRTF and an upgraded NIRSPEC at Keck. Our results may also be applied in the visible for smaller core diameter fibers where fiber modal noise is a significant factor, such as behind an adaptive optics system or on a small < 1-m class telescope such as is being pursued by the MINERVA and LCOGT collaborations.

8864-15, Session 3

Design of the CHARIS integral field spectrograph for exoplanet imaging

Tyler D. Groff, Mary Anne Peters, N. Jeremy Kasdin, Gillian Knapp, Michael Galvin, Michael A. Carr, Princeton Univ. (United States); Michael W. McElwain, NASA Goddard Space Flight Ctr. (United States); Robert Lupton, Timothy Brandt, Markus Janson, James Gunn, Princeton Univ. (United States); Olivier Guyon, Frantz Martinache, Nemanja Jovanovic, Subaru Telescope, National Astronomical Observatory of Japan (United States); Masahiko Hayashi, Subaru Telescope, National Astronomical Observatory of Japan (Japan); Naruhisa Takato, Subaru Telescope, National Astronomical Observatory of Japan (United States)

Princeton University is building an integral field spectrograph (IFS), the Coronagraphic High Angular Resolution Imaging Spectrograph (CHARIS), for integration with the Subaru Coronagraphic Extreme Adaptive Optics (SCExAO) system. CHARIS will measure spectra of hot Jovian planets in a coronagraphic image across Y, J, H, and K bands. The 80 milliarcsecond inner working angle and high throughput provides access to distant objects where we expect to see young, hot, Jupiter mass planets. SCExAO's coronagraphs and wavefront control system will make it possible to detect companions five orders of magnitude dimmer than their parent star. However, quasi-static speckles in the image contaminate the signal from the planet. In an IFS this also causes uncertainty in the spectra due to diffractive cross-contamination, commonly referred to as crosstalk. Post-processing techniques can subtract these speckles, but they can potentially skew spectral measurements, become less effective at small angular separation, and at best can only reduce the crosstalk down to the photon noise limit of the contaminating signal. CHARIS will address crosstalk effects of a high contrast image through hardware design, which drives the optical and mechanical design of the assembly. The work presented here sheds light on the optical and mechanical considerations taken in designing the IFS to provide high signal-to-noise spectra in a coronagraphic image from and extreme adaptive optics image. The design considerations and lessons learned are directly applicable to future exoplanet instrumentation for extremely large telescopes and space observatories capable of detecting rocky planets in the habitable zone.

8864-16, Session 4

Small-angle, high-contrast exoplanet imaging with the L-band AGPM vector vortex coronagraph now offered at the VLT

Dimitri Mawet, European Southern Observatory (Chile); Olivier Absil, Christian Delacroix, Univ. de Liège (Belgium); Julien H. V. Girard, Julien Milli, Jared O'Neal, European Southern Observatory (Chile); Pierre Baudoz, Anthony Boccaletti, LESIA - Observatoire de Paris (France); Pierre Bourget, European Southern Observatory (Chile); Pontus Forsberg, Uppsala Univ. (Sweden); Frederic J. Gonte Y., European Southern Observatory (Chile); Serge Habraken, Univ. de Liège (Belgium); Mikael Karlsson, Uppsala Univ. (Sweden); Markus Kasper, European Southern Observatory (Germany); Jean Surdej, Univ. de Liège (Belgium)

Context: High contrast imaging has thoroughly combed through the limited parameter space accessible with first-generation ground-based adaptive optics instruments and the Hubble Space Telescope (HST). Only a few objects were discovered, and many non-detections reported and statistically interpreted. The field is now in need of a technological breakthrough.

Aims: We aim at opening a new parameter space in terms of contrast and inner working angle (IWA) with first generation adaptive optics systems such as NACO at the Very Large Telescope, by providing ground-breaking IWA capabilities in the L' band.

Methods: An annular groove phase mask (AGPM) vector vortex coronagraph optimized for the L' band, made out of diamond subwavelength gratings has been manufactured and thoroughly qualified in the lab. It promises high contrast imaging to be reached at very small inner working angle, potentially being the key to a new parameter space.

Results: Here we present the result of the installation and successful on-sky tests of an L'-band AGPM vector vortex coronagraph on NACO. L' band is a sweet spot for high contrast coronagraphy since the planets-to-star brightness ratio is favorable, while Strehl ratio is naturally higher. Moreover the loss of angular resolution at L' is compensated by the smaller IWA of the AGPM.

8864-17, Session 4

Adaptive phase-mask coronagraph with amplitude and phase modulation for high dynamic range synchronous detection: APM2 coronagraph

Pierre Bourget, Dimitri Mawet, Nicolas Schuhler, Pedro Mardones, European Southern Observatory (Chile)

We present a new Adaptive Phase Mask (APM) coronagraph design enabling Amplitude and Phase Modulation control (APM). The extinction control Adaptive Phase mask coronagraph is a recent technique aiming at accommodating both high dynamic and high angular resolution

imaging of faint sources around bright objects. Discriminating faint sources from static speckles is a challenging problem. Our new concept is based on synchronous demodulation that allows high dynamic detection of a faint target immersed in a background. The APM2 uses the coherence of speckles to discriminate them from proper companions, using the mask itself as the electric field modulator. Synchronous detection in the radio frequency range is used to freeze the turbulence and enable the detection of low amplitude signals. The APM2 offers high dynamic range detection and provides a quick tool to quantify the probability of presence of a faint object close to the central star.

8864-19, Session 4

Electric field conjugation with the project 1640 coronagraph

Eric J. Cady, Jet Propulsion Lab. (United States); Christoph Baranec, Charles Beichman, California Institute of Technology (United States); Douglas Brenner, American Museum of Natural History (United States); Rick Burruss, Jet Propulsion Lab. (United States); Justin Crepp, Notre Dame Univ. (United States); Richard Dekany, David Hale, Lynne Hillenbrand, Sasha Hinkley, California Institute of Technology (United States); David King, Univ. of Cambridge (United Kingdom); Thomas Lockhart, Jet Propulsion Lab. (United States); Ben Oppenheimer, American Museum of Natural History (United States); Ian Parry, Univ. of Cambridge (United Kingdom); Laurent A. Pueyo, Space Telescope Science Institute (United States); Emily Rice, American Museum of Natural History (United States); Lewis C. Roberts Jr., Jennifer Roberts, Michael Shao, Jet Propulsion Lab. (United States); Anand Sivaramakrishnan, Remi Soummer, Space Telescope Science Institute (United States); Tuan Truong, Gautam Vasisht, Fred Vescelus, Kent K. Wallace, Chengxing Zhai, Jet Propulsion Lab. (United States); Neil Zimmerman, Max-Planck-Institut für Astronomie (Germany)

The Project 1640 instrument on the 200-inch Hale telescope at Palomar Observatory is a coronagraphic instrument with an integral field spectrograph at the back end, designed to find young, self-luminous planets around nearby stars. To reach the necessary contrast for this, the PALM-3000 adaptive optics system corrects for fast atmospheric speckles, while CAL, a phase-shifting interferometer in a Mach-Zehnder configuration, measures the quasistatic components of the complex electric field in the pupil plane following the coronagraphic stop. This field measurement may then be combined with a system model and data taken separately using a white-light source internal to the AO system to correct for both phase and amplitude aberrations. Here, we demonstrate we can create and maintain a half-plane dark hole in the image plane while the spectrograph is taking data, without requiring any additional probe images or other overhead during the science exposure. We outline the procedure, and report on the sensitivity achieved with this system, both in the lab and on the sky.

8864-20, Session 4

Estimate low- and high-order wavefront using P1640 calibrator measurements

Chengxing Zhai, Jet Propulsion Lab. (United States)

P1640 high contrast imaging system on the Palomar 200in Telescope consists of an apodized-pupil Lyot coronagraph, the PALM-3000 adaptive optics (P3K-AO), and P1640 Calibrator (CAL). Science images are recorded by an integral field spectrograph covering J-H bands for detecting and characterizing stellar companions. With aberrations from atmosphere corrected by the P3K-AO, instrument performance is limited mainly by the quasi-static speckles due to non-common path wavefront aberrations for the light to propagate to the P3K-AO wavefront sensor and to the coronagraph mask.

The non-common path wavefront aberrations are sensed by CAL, which measures the post-coronagraph E-field using interferometry, and can be effectively corrected by offsetting the P3K-AO deformable mirror target position accordingly.

Previously, we have demonstrated using CAL measurements to correct high order wavefront aberrations, which is directly connected to the static speckles in the image plane. Low order wavefront, on the other hand, usually of larger amplitudes, causes light to leak through the coronagraph making the whole image plane brighter. Knowledge error in low order wavefront aberrations can also affect the estimation of the high order wavefront.

Even though, CAL senses efficiently high order wavefront aberrations, the low order wavefront front can be infered with less sensitivity.

Here, we describe our method for estimating both low and high order wavefront aberrations using CAL measurements by propagating the post-coronagraph E-field to a pupil before the coronagraph. A dimension reduction technique is used to speed up numerical computation. We present the results from applying this method to both simulated and experiment data.

8864-21, Session 5

High-contrast imaging with a self-coherent camera *(Invited Paper)*

Raphaël Galicher, Univ. of Paris Diderot (France); Pierre Baudoz, Observatoire de Paris (France); Gérard Rousset, Univ. of Paris Diderot (France); Johan Mazoyer, Observatoire de Paris (France)

Direct imaging is the best solution to study exoplanets with long orbital periods but it requires dedicated instruments. The objective is the suppression of the light of the star that is 10^4 to 10^10 times brighter than its planet which is at less than 1”. Coronagraphs can suppress the light but their performance is limited by wavefront aberrations that induce stellar speckles in the science image. In ground telescopes, adaptive optics compensate for most of the atmospheric turbulence but quasi-static aberrations always remain (flexure with pointing, optical aberrations of moving optics, etc). In space, quasi-static aberrations also exist (thermal expansion). In this context, our team developed the self-coherent camera that is used to minimize quasi-static speckles in the science image. The SCC creates a reference beam that interferes with the speckles in a Fizeau scheme and spatially modulates them in the science image. Demodulating the signal, we retrieve the complex amplitude of the electric field in the science image and use a deformable mirror to enhance the contrast in a dark hole. During my presentation, I will present the principle of the SCC and the solution we use to easily implement it to any coronagraph that uses a Lyot stop. Then, I will show laboratory performance with contrasts of a few 1e-8 between 4 and 15 l/D that we obtain on our THD optical bench. Finally, I will talk about solutions that we study and test on the bench to correct for amplitude aberrations and chromatism effects.

8864-22, Session 5

Speckle correction in polychromatic light using the self-coherent camera for the direct detection of exoplanets

Johan Mazoyer, Pierre Baudoz, Raphaël Galicher, Gérard Rousset, LESIA - Observatoire de Paris (France)

Direct detection is a very promising field in exoplanets. It allows the detection of companions with large separation and, allows their spectral analysis. A few planets have already been detected and are under spectral analysis. But the full spectral characterization of smaller and colder planets requires higher contrasts over large spectral bandwidths. Coronagraphs can be used to reach these contrasts, but their efficiency

is limited by wavefront aberrations. These deformations induce speckles, star lights leaks, in the focal plane after a coronagraph. The wavefront aberrations should be estimated directly in the science image to avoid usual limitations by differential aberrations in classical adaptive optics.. In this context, we introduce the Self-Coherent Camera (SCC). The SCC uses the coherence of the star light to produce spatial modulation of the speckles in the focal plane and estimate the associated electric complex field in focal plane. Controlling the wavefront with a deformable mirror, high contrasts have already been reached in monochromatic light with this technique. The performance of the current version of the SCC is limited when widening the spectral bandwidth. We will present a theoretical analysis of these issues and their possible solution. Finally, we will present test bench performance in polychromatic light.

8864-23, Session 5

Experimental study of the low-order wavefront sensor for the high-contrast coronagraphic imager excede

Julien Lozi, The Univ. of Arizona (United States); Ruslan Belikov, NASA Ames Research Ctr. (United States); Glenn Schneider, The Univ. of Arizona (United States); Olivier Guyon, The Univ. of Arizona (United States) and Subaru Telescope, National Astronomical Observatory of Japan (United States); Eugene Pluzhnik, Thomas P. Greene, Fred C. Witteborn, Dana H. Lynch, Paul K. Davis, Sandrine J. Thomas, Eduardo A. Bendek, NASA Ames Research Ctr. (United States); Kevin E. Newman, The Univ. of Arizona (United States); Domenick Tenerelli, Lockheed Martin Space Systems Co. (United States)

The mission EXCEDE (EXoplanetary Circumstellar Environments and Disk Explorer), selected by NASA for technology development, is designed to study the formation, evolution and architectures of exoplanetary systems and characterize circumstellar environments into stellar habitable zones. It is composed of a 0.7 m telescope equipped with a Phase-Induced Amplitude Apodization Coronagraph (PIAA-C) and a 2000-element MEMS deformable mirror, capable of raw contrasts of 1e-6 at 1.2 lambda/D and 1e-7 above 2 lambda/D. One of the key challenges to achieve those contrasts is to remove low-order aberrations, using a Low-Order WaveFront Sensor (LOWFS). An experiment simulating the starlight suppression system is currently developed at NASA Ames Research Center, and includes a LOWFS controlling tip/tilt modes in real time at 1 kHz. The LOWFS allowed us to reduce the tip/tilt disturbances to 1e-3 lambda/D rms, enhancing the previous contrast by a decade, to 8e-7 between 1.2 and 2 lambda/D. A Linear Quadratic Gaussian (LQG) controller is currently implemented to improve even more that result by reducing residual vibrations. This testbed shows that a good knowledge of the low-order disturbances is a key asset for high contrast imaging, whether for real-time control or for post processing.

8864-24, Session 5

Assessing the performance limits of internal coronagraphs through end-to-end modeling

John E. Krist, Jet Propulsion Lab. (United States); Ruslan Belikov, NASA Ames Research Ctr. (United States); Dimitri Mawet, European Southern Observatory (Chile); Dwight Moody, Jet Propulsion Lab. (United States); Laurent A. Pueyo, Space Telescope Science Institute (United States); Stuart Shaklan, John T. Trauger, Jet Propulsion Lab. (United States)

As part of the NASA ROSES Technology Demonstrations for Exoplanet Missions (TDEM) program, we conducted a numerical modeling study of three internal coronagraphs (PIAA, vector vortex, hybrid bandlimited) to understand their behaviors in realistically-aberrated systems with wavefront control (deformable mirrors). This investigation consisted of two milestones: (1) develop wavefront propagation codes appropriate for each coronagraph that are accurate to 1% or better (compared to a reference algorithm) but are also time and memory efficient, and (2) use these codes to determine the wavefront control limits of each architecture. We discuss here how the milestones were met and identify some of the behaviors particular to each coronagraph. The codes developed in this study are being made available for community use.

8864-25, Session 5

HCIT contrast performance sensitivity studies: simulation versus experiment

Erkin Sidick, Stuart Shaklan, John E. Krist, Eric J. Cady, Brian D. Kern, Jet Propulsion Lab. (United States)

Using the High Contrast Imaging Testbed (HCIT) at the Jet Propulsion Laboratory, we have experimentally investigated the sensitivity of dark hole contrast in a Lyot coronagraph for the following factors: 1) Lateral and longitudinal translation of an occulting mask; 2) Bandwidth used in wavefront estimation; 3) Deformable mirror (DM) degrees of freedom vs. dark hole size; 4) Number of dead DM actuators. We have also observed an artificial planet adjacent to the artificial star to determine the ability to extract the planet image from the residual dark hole speckles. We use both MACOS (Modeling and Analysis for Controlled Optical Systems) and PROPER optical analysis programs with full three-dimensional near-field diffraction analysis to model HCIT's optical train and coronagraph.

8864-26, Session 5

Laboratory demonstration of phase induced amplitude apodization (PIAA) coronagraph with better than 10^-9 contrast

Brian D. Kern, Jet Propulsion Lab. (United States); Olivier Guyon, The Univ. of Arizona (United States); Andreas Kuhnert, Albert F. Niessner, Jet Propulsion Lab. (United States); Frantz Martinache, Subaru Telescope, National Astronomical Observatory of Japan (United States); Amir Give'on, Kunjithapatham Balasubramanian, Jet Propulsion Lab. (United States)

We present coronagraphic images from the Phase Induced Amplitude Apodization (PIAA) coronagraph on NASA's High Contrast Imaging Testbed (HCIT) at the Jet Propulsion Lab, showing contrasts of 5x10^-10 averaged from 2-4 lambda/D, in monochromatic light at 808 nm. In parallel with the coronagraph and its deformable mirror and coronagraphic wavefront control, we also demonstrate a low-order wavefront control system, giving 100x rms suppression of introduced tip/tilt disturbances down to residual levels of 10^-3 lambda/D. Current limitations, as well as broadband (10% fractional bandpass) preliminary results are discussed.

8864-27, Session 6

Image analysis with speckles altered by a deformable mirror

Elizabeth J. Young, N. Jeremy Kasdin, Alexis Carlotti, Princeton Univ. (United States)

Quasi-static speckles are one of the main limitations in imaging exoplanets, since the image of a planet looks similar to a speckle. However, speckles are light from the same coherent source, the star, and incoherent with the planet. By moving the deformable mirror after each image, the speckle pattern as seen on the camera changes between images. The change is very small within the full width half max of the planet, so changes in the planet image are minimal. This fundamental coherence property of the speckles (and incoherence with

the planet light) guides us to develop a planet detection method to distinguish a planet from a speckle by taking advantage of a changing speckle pattern. We present a method of changing the deformable mirror actuator pattern to create a series of images with a changing speckle pattern. These images are then analyzed using our previously developed planet detection algorithm, which conducts a Bayesian hypothesis test of multiple images presuming an independent source of aberrations between images. We present results using a 12 by 12 Boston Micromachines deformable mirror in the Exoplanet Direct Imaging Testbed at Princeton University.

8864-28, Session 6

Demonstration of symmetric dark holes using two deformable mirrors at the high-contrast imaging testbed

A. J. Eldorado Riggs, Tyler D. Groff, Alexis Carlotti, N. Jeremy Kasdin, Princeton Univ. (United States); Eric J. Cady, Brian D. Kern, Andreas Kuhnert, Jet Propulsion Lab. (United States)

The High Contrast Imaging Laboratory (HCIL) at Princeton has developed several important algorithms and technologies for space-based coronagraphy missions to detect earth-like exoplanets. The HCIL is currently the only facility with two deformable mirrors (DMs) in series for focal plane wavefront control, which allows for symmetric dark holes in the image plane. Starting in June 2013, the High-Contrast Imaging Testbed (HCIT) at JPL will have installed two similar deformable mirrors. In this paper we report on the results of our Technology Development for Exoplanet Missions project to verify contrasts of better than 1e-9 in two symmetric dark holes using a shaped-pupil coronagraph at the HCIT. Our previous experiment with a shaped pupil (SP) coronagraph at the HCIT in 2007 yielded single-sided dark holes. That experiment utilized an iterative, least-squares wavefront estimator and the Electric Field Conjugation algorithm for wavefront control. Our current experiment uses the faster Kalman filter estimator and the Stroke Minimization control algorithm to create symmetric dark holes. For tests in 10% broadband light, we use the Windowed Stroke Minimization algorithm to extrapolate estimates of bounding wavelengths from the exposures of the central one. We use the same ripple-style SPs as in the previous HCIT experiment because that mask manufacturing technique proved successful. Our tests of symmetric dark holes in monochromatic and 10% broadband light at the HCIT demonstrate the steady improvements being made by Princeton toward a space-based coronagraphy mission.

8864-29, Session 6

MEMS deformable mirror CubeSat testbed

Kerri L. Cahoy, Anne Marinan, Matthew Webber, Benjamin Novak, Caitlin Kerr, Massachusetts Institute of Technology (United States); Ruslan Belikov, NASA Ames Research Ctr. (United States); N. Jeremy Kasdin, Princeton Univ. (United States); Eduardo A. Bendek, NASA Ames Research Ctr. (United States); Frantz Martinache, Subaru Telescope, National Astronomical Observatory of Japan (United States)

To meet the high contrast requirement of 1 ? 10^?10 to image an Earth-like planet around a Sun-like star, space telescopes equipped with coronagraphs require wavefront control systems. Deformable mirrors (DMs) are a key element of a exoplanet direct imaging wavefront control system, as they correct for optical imperfections, thermal distortions, and diffraction that would otherwise corrupt the wavefront and ruin the contrast. However, the high-actuator count microelectromechanical system (MEMS) deformable mirrors needed for this task have yet to fly in space for a period of time long enough to characterize their on-orbit performance and reduce risk by developing and operating their supporting software and hardware systems. The goal of the MEMS Deformable Mirror CubeSat Testbed is to develop a CubeSat-scale flight-like hardware, software, and remote operation demonstration of MEMS deformable mirror and wavefront sensing technology. The goal is to test the ability of a MEMS deformable mirror to perform wavefront control on-orbit using a CubeSat platform, because of the increasingly straightforward and cost-effective access to space for CubeSats and the ability to characterize performance over a longer mission lifetime than suborbital sounding rockets. At least two MEMS deformable mirrors and drivers will fit in a CubeSat as commercial off-the shelf parts that require only minor modifications, and their mirror technology is identical to their higher actuator-count siblings that could be selected for an exoplanet direct imaging mission. The testbed could be modified to test other small form-factor mirror technologies as well. The wavefront sensing technology that would be developed and evaluated as part of this demonstration to characterize on-orbit mirror performance includes sensorless wavefront sensing (e.g. masks, diversity), as well as more traditional Shack-Hartmann and interferometric approaches. After development, functional, and environmental testing, we expect that the CubeSat-scale MEMS deformable mirror and wavefront sensing payload in addition to the supporting CubeSat subsystems (attitude control, command and data handling, communications, thermal, and power) that comprise the laboratory testbed would be ready for launch. Characterizing MEMS deformable mirror devices and simple wavefront control algorithms over months in space on a CubeSat would establish on-orbit heritage and would be valuable inputs to the scientists, engineers, and mission planners for a dedicated exoplanet direct imaging space telescope mission.

8864-30, Session 6

Planar waveguide integrated spatial filter array

Jun Ai, Fedor Dimov, Luminit LLC (United States); Richard Lyon, NASA Goddard Space Flight Ctr. (United States); Neven Rakuljic, Chris Griffo, Xiaowei Xia, Engin Arik, Luminit LLC (United States)

An innovative integrated spatial filter array (iSFA) was developed for the nulling interferometer for the detection of Earth-like planets and life beyond our solar system. The coherent iSFA comprised a 2D planar lightwave circuit (PLC) array coupled with a pair of 2D lenslet arrays in a hexagonal grid to achieve the optimum fill factor and throughput. The silica-on-silicon waveguide mode field diameter and numerical aperture (NA) were designed to match with the Airy disc and NA of the microlens for optimum coupling. The lenslet array was coated with a chromium pinhole array at the focal plane to pass the single-mode waveguide but attenuate the higher modes. We assembled a 30 by 30 array by stacking 30 chips that were produced by photolithography from a 6 in. silicon wafer. Each chip has 30 planar waveguides. The PLC array is inherently polarization-maintaining (PM) and requires much less alignment in contrast to a fiber array, where each PM fiber must be placed individually and oriented correctly. The PLC array offers better scalability than the fiber bundle array for large arrays of over 1,000 waveguides. This project is sponsored by NASA contract NNX-10-C-A56C.

8864-18, Session 7

Improving image contrast for the direct detection of exoplanets at small inner working angles

Sandrine J. Thomas, Ruslan Belikov, NASA Ames Research Ctr. (United States); Laurent A. Pueyo, Space Telescope Science Institute (United States); Eugene Pluzhnik, NASA Ames Research Ctr. (United States); Julien Lozi, The Univ. of Arizona (United States)

The detection of extrasolar planets, using both space- and ground-based telescopes, is one of the most exciting fields in astronomy today. The ultimate goal that we all work towards is to directly image exoplanets and potentially directly detect planets in the habitable zone. It is with this vision that the explorer mission EXCEDE selected by NASA for technology development, is designed. EXCEDE (Exoplanetary Circumstellar Environment and Disk Explorer) is composed of a 0.7 m telescope equipped with a Phase-Induced Amplitude Apodization Coronagraph (PIAA-C) and a 2000-element MEMS deformable mirror, capable of raw contrasts of 1e-6 at 1.2 lambda/D and 1e-7 above 2 lambda/D. To obtain such contrasts requires precise wavefront control algorithms using deformable mirrors. Unlike other optical systems where the goal is to obtain the best wavefront, we aim at canceling the diffracted light coming from the parent star to increase the signal coming from the planet. To do so, we use wavefront control techniques, such as Electric Field Conjugation (EFC) and stroke minimization, already developed and soon be operational on 8-m class telescopes. One caveat is that they primarily function at moderate separations (r>3 lambda/D). In this paper, we present variants of EFC that aim at canceling on-axis diffracted light close to the parent star in order to increase our discovery region. We will use the NASA Ames Coronagraphic Experiment (ACE) testbed to test these algorithms.

8864-31, Session 7

EXCEDE technology development II: demonstration of high contrast at 1.2 L/D and first broadband results

Ruslan Belikov, Eduardo A. Bendek, Thomas P. Greene, NASA Ames Research Ctr. (United States); Olivier Guyon, Julien Lozi, The Univ. of Arizona (United States); Dana H. Lynch, NASA Ames Research Ctr. (United States); Kevin E. Newman, The Univ. of Arizona (United States); Eugene Pluzhnik, NASA Ames Research Ctr. (United States); Glenn Schneider, The Univ. of Arizona (United States); Domenick Tenerelli, Lockheed Martin Space Systems Co. (United States); Sandrine J. Thomas, Fred C. Witteborn, NASA Ames Research Ctr. (United States)

Coronagraph technology is advancing and promises to enable space telescopes capable of directly detecting low surface brightness circumstellar debris disks as well as giant planets as close as in the habitable zones of their host stars. One mission capable of doing this is called EXCEDE (EXoplanetary Circumstellar Environments and Disk Explorer), which in 2011 was selected by NASA's Explorer program for technology development (Category III). EXCEDE is a 0.7m space telescope concept designed to achieve raw contrasts of 1e-6 at an inner working angle of 1.2 l/D and 1e-7 at 2 l/D and beyond. In addition to doing fundamental science on debris disks, EXCEDE will also serve as a technological and scientific precursor for an exo-Earth imaging mission. EXCEDE uses a Starlight Suppression System (SSS) based on the Phase Induced Amplitude Apodization (PIAA) coronagraph to provide high throughput and high contrast close to the diffraction limit, enabling aggressive performance. We report on our continuing progress of developing the SSS for EXCEDE, including (a) high contrast performance demonstrations at 1.2 l/D, which includes a lab demonstration of 8e-7 contrast at 1.2 l/D, 2e-8 at 2 l/D in monochromatic light at 655nm, and a preliminary 10% broadband result of 6e-6 contrast at 1.2 l/D; (b) the installation of a new Low Order Wavefront Sensor (LOWFS) which enabled achieving deep contrasts at aggressive inner working angles; (c) implementation of more efficient model-based wavefront control algorithms; and (d) preliminary demonstrations of new focal plane masks achieving better broadband performance than standard hard-edge masks.

8864-32, Session 7

High-contrast imaging with the vortex coronagraph

Eugene Serabyn, Jet Propulsion Lab. (United States); Dimitri Mawet, European Southern Observatory (Chile); John T. Trauger, Dwight Moody, Kurt Liewer, John E. Krist, Brian D. Kern, Jet Propulsion Lab. (United States)

The vortex coronagraph has great potential for enabling high-contrast observations very close to bright stars, and for reducing the size of space telescopes needed for exoplanet characterization. Here we discuss recent progress in vortex coronagraphy, including the production of vector vortex masks ,and their measured contrast performance. Monochromatic contrasts of 1e-9 have recently been demonstrated, and broadband operation is the next step. Development of broadband vortices should enable their use on future space-based coronagraphic instruments and missions.

8864-33, Session 8

High-contrast imaging with an arbitrary aperture: active correction of aperture discontinuities *(Invited Paper)*

Laurent A. Pueyo, Colin Norman, Johns Hopkins Univ. (United States)

We present a new method to achieve high-contrast images using segmented and/or on-axis telescopes. Our approach relies on using two sequential Deformable Mirrors to compensate for the large amplitude excursions in the telescope aperture due to secondary support structures and/or segment gaps. In this configuration the parameter landscape of Deformable Mirror Surfaces that yield high contrast Point Spread Functions is not linear, and non-linear methods are needed to find the true minimum in the optimization topology. We solve the highly non-linear Monge-Ampere equation that is the fundamental equation describing the physics of phase induced amplitude modulation. We determine the optimum configuration for our two sequential Deformable Mirror system and show that high-throughput and high contrast solutions can be achieved using realistic surface deformations that are accessible using existing technologies. We name this process Active Compensation of Aperture Discontinuities (ACAD). We show that for obscured, on-axis of geometries analogous to the Hubble Space Telescope ACAD can reach broadband contrasts of 10^-8 with a variety of coronagraphs. We then discuss the applicability of this technique to future space-based observatories.

8864-34, Session 8

Shaped pupil coronagraphy with the AFTA telescope

Alexis Carlotti, N. Jeremy Kasdin, Robert J. Vanderbei, Princeton Univ. (United States)

The recently completed study of using the AFTA telescopes for a potential WFIRST mission included a coronagraph instrument for exoplanet imaging. The challenge is to design a coronagraph that achieves the desired high contrast in the presence of the complicated on-axis optical architecture of the AFTA. This is especially difficult if contrast levels as small as 1e-9 must be achieved at a few lambda/D from the star. In this paper we present shaped pupil designs using our new two-dimensional formulation. These designs also include constraints given by the wavefront control system, a necessary element of a complete high-contrast system in space. We have computed various shaped pupils for different contrast floors, inner working angles, and high-contrast region shapes. Two main types of masks are presented: discovery masks

that offer wide discovery space with moderate inner working angles, and characterization masks which are designed for narrower discovery space and smaller inner working angles. A discovery mask would be used first to locate potential candidates at shorter wavelengths. Once the location of a planet is known, a characterization mask would be used to measure its spectrum in broadband.

8864-35, Session 8

The ring-apodized and multistage vortex coronagraph: two simple, small-angle coronagraphic solutions for heavily obscured apertures

Dimitri Mawet, European Southern Observatory (Chile); Pierre Baudoz, LESIA - Observatoire de Paris (France); Laurent A. Pueyo, Space Telescope Science Institute (United States); Alexis Carlotti, Princeton Univ. (United States); Bertrand Mennesson, Eugene Serabyn, James K. Wallace, Jet Propulsion Lab. (United States)

The vortex coronagraph is a well-proven new generation coronagraph currently offered or soon to be offered on various 8-meter class telescopes (Palomar, VLT, and soon LBT and Subaru). The current level of performance on ground-based telescopes is not limited by intrinsic properties of the actual vortex devices, but by thermal background and/or partially corrected wavefronts. However, in the particular case of unfriendly apertures (mainly large central obscuration) when very high contrast is needed (second-generation instruments, ELTs, space- based missions), a vortex coronagraph alone can not deliver because of the contamination due to the diffraction from the obscured part of the pupil. Based on remarkable properties of optical vortices, we recently proposed a method, based on the self-similarity of the topological charge 2 Lyot-plane 1/r^2 amplitude distribution, that reduces the residual light leakage of on-axis telescopes to (a/A)^2n, with n, the even number of stages satisfying n ≥ 2, and a and A, the radii of the central obscuration and primary mirror, respectively. This method was a first step towards enabling high contrasts with an on-axis telescope. However, when the central obscuration exceeds 20%, or if very high contrast is needed, the number of stages required might become prohibitive. In this paper, we present two simple optical solutions to alleviate this issue: (i) We first show that a simple single-stage ring apodizer, exploiting the self-similarity of the vortex Lyot-plane amplitude distribution, allows perfectly nulling the diffraction from the central obscuration. (ii) A 3-stage VC can restore the vortex full null property for any obscuration geometry.

8864-36, Session 8

Complex apodized Lyot coronagraph for exoplanet imaging with partially obscured telescope apertures

John T. Trauger, John E. Krist, Dwight Moody, Brian Gordon, Jet Propulsion Lab. (United States); Dimitri Mawet, European Southern Observatory (Chile)

We update the design, fabrication, performance, and future prospects for the complex apodized Lyot coronagraph. We report new circular focal plane mask designs for high-contrast exoplanet imaging and spectroscopy with telescope apertures that are unobscured, centrally obscured, as well as apertures with complicated obscurations such as the AFTA/SALSO reuse telescopes. Together with a pair of deformable mirrors for active wavefront control, the complex Lyot coronagraph provides high contrast dark fields of view extending to within angular separations of 2.5 ?/D from the central star, over spectral bandwidths of 20% or more, and with throughput efficiencies up to 60%.

8864-37, Session 8

Wavefront control scenarios for a coronagraph on the AFTA space telescope

Tyler D. Groff, N. Jeremy Kasdin, Princeton Univ. (United States); Laurent A. Pueyo, Space Telescope Science Institute (United States); Stuart Shaklan, Jet Propulsion Lab. (United States)

A coronagraph on the Astrophysics Focused Telescope Asset (AFTA) provides a unique opportunity to conduct space based spectroscopic characterization of faint planets orbiting nearby stars. The principal components of such an instrument are the coronagraph itself, the integral field spectrograph (IFS) imager, and a wavefront control system to remove observatory instabilities and quasi-static speckles. Such a system will need to reach contrast levels of approximately 1e-9 at small angular separations to detect super-earths and characterize exo-zodiacal light for any future flagship class missions. We perform a sensitivity study to demonstrate the achievable performance using the proposed first-order AFTA instrument hardware and a focal plane wavefront controller with the IFS and a low order wavefront sensor. The wavefront estimation scheme is assumed to be a closed loop Kalman filter estimator, which can provide estimates at multiple wavelengths thanks to the IFS, with an optimal control law sending commands to the DM. The limiting magnitude of the target is driven by the integration time required to achieve adequate signal-to-noise in the estimation step, the detector noise characteristics, and the stability of the observatory. We demonstrate these effects and define observatory stability limits and the performance required from the low-order wavefront sensor by simulating the optical system with appropriate noise and intensity levels. The primary conclusions are centered around detector noise limits, limiting apparent magnitudes for the parent star, observatory stability requirements, and time budgeting required for wavefront control, preferential observational strategies, and post-processing schemes.

8864-38, Session 8

Imaging Earth-like planets around late-type stars with low-inner working angle PIAA coronagraphy

Olivier Guyon, Subaru Telescope, National Astronomical Observatory of Japan (United States)

The phase-induced amplitude apodization (PIAA) technique, by performing lossless apodization, allows high performance coronagraph architectures simultaneously offering low inner working angle and high throughput. The most recent designs, the PIAA complex mask coronagraph (PIAACMC), use a phase-shifting focal plane mask and offer ~1 lambda/D inner working angle on centrally obscured or segmented apertures. Scientifically, this enables direct imaging of potentially habitable rocky planets around the ~20 nearest stars with a 2.4 m diameter telescope in visible light. The optimal targets for this application are early M and K type stars, for which the planet to star contrast is most moderate than for Sun-like stars, and become accessible thanks to the coronagraph's small inner working angle. On the next generation of ground-based extremely large telescopes (ELTs), PIAACMC allows imaging and spectroscopic characterization of habitable planets around nearby M-type stars, for which the planet-to-star contrast, at ~1e-7, is within reach.

8864-39, Session 8

Coronagraph design for the AFTA telescope

Stuart Shaklan, Marc C. Foote, Marie Levine, Jet Propulsion Lab. (United States); J. Michael Rodgers, Synopsys, Inc. (United States); Michael Underhill, Luis Marchen, Daniel B. Klein, Jet Propulsion Lab. (United States)

The Astrophysics Focused Telescope Assets (AFTA) study in 2012-2013 included a high-contrast stellar coronagraph to complement the wide-field infrared survey (WFIRST) instrument. The idea of flying a coronagraph on this telescope was met with some skepticism because the AFTA pupil has a large central obscuration with six secondary mirror struts that impact the coronagraph sensitivity. However, several promising concepts have emerged, and a corresponding initial instrument design has been completed. Requirements on the design include sharing of the Cassegrain field with WFIRST, on-orbit robotic serviceability, operation in a geosynchronous orbit, and room-temperature operation (driven by the coronagraph's deformable mirrors). We describe the optical, mechanical, and thermal properties of the instrument, its operation, its expected performance, and the stability requirements that the coronagraph places on the observatory.

8864-40, Session 8

Starshade Earth characterizer with AFTA/SALSO telescope

P. Douglas Lisman, Jet Propulsion Lab. (United States)

A starshade experiment can leverage the AFTA/SALSO telescope to capture spectra from earthlike exoplanets much earlier and at significantly lower cost than otherwise possible. Demanding telescope requirements, or compromised exoplanet performance, is avoided by suppressing starlight to entering the telescope. Starshades can stow in a compact volume enables a combined launch with the telescope using standard 5 m fairings. Starshade related instrumentation with the telescope is limited, leaving ample resources for a broad range of other experiments. Starshade observation time is limited to less than 20%, while the remaining time is spent repositioning the starshade for the next target star. We present the starshade and occulter system designs and the technology development plan. We also survey potential mission scenarios, including both joint and separate launches. One low-cost separate launch option addressed is to launch as a shared ride to geostationary orbit using an ESPA ring based bus system with the onboard propulsion capability to maneuver to Earth-Sun L2.

8864-41, Session 9

Verifying occulter deployment tolerances as part of NASA's technology development for exoplanet missions

N. Jeremy Kasdin, Princeton Univ. (United States); Stuart Shaklan, Doug Lisman, Mark W. Thomson, David Webb, Eric J. Cady, Jet Propulsion Lab. (United States); Geoffrey W. Marks, Amy Lo, Northrop Grumman Aerospace Systems (United States); Bruce Macintosh, Lawrence Livermore National Lab. (United States)

An external occulter is a satellite employing a large screen, or starshade, that flies in formation with a spaceborne telescope to provide the starlight suppression needed for detecting and characterizing exoplanets. Among the advantages of using an occulter are the broadband allowed for characterization and the removal of light before entering the observatory, greatly relaxing the requirements on the telescope and instrument. In support of NASA's Exoplanet Exploration Program and the Technology Development for Exoplanet Missions (TDEM), we recently completed a 2 year study of the manufacturability and metrology of starshade petals. In this paper we review the results of that successful first TDEM which demonstrated an occulter petal could be built and measured to an accuracy consistent with close to 10^-10 contrast. We then present the results of our second TDEM to demonstrate the next critical technology milestone: precision deployment of the central truss and petals to the necessary accuracy. We show the deployment of an existing deployable truss outfitted with four sub-scale petals and a custom designed central hub. We demonstrate that the system can be deployed multiple times with a repeatable positioning accuracy of the petals better than the requirement of 1.0 mm.

8864-42, Session 9

Achieving high-contrast ratios with a 60-cm starshade

Tiffany Glassman, Suzanne Casement, Steven Warwick, Onur Armagan, Northrop Grumman Aerospace Systems (United States)

The external starshade is a prospective method for the direct detection and spectral characterization of terrestrial planets around other stars, a key goal identified in ASTRO2010. Validation of this approach has been challenging at very small scales (~4 cm) in the lab (e.g. Samuele et al. 2010). We have successfully fabricated 60 cm starshades and begun a series of ground test experiments with them. Our first experiment, limited by city lights and a short (300 m) baseline between the telescope and the starshade, showed excellent light suppression of >10^6. We enhanced our experimental setup to provide longer baselines and reduced aperture size to provide a closer match to the Fresnel number and Inner Working Angle (in ?/D) expected for the flight system. We measured the starshade performance with baselines between starshade and telescope ranging from 0.75 to 1.5 km and demonstrated contrast ratios from ~10^-7 to better than 10^-9, depending on the test conditions and experimental setup. In this paper, we describe the test setup, the reduction techniques, and an analysis of the relevance of these measurements to a flight starshade system.

8864-43, Session 9

Position sensing and control at the Princeton occulter testbed

Dan Sirbu, N. Jeremy Kasdin, Robert J. Vanderbei, Princeton Univ. (United States)

For direct imaging of Earth-like planets, image plane contrast of ten orders of magnitude is required to be achieved through starlight suppression. One promising method for achieving this level of contrast is through the usage of an external occulter, a second spacecraft whose shape is designed through optimization methods to control diffraction and produce deep shadow at the location of the space telescope. At the Princeton Occulter Testbed, we have designed a subscale experiment to verify the numerical diffraction routines used to create optimal occulter shapes and have presented high-contrast imaging results from our testbed. Here we present the design and experimental verification of a new mask designed for high-contrast in the blue portion of the optical spectrum, and designed to leak light at the red end. We demonstrate the feasibility of using such out-of-band diffraction leakage for optical alignment of the occulter and space telescope to enable formation flight.

8864-44, Session 9

Starshade optical edge modeling, requirements, and laboratory tests

Stefan R. Martin, Jet Propulsion Lab. (United States); Siu-Chun Lee, Applied Sciences Lab. Inc. (United States); Eric J. Cady, P. Douglas Lisman, Stuart B. Shaklan, Samuel L. Crawford, Jet Propulsion Lab. (United States)

In conjunction with a space telescope of modest size, a starshade can be used as an external occulter to block light from a target star, enabling the detection of exoplanets in close orbits. Typically, the starshade will be placed some 50,000 km from the telescope and the system oriented so that the sun is on the opposite side of the shade to the telescope, but somewhat away from the line of sight. A small amount of sunlight

can scatter from the edges of the shade directly into the telescope. Since the photon rate from an earthlike exoplanet might be only a few photons per minute, it is desirable that the scattered sunlight is also near this level. We have built an analytical model of the performance of starshade edges for both specular and Lambertian surfaces and derived requirements for properties such as reflectivity and radius of curvature. A computer model was also developed to show the appearance of the sunlight from the starshade and assess the contrast with the exoplanet. We also constructed a Scatterometer with which various test edges were measured and derived the likely performance if used in a starshade. We discuss these models and give the principal results.

The work was conducted at the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration.

8864-45, Session 10

Astrometric detection of exoplanets from the ground *(Invited Paper)*

Johannes Sahlmann, Observatory of Geneva (Switzerland); Petro F. Lazorenko, National Academy of Sciences of Ukraine (Ukraine); Antoine Mérand, European Southern Observatory (Chile); Didier Queloz, Damien Ségransan, Observatory of Geneva (Switzerland); Julien Woillez, European Southern Observatory (Germany)

Astrometry is a powerful tool to study the populations of extrasolar planets around nearby stars. It gives access to a parameter space not reachable by other observing techniques and is therefore required for obtaining a comprehensive picture of the properties, abundance, and architectures of exoplanetary systems. Ground-based observations with the necessary accuracy of one milli-arcsecond and better are challenging due to turbulence in the Earth's atmosphere and instrumental effects. We will present results from infrared interferometric observations with the VLTI and a programme employing optical imaging with the VLT, both aimed at the astrometric detection of exoplanets. We will discuss these in the context of other ground-based efforts and of GAIA, ESA's astrometry mission scheduled for launch in 2013.

8864-47, Session 10

First experimental results of very high accuracy centroiding measurements for the neat astrometric mission

Antoine Crouzier, Fabien Malbet, Olivier Preis, Francois F. Henault, Pierre Kern, Guillmero Martin, Eric Stadler, Morgan Saint-Pe, Philippe Feautrier, Institut de Planétologie et d'Astrophysique de Grenoble (France); Christophe Cara, Pierre-Olivier Lagage, Commissariat à l'Énergie Atomique (France); Alain M. Léger, Institut d'Astrophysique Spatiale (France); Michael Shao, Renaud Goullioud, Jet Propulsion Lab. (United States)

NEAT is an astrometric mission proposed to ESA with the objectives of detecting Earth-like exoplanets in the habitable zone of nearby solar-type stars. In NEAT, one fundamental aspect is the capability to measure stellar centroids differences at the precision of 5 ? 10?6 pixel.

The NEAT consortium is designing and building a testbed in vacuum in order to demonstrate 5?10?6 pixel precision for the centroid estimation. The goal is to provide a proof of concept for the precision requirement of the NEAT spacecraft. In this paper we give the basic relations and trade-offs that come into play for the design of a centroid testbed and its metrology system. We detail the different conditions necessary to reach the targeted precision and present the characteristics of our current design.

Finally, we will present the experimental results obtained since we began to assemble the bench in February 2013.

8864-48, Session 10

NEAT: an astrometric mission to detect nearby planetary systems down to the Earth mass

Fabien Malbet, Antoine Crouzier, Institut de Planétologie et d'Astrophysique de Grenoble (France); Alain M. Léger, Institut d'Astrophysique Spatiale (France); Michael Shao, Renaud Goullioud, Jet Propulsion Lab. (United States); Pierre-Olivier Lagage, Commissariat à l'Énergie Atomique (France)

High precision astrometry, combined with radial velocity and Gaia's astrometric measurements, has a unique potential to detect and characterize nearby habitable planetary systems. We will present progress on the concept of an high precision astrometric space mission called NEAT that will have the capability to reach the Earth mass limit in the Habitable zone of nearby solar-type stars. We will discuss the scientific objectives of this mission, the technical challenges and also the results of a demonstration that has been performed with the PRISMA satellites flying in formation. The presentation of the experimental test bench that is aimed at demonstrating micro-pixel accuracy measurements will be presented by another paper by Crouzier et al.

8864-49, Session 10

Microarcsec narrowfield astrometry

Michael Shao, Jet Propulsion Lab. (United States)

The focal plane calibration and centroiding experiment consisted of white light images from two single mode fibers focused on to a CCD with a single curved optic. We measured the separation of the two images as the CCD was translated so the images moved ~3 pixel. After appropriate averaging, the rms difference of the separation of the two images was calculated to be 9e-6 lambda/D in both X and Y.

There are many ways to use a diffractive mask to calibrate the field distortion of a telescope. The calibration can be done while making science measurements, or the calibration can be performed every hour or few hours if the system is sufficiently stable. In this experiment, we use a diversity of images to solve for both errors in the diffractive grating and errors in the telescope.

8865-1,

Memorial tribute to astrobiology pioneers Dr. David S. Mckay and academician Georgi Zavarzin

Alexei Yu. Rozanov, Astrobiology Institute, Joint Institute for Nuclear Research in Dubna (Russian Federation); Richard B. Hoover, Athens State Univ. (United States) and Univ. of Buckingham (United Kingdom)

No Abstract Available

8865-2, Session 1

Implications of Curiosity's findings for the Viking labeled-release experiment and life on Mars *(Invited Paper)*

Gilbert V. Levin, Arizona State Univ. (United States)

Curiosity's latest reported findings, or lack thereof, are interpreted from the standpoint of their implications for the Viking Labeled Release experiment, and for life on Mars in general. As of the writing of this abstract, Curiosity has reported no findings related to those anticipated by the author's last year's paper, "Stealth Life Detection Experiments Aboard Curiosity." However, Curiosity scientists have stated that soil and rock samples have been taken and analyzed, and abundant images have been downloaded. The only indirectly relevant reports issued by Curiosity scientists concern small-molecule organics found in a soil sample, which simple compounds might be terrestrial contamination, and images of rocks with colored (green) patches, the latter not of sufficient resolution, of which the cameras are capable, to detect possible evidence of biology. Hopefully, by the time of preparation of the body of this paper, more information will be available.

8865-3, Session 1

On the interpretations of curiosity results as related to the possibility of life on Mars

Vera M. Kolb, Univ. of Wisconsin-Parkside (United States); Richard B. Hoover, Athens State Univ. (United States) and Univ. of Buckingham (United Kingdom)

As the results from the Mars Mission "Curiosity" trickle in, questions about their relevance to the possibility of life on Mars are posed. We review recent reports concerning the distribution of subsurface water in Gale Crater and the possible detection of chloromethane, fluorinated hydocarbons and other organics in view of terrestrial microbiology and implications to the possibility of present day life on Mars. We examine the reductive chlorination in the energy metabolism of anaerobic bacteria on Earth, as potentially relevant to the findings of chlorinated organics on Mars. In addition, we present cases of chlorinated products as metabolic products from some species living in permafrost on Earth. We will discuss also other relevant scenarios, as more results become available from "Curiosity".

8865-4, Session 2

Impact of prebiotic synthesis and diagenesis on the distribution, stereochemistry, and stable isotope composition of amino acids in carbonaceous meteorites *(Invited Paper)*

Michael H. Engel, The Univ. of Oklahoma (United States)

Simulation experiments for prebiotic synthesis result in racemic mixtures (D/L = 1.0) for protein and non-protein amino acids, irrespective of the composition of the precursor gas mixtures or the energy sources employed. It is therefore not surprising that it was commonly assumed that if amino acids in carbonaceous meteorites were formed by similar reactions they would also be racemic. Engel and Nagy (1982) and more recently Glavin et al. (2012) have shown that protein amino acids in carbonaceous meteorites often exhibit a moderate to strong L-amino acid excess (D/L ? 1.0). Engel (1980) hypothesized that this extraterrestrial L-excess might be the precursor material from which life as we know it originated. Stable isotope analyses (e.g. Engel and Macko, 1997) confirmed that the L-amino acid excess in meteorites was indigenous rather than the result of contamination subsequent to impact on Earth.

A key question that arises is that since there are no known mechanisms for the direct prebiotic synthesis of amino acids with an L-enantiomer excess, how did these compounds come to exist in carbonaceous meteorites? It has been proposed (e.g. Engel, 2012 and references therein) that a series of diagenetic reactions subsequent to synthesis are responsible for the L-enantiomer excess. In this paper, this hypothesis is further explored with respect to explaining the range of D/L values for amino acids in the various types of carbonaceous meteorites as well as in different stones of the same meteorite. Possible effects of diagenesis on the stable isotope compositions of these compounds are also addressed.

8865-5, Session 2

Fossilized diatoms in meteorites from recent falls in Sri Lanka *(Invited Paper)*

Richard B. Hoover, The Univ. of Buckingham (United Kingdom) and Athens State Univ. (United States); J. Wallis, Cardiff Univ. (United Kingdom); Daryl H. Wallis, The Univ. of Buckingham (United Kingdom); Keerthi Wickramarathne, Anil Samaranayake, Medical Research Institute Sri Lanka (Sri Lanka); Gregory . Jerman, NASA Marshall Space Flight Ctr. (United States); George Williams, Athens State Univ. (United States); Chandra Wickramasinghe, The Univ. of Buckingham (United Kingdom)

Field Emission and Environmental Scanning Electron Microscopy studies have been carried out on samples from observed meteorite falls in central Sri Lanka. The elemental abundances and mineralogy of the stones and the stable isotope data confirm that these stones are non-terrestrial. Observations of motility and exopolysaccharides with detectable nitrogen content are interpreted as indicating that some of the diatoms were recently living. Freshly fractured interior surfaces of the black stones have also been observed to contain fossilized diatom frustules establishing that these diatoms are indigenous to the meteorite rather than post-arrival contaminants. This was confirmed by the observation that these diatoms were embedded in the meteorite rock matrix and exhibit nitrogen content below the EDX detection limit. The carbon content and mineralogy suggests that these stones may represent a previously ungrouped clan of carbonaceous meteorites with density and mineralogy consistent with data obtained on the nuclei of comets. These observations are interpreted as supporting the Hoyle-Wickramasinghe Panspermia hypothesis and the hypothesis advanced in by Hoover et

al. (Earth, Moon and Planets, 35, 19-45, 1986) that diatoms and other microorganisms might be able to live and grow in comets.

8865-7, Session 2

Physical, chemical, and mineralogical properties of the Polonnaruwa meteorite stones

Jamie Wallis, Cardiff Univ. (United Kingdom); Daryl H. Wallis, Univ. of Buckingham (United Kingdom); Chandra Wickramasinghe, The Univ. of Buckingham (United Kingdom); Richard B. Hoover, Athens State Univ. (United States) and Univ. of Buckingham (United Kingdom)

No Abstract Available

8865-8, Session 2

Acritarchs in carbonaceous meteorites and terrestrial rocks

Alexei Yu. Rozanov, Astrobiology Institute, Joint Institute for Nuclear Research in Dubna (Russian Federation); Richard B. Hoover, Athens State Univ. (United States) and Univ. of Buckingham (United Kingdom)

No Abstract Available

8865-9, Session 2

Comets and entropy hydrodynamics: how does evolution violate the 2nd law?

Robert B. Sheldon, NASA Marshall Space Flight Ctr. (United States)

Darwinian evolution has long proposed that "descent with modification" plus "natural selection" was capable of creating the increasing complexity seen in the fossil record. In the past few decades, computer simulations have been developed to understand the process, using the methods of "genetic algorithms" or codes such as "Ev" or "Avida". The results have been discouraging, suggesting that all the information that arises in such simulations was injected in the rule sets from the outset, and indeed, mathematicians have shown that there cannot be any method that performs better than a random search, if the initial conditions are chosen randomly. This "No Free Lunch" theorem has been interpreted as an outcome of the physical laws of thermodynamics, which say that within closed systems, complexity or "information" cannot increase. This physical result has been applied by cosmologists to the entire universe--a manifestly closed system--to argue that even black holes are not capable of adding or subtracting information. All this leads to the absurd result that we cannot exist, at least, without violating the laws of physics.

We argue instead that information density can increase locally if one is careful to control the flow of entropy. This cannot be done diffusively as many have argued, but can be accomplished through clever use of "invariants of the flow". Since most physics texts discuss simple entropy, they infer unphysical properties of entropy flow as if it were an invariant. But by replacing the entropy with true invariants, it is possible to show how information can be concentrated and "added" in ways that are consistent with the observation of increasing complexity on the Earth. This is analogous to constructing a digital computer out of fluid components, wherein the "calculation" is permitted by clever manipulation of the boundary conditions. Magnetized comets possess exactly the properties needed to produce the simplest invariant, making them a prime candidate for driving evolution. Thus the evolution paradox can be solved, but at the cost of requiring the universe to be in a highly information-dense initial state. Such an initial state must be coherent in order to explain the information density, so that in some sense the universe began "alive".

8865-24, Session 2

Red rain in Sri Lanka *(Invited Paper)*

D. Dhanayake, S. Katugampala, S. Gunasekera, Sri Lanka Institute of Nanotechnology (Sri Lanka); K. Wickrmarathne, Medical Research Institute Sri Lanka (Sri Lanka); A. D. De Silva, Genetech Research Institute (Sri Lanka); K. M. N. De Silva, V. Karunaratne, G. A. J. Amaratunga, Sri Lanka Institute of Nanotechnology (Sri Lanka)

In November 2012 several locations in the North Central province of Sri Lanka were subject to showers of red colour rain. Previously red rain had been reported in the South Indian state of Kerala in 2001 and 2010. Samples of the red rain were subject to detailed analysis. Here we report some of the key results. The 'red' component of the rain arises from planar circular/oval shaped structures with diameters in the range 3 – 10 ?m. Under the optical microscope they have a red-brown coloration and are similar to red blood cells, with an outer wall-like region and in some a central nucleus-like region within it.

However, unlike red blood cells, they do not deteriorate in-vitro and have retained their appearance over what has now been a period of five months. In the scanning electron microscope (SEM) the cell-like structures retain their morphology which is seen at high magnification to have a saucer-like thinner interior with a thick wall-like region. Under energy dispersive X-Ray analysis(EDAX) C, O, N, are the elements detected in the highest abundance with much lower levels of Si, Ca and Al and some trace amounts of Na, K, Mg, Fe and Ti. Analysis of a normal rain sample does not reveal any cell- like structures and contain similar trace levels of Fe, ruling out the possibility of the redness arising from the presence of excessive iron oxide. Additionally atomic absorption spectroscopy (AAS) was carried with hyper-pure chemicals to digest the red rain cell-like structures in order to detect metals below ppm levels. No additional metallic elements were identified, in particular no As, Ag nor U were detected as cited in other reports and analyses of red rain from Sri Lanka1,2.

The most significant difference of the red rain cell-like structures compared to organic terrestrial cells is the inability to detect any phosphorus (P). Detectable levels of P would be expected if DNA were present in a cell nucleus or phospholipids in a cell wall structure. Detailed spatial correlation with elemental analysis in the SEM did not reveal the presence of P in the cell wall like structure, nucleus like localioties or intermediate regions. In comparison, with red blood cells which have similar dimensions but lack a nucleus with DNA, P was detected most probably due to phospholipids in the cell wall. Further chemical tests (Stannous chloride and Vanado molybdate) for P, which are capable of revealing trace amounts below ppm levels, on the red rain cell-like structures also failed to reveal its presence. It should be noted that no staining methods were employed as in the recent work which claims evidence for the presence of DNA in red rain cells from Kerala1. Our analysis was centred on the direct detection of elemental P. These initial results point to the cell-like structures which are found in red rain to be distinct from similar sized red cell structures, such as those from algae, of common terrestrial origin.

8865-10, Session 3

Development of the algorithm for life for the search for extraterrestrial life

Vera M. Kolb, Univ. of Wisconsin-Parkside (United States)

Search for extraterrestrial life is typically based on the assumption that extraterrestrials will have science similar to ours, in particular the knowledge of the electromagnetic theory and its applications. This knowledge could serve as a basis for communication. In contrast, Nicholas Rescher, a philosopher of science, vigorously maintains that the extraterrestrials would be critically different than us, and thus their science would also be different than ours. He presents various arguments to support this idea. If he is correct, the likelihood of communication would be minimal. We critically review his arguments and offer a chemical counterargument. We propose functional equivalents of the key chemical processes in life on Earth. These algorithms would accommodate different chemistry, but functionally the same, elsewhere. Thus, we would expect aliens to be substantially similar to us, and this could then extend to their science as well.

8865-11, Session 3

On the role of the molecular recognition principles in astrobiology

Vera M. Kolb, Univ. of Wisconsin-Parkside (United States)

Chemical evolution operates in various extraterrestrial media. Limited observations have been made of small molecules in the space, comets and meteorites. Complex molecules which are precursors of life on Earth have not yet been observed. However, such molecules may be ubiquitous in the universe, based on some universal physico-chemical principles.

We propose that principles of molecular recognition, which include both intra- and inter-molecular non-covalent interactions, guide syntheses of complex molecules. These principles have been studied in drug-receptor interactions, protein folding and chemical self-assembly, for example. We categorize and apply these principles to selected examples that are relevant to astrobiology.

8865-12, Session 3

Potential alternate life biochemistries

Gregory A. Konesky, K-Plasma Ltd. (United States)

Life on Earth is based on the element carbon which currently is the fourth most abundant element in the cosmos, and also requires liquid water, which is composed of hydrogen and oxygen, the first and third most abundant elements, respectively. However, our present understanding of carbon-based life also requires a number of other elements which are not particularly abundant. Phosphorous, for example, is necessary for DNA and ADP/ATP energy carriers. Elemental abundance alone may not be the only prerequisite for the foundations of life. Furthermore, the abundance ratio of silicon to carbon is approximately 925:1 in the Earth's crust.

We briefly review common carbon-based metabolic pathways and then consider alternate elemental substitutions for the carbon "backbone" and their advantages and difficulties. Other considerations include simple substitutions for some of the additional elements of carbon-based life such as selenium or tellurium for sulfur, or arsenic for phosphorus, which has been the subject of recent research. Alternate terminal electron acceptors are also discussed. Storage and transfer of genetic information, another basic requirement of life, is also considered in terms of elemental substitution.

A fundamental issue of life detection, whether based on carbon or not, relates to life's ability to modify its environment and alter equilibriums, both locally and globally. However, we consider how alternate metabolic rates, operating on vastly different time scales, may complicate detection.

In an extreme speculative example of "life as we don't (yet) know it," dusty plasma lattices are discussed which have shown the ability to self-organize and "reproduce."

8865-13, Session 4

Three-dimensional modeling of evolution of life *(Invited Paper)*

Elena V. Pikuta, Athens State Univ. (United States)

In our previous work, the model of Evolution of Life was constructed based on the data from Archaea, as the most limiting life groups. Geometry of the coordinates for physiological optima of Archaea demonstrated the function of a hyperbola in two dimensions, and of a hyperboloid in three dimensions modeling. It was shown that the hyperboloid has an inclination of 22.5 o. In previous work, both hyperboloids (one- and two-sheet) were positioned vertically, as schematic data for a preliminary result's demonstration.

In this work, we have constructed a hyperboloid with respect to the precise coordinates of physiological groups, and we have added the data for other key groups of microorganisms that interfered and co-evolved with relic groups of Archaea. Consequently, the inclined hyperboloid was composed to demonstrate the evolution of microorganisms in space and time. Here, we present a complete model of the Evolution of Life, discuss interpretation of results, and outlining major conclusions about evolution of the central biological groups on Earth.

In this article, we discuss some critical changes of geometry for separate physiological groups during evolution, and we present conjectures regarding the impact of major environmental cataclysms and climate changes on Earth.

8865-14, Session 4

Elongation Factor-Tu (EF) proteins structural stability and bioinformatics in ancestral gene reconstruction

Sunil Dehipawala, Todd Holden, George Tremberger Jr., David Lieberman, Tak D. Cheung, Queensborough Community College (United States)

A recent paleo-experimental evolution report suggested that the insertion of an ancient version of Elongation Factor-Tu (EF) in E-coli would give rise to mutations of other genes while the inserted ancient sequence has remained intact without mutation. Knowing that EF proteins show strong thermostability via structural divergence and adapt readily to the host organism operating temperatures, the correlations of the thermo-adaptability with the associated DNA sequence bioinformatics have been studied. Fractal dimension via the Higuchi fractal method and Shannon entropy of the DNA sequence classification could be used in a 2-D map as a simple summary. The identification of adaptive selection using entropy marker and functional-structural diversity using fractal dimension would support a regression analysis where the coefficient of determination would serve as evolutionary pathway marker. Comparisons between genes such as 16S rRNA with EF Tu sequences in this study have accounted for the observed thermostability systematically. The limits of fractal dimension and Shannon entropy could be used to predict the thermostability of extremophiles in astrobiological conditions.

8865-15, Session 4

Assessing fluctuating evolutionary pressure in yeast and mammal by bioinformatics of meiotic protein genetic sequences

Todd Holden, Sunil Dehipawala, George Tremberger Jr., David Lieberman, Tak D. Cheung, Queensborough Community College (United States)

The evolutionary rate co-variation in meiotic proteins has been reported for yeast and mammal using phylogenic branch lengths. The corresponding DNA sequences could be classified as a 2D map of fractal dimension and Shannon entropy. The co-variation assessment using phylogenic branch length was found to be consistent with the 2D map distance, thus opening up the 2D map for assessing fluctuating evolutionary pressure on a fundamental genetic level important for retention and duplication. The identification of adaptive selection using entropy marker and functional-structural diversity using fractal dimension would support a regression analysis where the coefficient of determination would serve as evolutionary pathway marker. Comparisons between yeast with mammal sequences in this study have accounted for the observed fluctuating evolutionary pressure systematically. Convergent and divergent fluctuating evolutionary pressure could be studied with extension to genetic sequences in organisms in astrobiological conditions, with the assumption that the continuation of a book of life would require meiotic proteins and their corresponding DNA sequence bioinformatics everywhere in the universe

8865-17, Session 5

Autofluorescence characteristics of the red rain cells *(Invited Paper)*

Godfrey Louis, Cochin Univ. of Science & Technology (India); A. Santhosh Kumar, Mahatma Gandhi Univ. (India)

Red rain cells are the microscopic biological cells which appear mixed in rain water in large quantity imparting visibly red color to the rain water in a strange event called red rain phenomenon. Our study of this phenomenon which happened in Kerala, India in 2001 has shown that the origin of these cells is possibly extraterrestrial. These cells are not so far successfully identified as any organism known on earth. The cells have unusual property like ability to reproduce at extreme high temperature and the colorless daughter cells cultured from the red cells show unusual autofluorescence characteristics. A similar unusual autofluorescence was also observed in yellow rainwater. In this paper we report the auto-fluorescence characteristics of the original red rain cells. High resolution fluorescence microscopy is employed to study the fluorescence images of the cells under UV-Visible excitation. The results are discussed.

8865-18, Session 5

Analysis of Sri Lankan red rain cells

Norimune Miyake, Takafumi Matsui, Chiba Institute of Technology (Japan); Chandra Wickramasinghe, The Univ. of Buckingham (United Kingdom); Anil Samaranayake, Keerthi Wickramarathne, Medical Research Institute Sri Lanka (Sri Lanka)

We present results of SEM, TEM and fluorescence microscope studies of the red rain cells recovered in Sri Lanka in December 2012. Preliminary analysis reveals the presence of an organism, generally similar to the Kerala red rain cells, that appear to reproduce through a process of internal budding. We are not yet to classify the organism as either a eukaryote or prokaryote on the basis of our tests. Further work is in progress.

8865-19, Session 5

Microorganisms in the coloured rain of Sri Lanka

Anil Samaranayake, Keerthi Wickramarathne, Medical Research Institute Sri Lanka (Sri Lanka); Chandra Wickramasinghe, The Univ. of Buckingham (United Kingdom)

A variety of pigmented microorganisms have been identified in the red, yellow, blue and black rain that fell over Sri Lanka in December 2012 and January 2013. There is tentative evidence for the presence of similar organisms, including diatoms, in meteorites falling over the same time period.

8865-20, Session 6

Horizontal gene transfer *(Invited Paper)*

W. Brigham Klyce Jr., Astrobiology Research Trust (United States)

Horizontal Gene Transfer is the primary means by which prokaryotes acquire new genetic programs. In the past two decades, the importance of HGT for evolution among eukaryotes has become apparent as well. The latest examples of HGT among eukaryotes and the implications that HGT may have for evolution and panspermia will be explored.

8865-21, Session 6

Influence of salts, including amino acids, on the rate and outcome of the in-water prebiotic reactions

Vera M. Kolb, Univ. of Wisconsin-Parkside (United States)

Most prebiotic reactions are hypothesized to have occurred in water. However, most organic compounds are insoluble in water. This has provided a great problem for prebiotic chemistry. Recently, it has been shown that many organic materials which are not soluble in water are still capable of reacting in water, often at faster rates than in the organic solvents. This has provided a new era in the study of the prebiotic reactions. The presence of the inorganic salts and the amino acids was ubiquitous in the aqueous media on the prebiotic Earth. We review the most recent work on the influence of salts on the rate and outcome of two organic reactions, Diels-Alder and multicomponent Passerini reaction, as models for other prebiotic reactions.

8865-22, Session 6

Panspermia: a transformative paradigm with sociological and commercial implications

Camilo Urbina, Univ. de Tarapacá (Chile); Chandra Wickramasinghe, The Univ. of Buckingham (United Kingdom)

Despite the rapidly growing body of evidence that favours a non-terrestrial origin of life and ongoing panspermia, a sometimes fierce resistance pervades the scientific community. Gene sequencing studies carried out in many laboratories over the past two decades indicate that the evolution of higher organisms including Homo sapiens sapiens has involved periodic and recurrent insertions of viral DNA into an evolving line. These viral inserts remain dormant in our genes, and most likely contribute to evolutionary/adaptation potential of organisms. The extension of the process of HGT and gene exchange over a galaxy-wide scale was a prediction of the Hoyle-Wickramasinghe theory of evolution published over 3 decades ago. Adopting the correct origin of life/evolution model is not merely of academic interest; it would have profound and far-reaching implications not only in biotechnology and medical science, but also in reassessing sociological perspectives of ourselves and our connections to the wider universe.

8865-23, Session 6

Galactic evolution and the increasing opportunities for life

Gregory A. Konesky, K-Plasma Ltd. (United States)

Enrico Fermi once looked into the night sky and famously asked "Where are they?" in reference to the apparent lack of obvious indications of advanced extraterrestrial civilizations. As our understanding of astrophysics, and its consequences for the emergence of life, continues to grow, a range of possible answers can be suggested for the question "where are they?" At one extreme, the night sky may indeed be filled with examples of the work of advanced extraterrestrial civilizations, but we ourselves are simply too young a civilization to recognize them as such. Consequently, we construct elaborate "natural" explanations of our observations, using our current understanding of physical laws. Occam's Razor may, on occasion, have two edges.

At the other extreme, the universe is still relatively young. The synthesis of heavy elements in the interior of stars continues to enrich their availability to construct new solar systems with an increasing abundance of rocky terrestrial planets such as our own, and provide increasing opportunities for life to take hold.

We consider the present state of our Milky Way Galaxy and the concept of Galactic Habitable Zones, and then show how stellar evolution will modify the boundaries of this Zone over time. The discovery of extremophiles on this planet, such as Deinococcus radiodurans, may also suggest an extension of those boundaries. The importance of long term stability and resources for the emergence and detection of life over interstellar distances is also considered.

It may well be that we are indeed alone. But not for long.

8866-1, Session 1

MODIS SDSM sun view response simulation and SD degradation-tracking improvements

Junqiang Sun, Sigma Space Corp. (United States); Xiaoxiong Xiong, NASA Goddard Space Flight Ctr. (United States); Hongda Chen, Zhipeng Wang, Sigma Space Corp. (United States)

MODIS reflective solar bands (RSBs) are calibrated on-orbit using an onboard Solar Diffuser (SD) panel and the SD degradation is tracked by an onboard Solar Diffuser Stability Monitor (SDSM). The SDSM views the sun through a 1.44% attenuation screen during SD calibration. The observed SDSM sun view response has shown unexpected ripples that are as large as 10% of the averaged response. As a result, an alternative approaches was developed to better track SD on-orbit degradation. Meanwhile, a model based on geometric factors and design parameters was developed to simulate the SDSM sun view response from MODIS yaw measurements. It illustrated that the ripples were likely induced by erroneous design parameters or misalignment of the opto-mechanical components involved. The model has been further improved by simulating the SDSM sun view response from the first three-year on-orbit SDSM measurements as well. In this report, the improvements of the model are described and the performance of the model is accessed. The model is compared to another simulation approach which simulates the SDSM sun view response using a spline method. The derived SD degradations using the two different simulations for the sun view responses are also compared.

8866-2, Session 1

On-orbit radiometric stability assessment of MODIS thermal emissive bands using lunar observations

Zhipeng Wang, Sigma Space Corp. (United States); Xiaoxiong Xiong, NASA Goddard Space Flight Ctr. (United States); Hongda Chen, Sigma Space Corp. (United States); Sriharsha Madhavan, Science Systems and Applications, Inc. (United States)

The MODIS thermal emissive bands (TEB) are calibrated on-orbit on a scan-by-scan basis, with reference to an aboard blackbody (BB) operated at 290K for Terra MODIS and 285K for Aqua MODIS. The evaluation of calibration quality at other temperatures requires independent thermal sources. As a radiometrically stable source, the moon has become more important for the on-orbit calibration of space-borne spectral sensors that have regular lunar observation capability. MODIS observes the moon at almost the same lunar phase through its space view (SV) port approximately every month. The stability of MODIS TEB calibration can be assessed with its lunar observations. In general, the surface temperature of the Moon varies considerably with location and the relative position of the Sun. To overcome the difficulty, in this paper, this assessment is primarily based on the lifelong trending of the highest brightness temperatures retrieved from each lunar observation. The temperatures are assumed stable year by year. The seasonal oscillation of the temperatures is partially corrected with calculated Moon-Sun distances. The highest temperature on the lunar surface is roughly 390K, higher than the saturation temperatures of most TEB bands. For these partially saturated bands, the stability trending is based on the ratios of the highest radiances from unsaturated pixels to the radiances of a reference band with no saturation from the spatially matched pixels. Overall, the lunar trending results show that MODIS TEB bands are stable within ±1K throughout its lifetime at the angle of incidence (AOI) of SV and at temperatures of nearly 100K higher than its BB temperatures used for calibration. Additional discussions are focused on the improvement of the trending methodology and its application to VIIRS TEB trending.

8866-3, Session 1

On-orbit calibration performance of MODIS TDI bands

I-Wen M. Chu, Junqiang Sun, Sigma Space Corp. (United States); Amit Angal, Science Systems and Applications, Inc. (United States); Hongda Chen, Xu Geng, Taeyoung J. Choi, Sigma Space Corp. (United States); Xiaoxiang Xiong, NASA Goddard Space Flight Ctr. (United States)

The gain coefficients of MODIS bands 13 (667nm) and 14 (678nm) require a treatment different from other reflective solar bands (RSB) due to their time delayed integration (TDI) design and a high-low dual-gain setting. During on-orbit calibration using the onboard solar diffuser (SD) the high-gain output 13H and 14H tend to saturate, thus their gain coefficients are derived from the low-gain output 13L and 14L via a calculated high-to-low scaling ratio. Band 13L/H and 14L/H also saturate during lunar observations thus the lunar gain coefficients are referenced and calibrated against other non-saturated bands. As it also has been observed that the response vs scan-angle (RVS) exhibits noticeable changes with time, a time-dependent RVS calibration algorithm has been developed based on the SD and lunar calibration results to improve the quality of the level 1B (L1B) products. This paper reviews the electronic design and built of band 13 and 14, discusses the details of their SD and lunar calibration as well as the time-dependent RVS algorithms, and presents the long-term performance of the calibration coefficients. The long-term trend shows that the gain change for Terra MODIS band 13 and 14 is significant at 6% and 24%, but more modest for Aqua MODIS band 13 and 14 at 6% and 2%. The ratios 13H/13L and 14H/14L are very stable at the level of 0.1% for both MODIS. For RVS, the long-term change is at the level of 3% for Terra MODIS and about 2% for Aqua MODIS.

8866-4, Session 1

Performance assessment of the clouds and the Earth's radiant energy system (CERES) instruments aboard terra and aqua spacecraft

Susan Thomas, Science Systems and Applications, Inc. (United States); Kory J. Priestley, NASA Langley Research Ctr. (United States); Mohan Shankar, Natividad M. Smith, Science Systems and Applications, Inc. (United States); Norman G. Loeb, NASA Langley Research Ctr. (United States); Dale R. Walikainen, Phillip C. Hess, Science Systems and Applications, Inc. (United States)

Clouds and the Earth's Radiant Energy System (CERES) instruments were designed to measure the reflected shortwave and emitted longwave radiances of the Earth's radiation budget and to investigate the cloud interactions with global radiances for the long-term monitoring of Earth's climate. The three scanning thermistor bolom¬eter sensors on CERES measure broadband radiances in the shortwave (0.3 to 5.0 micrometer), total (0.3 to >100 micrometer) and in 8 - 12 micrometer water vapor window regions. Of the five CERES instruments that are currently in operation, four of the CERES instruments (Flight Models1 through 4) fly aboard Earth Observing System (EOS) Terra and Aqua platforms with two instruments aboard each spacecraft, in 705 KM sun-synchronous orbits of 10:30 AM and 1:30 PM equatorial crossing time.

A rigorous and comprehensive radiometric calibration and validation protocol comprising of various studies was developed to evaluate to calibration accuracy of the CERES instruments. The in-flight calibration of CERES sensors are carried out using the internal calibration module (ICM) comprising of blackbody sources and quartz-halogen tungsten lamp, and a solar diffuser plate known as the Mirror Attenuator Mosaic (MAM). The ICM calibration results are instrumental in determining the changes in CERES sensors' gains after launch from the pre-launch

determined values and the on-orbit gain variations. In addition to the broadband response changes derived from the on-board blackbody and the tungsten lamp, the shortwave and the total sensors show a spectrally dependent drop in responsivity in the shorter wavelegth region below one micron that were brought to light through validation studies. The spectrally dependent changes were attributed to the instrument operational modes and the corrections were derived using the sensor radiance comparisons. This paper covers the on-orbit behavior of CERES sensors aboard the Terra and Aqua spacecraft and the determination of the sensor response changes utilising the in-flight calibration and the radiance measurement comparisons viewing various targets. The corrections for the sensor response changes were incorporated in the radiance calculations of CERES Edition3 data products.

8866-5, Session 1

On-orbit solar calibration methods using the clouds and Earth's radiant energy system (CERES) on-orbit calibration system: lessons learned

Robert S. Wilson, Science Systems and Applications, Inc. (United States); Kory J. Priestley, NASA Langley Research Ctr. (United States); Susan Thomas, Phillip C. Hess, Mohan Shankar, Nathaniel P. Smith, Zbigniew P. Szewczyk, Science Systems and Applications, Inc. (United States)

The Clouds and Earth's Radiant Energy System (CERES) scanning thermistor bolometers measure earth-reflected solar and earth-emitted long-wave radiance, at the top- of-the-atmosphere. The bolometers measure the earth radiance in the broadband shortwave solar (0.3-5.0 microns) and total (0.3->100 microns) spectral bands as well as in the 8->12 microns water vapor window spectral band over geographical footprints as small as 10 kilometers at nadir. December 1999, the second and third set of CERES bolometers was launched on the Earth Observing Mission Terra Spacecraft. May 2003, the fourth and fifth set of bolometers was launched on the Earth Observing Mission Aqua Spacecraft. Recently, (October 2011) the sixth instrument was launched on the National Polar-orbiting Operational Environmental Satellite System Preparatory Project (Suomi NPP) Spacecraft. Ground vacuum calibrations define the initial count conversion coefficients that are used to convert the bolometer output voltages into filtered earth radiance. The mirror attenuator mosaic (MAM), a solar diffuser plate, was built into the CERES instrument package calibration system in order to define on-orbit shifts or drifts in the sensor responses. The shortwave and shortwave part of the total-wave sensors are calibrated using the solar radiance reflected from the MAM's. Each MAM consists of baffle-solar diffuser plate systems, which guide incoming solar radiance into the instrument fields of view of the shortwave and total wave sensor units. The MAM diffuser reflecting type surface consists of an array of spherical aluminum mirror segments, which are separated by a Merck Black A absorbing surface, over-coated with SIOx (SIO2 for PFM). Thermistors are located within each MAM plate and the total channel baffle. The CERES MAM is designed to yield calibration precisions approaching .5 percent for the total and shortwave detectors. The Terra FM1 and FM2 shortwave channels and the FM1 and FM2 total channels MAM calibration

8866-6, Session 1

Early trends on the clouds and the Earth's radiant energy system (CERES) flight model 5 (FM5) instrument's performance using in-flight calibration sources

Nathaniel P. Smith, Science Systems and Applications, Inc. (United States)

The Clouds and the Earth's Radiant Energy System (CERES) scanning radiometer is designed to measure the solar radiation reflected by the Earth and thermal radiation emitted by the Earth. Four CERES instruments are already in service; two aboard the Terra spacecraft, launched in 1999; and two aboard the Aqua spacecraft, launched in 2002. A fifth instrument, flight model 5 (FM5), launched in October 2011 aboard the NPP satellite, began taking radiance measurements on January 27th, 2012. The CERES FM5 instrument uses three scanning thermistor bolometers to make broadband radiance measurements in the shortwave (0.3 – 5.0 micrometers), total (0.3 - >100 micrometers) and water vapor window (8 – 12 micrometer) regions. An internal calibration module (ICM) used for in-flight calibration is built into the CERES instrument package consisting of an anodized aluminum blackbody source for calibrating the total and window sensors, and a shortwave internal calibration source (SWICS) for the shortwave sensor. The calibration sources are used to define shifts or drifts in the sensor response over the life of the mission. In order to better understand the sensors adaptation to the space environment, daily internal calibrations were conducted on all three channels for the first week after opening the instrument's main covers. Over the next month, the frequency of internal calibrations was reduced to the standard mission schedule of three total and window channel calibrations per week and one shortwave channel calibration per week. This paper presents the results of FM5 on-orbit internal calibrations, discusses any ground to flight changes, and describes trends in the calibration data.

Innovative approaches to remote sensing in NASA's Earth system science pathfinder (ESSP) program

Frank Peri, NASA Langley Research Ctr. (United States); Stephen M. Volz, NASA Headquarters (United States)

Following recommendations of the National Research Decadal Survey in 2007, NASA's Earth System Science Pathfinder Program introduced the Earth Venture-class (EV) of mission opportunities. EV investigations are competitively selected, PI-led, relatively low cost and narrowly focused in scientific scope. Investigations may address a full spectrum of earth science objectives, including studies of the atmosphere, oceans, land surface, polar ice regions, and solid Earth. EV investigations complement the larger, strategic missions identified by name in the Decadal Survey, and provide flexibility to accommodate scientific advances and new implementation approaches.

EV has three program elements. The EV-Suborbital (EVS) are suborbital/airborne investigations with 5-year duration and managed to NPD 7120.8. The EV-Mission (EVM) element comprises small complete missions launched within 5 years of initiation, managed as Class D missions per NPD 7120.5, and cost-capped at $150M. The EV-Instrument (EVI) element develops spaceborne instruments for flight as missions-of-opportunity (MoO). Instruments are managed according to Class C per NPD 7120.5, limited to 5-year development duration and cost capped at $90M. NASA separately secures and funds the access to space for these instruments.

To ensure the success of EV, the management approach of each element is tailored according to the specific needs of the element. For example, for EVI MoOs NASA employs typical oversight consistent with Class C missions, while for Class D EVM missions, industry best practices may be used. Similarly, for EVS best practices from NASA's science research investigations are employed to minimize overhead while enforcing strong project management principles. This paper will explore the differences in management approaches and the advantage of tailoring to ensure mission success.

8866-8, Session 2

Management approach for Earth venture instruments

Diane L. Hope, NASA Langley Research Ctr. (United States); Sanghamitra B. Dutta, NASA Goddard Space Flight Ctr. (United States)

The Earth Venture Instrument (EVI) element of the Earth Venture Program calls for developing instruments for participation on a NASA-arranged spaceflight mission of opportunity to conduct innovative, integrated, hypothesis or scientific question-driven approaches to pressing Earth system science issues.

The Announcement of Opportunity (AO) for EVI-1 stressed the importance of "accommodatibility." Although it was not an evaluation factor, those proposals that proposed an instrument "…with a high probability of being compatible with several potential platforms is more likely to be selected than an instrument with less flexible accommodation and orbit requirements." This approach to the AO leads to a potential broad spectrum of instruments requiring hosting on LEO, GEO, or ISS platforms. In addition to the breadth of host platforms, the Principal Investigators were not limited to NASA only participation. The intent was to encourage input from a broad range of PIs including NASA, other agencies, industry and academia.

The management approach for EVI was developed in advance of the selection of the first instrument and was based on this broad spectrum of potential host platforms and PI organizations. This paper will discuss the variations in management approach as dictated by the numerous potential selections. It will further focus on the specific approach for the EVI-1 selection, Tropospheric Emissions: Monitoring of Pollution (TEMPO), whose PI is from the Smithsonian Astrophysical Observatory, a trust establishment of the United States, and will be hosted on a commercial GEO satellite.

8866-9, Session 2

Management approach for NASA's Earth Venture-1 (EV-1) airborne science investigations

Anthony R. Guillory, Todd C. Denkins, Danette Allen, NASA Langley Research Ctr. (United States)

The Earth System Science Pathfinder (ESSP) Program Office (PO) is responsible for programmatic management of National Aeronautics and Space Administration (NASA) Science Mission Directorate's (SMD) Earth Venture (EV) missions. EV is composed of both orbital and suborbital Earth science missions. The first of the Earth Venture missions is EV-1, which are Principal Investigator-led, temporally-sustained, suborbital (airborne) science investigations cost-capped at $30M each over five years. Traditional orbital procedures, processes and standards used to manage previous ESSP missions, while effective, are disproportionally comprehensive for suborbital missions. Conversely, existing airborne practices are primarily intended for smaller, temporally shorter investigations, and traditionally managed directly by a program scientist as opposed to a program office such as ESSP. ESSP has crafted a management approach for the successful implementation of the EV-1 missions within the constructs of current governance models. NASA Research and Technology Program and Project Management Requirements form the foundation of the approach for EV-1. Additionally, requirements from other existing NASA Procedural Requirements (NPRs), systems engineering guidance and management handbooks were adapted to manage programmatic, technical, schedule, cost elements and risk. The program management approach presented for EV-1 will set the precedent for future suborbital EV missions.

8866-10, Session 2

Class D management implementation approach of the first orbital mission of the Earth Venture series

James E. Wells, NASA Langley Research Ctr. (United States); John R. Scherrer, Southwest Research Institute (United States); Richard C. Law, NASA Langley Research Ctr. (United States); Christine Bonniksen, NASA Headquarters (United States)

A key element of the National Research Council's Earth Science and Applications Decadal Survey called for the creation of the Venture Class line of low-cost research and application missions within NASA (National Aeronautics and Space Administration). One key component of the architecture chosen by NASA within the Earth Venture line is a series of self-contained stand-alone spaceflight science missions called "EV-Mission". The first mission chosen for this competitively selected, cost and schedule constrained, Principal Investigator-led opportunity is the CYclone Global Navigation Satellite System (CYGNSS).

As specified in the selecting Announcement of Opportunity, the Principal Investigator is held responsible for successfully achieving the science objectives of the selected mission and the management approach that he chooses to obtain those results has a significant amount of freedom as long as it meets the intent of key NASA guidance like NPR 7120.5 and 7123. CYGNSS is classified under NPR 7120.5E guidance as a Category 3 (low priority, low cost) mission and carries a Class D risk classification (low priority, high risk) per NPR 8705.4. As defined in the NPR guidance, Class D risk classification allows for a relatively broad range of implementation strategies. The management approach that will be utilized on CYGNSS is a streamlined implementation that starts with a higher risk tolerance posture at NASA and that philosophy flows all the way down to the individual part level. This paper will discuss details of the Class D management approach at Program and Project levels.

8866-11, Session 2

Tropospheric emissions: monitoring of pollution (TEMPO)

Kelly Chance, Xiong Liu, Raid M. Suleiman, Smithsonian Astrophysical Observatory (United States); David E. Flittner, Jassim A. Al-Saadi, NASA Langley Research Ctr. (United States); Scott J. Janz, NASA Goddard Space Flight Ctr. (United States)

TEMPO has been selected by NASA as the first Earth Venture Instrument. It will measure atmospheric pollution for greater North America from space using ultraviolet/visible spectroscopy. TEMPO measures from Mexico City to the Canadian tar/oil sands, and from the Atlantic to the Pacific, hourly and at high spatial resolution. TEMPO provides a tropospheric measurement suite that includes the key elements of tropospheric air pollution chemistry. Measurements are from geostationary (GEO) orbit, to capture the inherent high variability in the diurnal cycle of emissions and chemistry. The small product spatial footprint resolves pollution sources at sub-urban scale. Together, this temporal and spatial resolution improves emission inventories, monitors population exposure, and enables effective emission-control strategies.

TEMPO takes advantage of a GEO host spacecraft to provide a modest cost mission that measures the spectra required to retrieve O3, NO2, SO2, H2CO, C2H2O2, H2O, aerosols, cloud parameters, and UVB radiation. TEMPO thus measures the major elements, directly or by proxy, in the tropospheric O3 chemistry cycle. Multi-spectral observations provide sensitivity to O3 in the lowermost troposphere, reducing uncertainty in air quality predictions by 50%. TEMPO quantifies and tracks the evolution of aerosol loading. It provides near-real-time air quality products that will be made widely, publicly available.

TEMPO makes the first tropospheric trace gas measurements from GEO, by building on the heritage of five spectrometers flown in low-earth-orbit (LEO). These LEO instruments measure the needed spectra,

although at coarse spatial and temporal resolutions, to the precisions required for TEMPO and use retrieval algorithms developed for them by TEMPO Science Team members and currently running in operational environments. This makes TEMPO an innovative use of a well proven technique, able to produce a revolutionary data set.

TEMPO provides much of the atmospheric measurement capability recommended for GEO-CAPE in the 2007 National Research Council Decadal Survey, Earth Science and Applications from Space: National Imperatives for the Next Decade and Beyond. GEO-CAPE is not planned for implementation this decade. However, instruments from Europe (Sentinel 4) and Asia (GEMS) will form parts of a global GEO constellation for pollution monitoring later this decade, with a major focus on intercontinental pollution transport. TEMPO will launch at a prime time to be a component of this constellation.

8866-65, Session PMon

Impact of hyperspectral sensor spectral resolution and bandwidth on cross-comparison with broadband sensor for reflective solar bands

Aisheng Wu, Sigma Space Corp. (United States); Brian Wenny, Sigma Space Corp. (United States); Xiaoxiong Xiong, NASA Goddard Space Flight Ctr. (United States)

A new generation of hyperspectral imagers requires a much high absolute accuracy for reflected solar radiation measurements to better understand climate change. The Climate Absolute Radiance and Refractivity Observatory (CLARREO) mission, a future satellite mission led and developed by NASA and partner organizations, is currently considered to consist of two hyperspectral imagers that cover the reflected solar (RS) and infrared radiation. The design of the CLARREO instrument for the RS region operates from 320 to 2300 nm with 8 nm in spectral resolution and 4 nm in bandwidth. In this study, the sensitivity of various spectral resolution and bandwidths is tested for their impacts on integrated radiances using the relative spectral responses (RSR) of broadband sensors. Our hyperspectral data is based on MODTRAN simulations and SCIAMACHY observations and the RSR data is from those used in MODIS and VIIRS level 1B (L1B) product. The sensitivity is conducted for ocean, desert, snow and cloud. The differences among simulated radiances are examined and used to determine the spectral resolution and bandwidth of future CLARREO-type hyperspectral instrument.

8866-66, Session PMon

Vicarious calibration of S-NPP/VIIRS day-night band

Xi Shao, Univ. of Maryland, College Park (United States); Changyong Cao, National Oceanic and Atmospheric Administration (United States); Sirish Uprety, Colorado State Univ. (United States)

The Day Night Band (DNB) of the Visible Infrared Imaging Radiometer Suite (VIIRS) onboard the Suomi National Polar-orbiting Partnership (S-NPP) satellite launched in October 2011 represents a major advancement in night time imaging capabilities. The primary mission of the DNB is to provide imagery of clouds and other Earth features over illumination levels ranging from full sunlight to quarter moon. In order to cover this extremely broad measurement range, the DNB employs four imaging arrays that comprise three gain stages. The low gain stage (LGS) gain values are determined by solar diffuser data (aka the onboard calibration). The medium and high gain stages (MGS and HGS) cannot be calibrated directly because these gain stages saturate at solar diffuser illumination levels. In operation, the medium and high gain stage values are determined by multiplying the LGS gains by the MGS/LGS and HGS/LGS gain ratios, respectively. To independently verify the radiometric accuracy of HGS of DNB, we perform vicarious calibration of DNB when S-NPP flies above the vicarious site such as Dome C in Antarctic at night and the moon illuminates the site with lunar phase being more than half moon. Lunar spectral irradiance model as a function of Sun-Earth-Moon distances and lunar phase is used to assist the determination of top-of-atmosphere reflectance at vicarious site. The trending of vicariously-derived time series of reflectance is compared with the trending determined from other means such as observations of deep convective cloud and stable light sources.

8866-67, Session PMon

Assessment of the MODIS RSB detector differences using Earth-View targets

Amit Angal, Science Systems and Applications, Inc. (United States); Junqiang Sun, Xu Geng, I-Wen M. Chu, Sigma Space Corp. (United States); Xiaoxiong (Jack) Xiong, NASA Goddard Space Flight Ctr. (United States)

MODIS has 20 reflective solar bands (RSB) with a total of 330 individual detectors. Currently, there are two nearly identical MODIS instruments operating in space: one on the Terra spacecraft launched in December 1999 and another on the Aqua spacecraft launched in May 2002. MODIS reflective solar bands (RSB) are calibrated on-orbit by a system that consists of a solar diffuser (SD) and a solar diffuser stability monitor (SDSM). Near-monthly lunar observations are also used to track the sensor response versus scan angle (RVS) change on-orbit. On-orbit observations show that the changes in the detector response are wavelength, scan-angle and mirror side dependent. This paper provides a comprehensive assessment of the detector-detector calibration differences in the MODIS VIS/NISR spectral bands using the on-board calibrators and earth-view (EV) level 1B (L1B) data products. Different EV targets are analyzed to accommodate the high-gain ocean bands which tend to saturate over land surfaces. The results from this study highlight the necessity of the constant monitoring of the detector-level gain and its change as a function of scan-angle, as implemented in the MODIS Collection 6 (C6) products.

8866-68, Session PMon

The preliminary investigation of in-flight radiometric calibration plan of FORMOSAT-5 remote sensing instrument

Kuo-Hsien Hsu, National Space Organization (Taiwan); Hirokazu Yamamoto, National Institute of Advanced Industrial Science and Technology (Japan)

FORMOSAT-5 is the fourth satellite owned by National Space Organization (NSPO), National Applied Research Laboratory (NARL) of Taiwan. The primary payload of FORMOSAT-5 is a high-spatial-resolution (2meters) optical Remote Sensing Instrument (RSI). FORMOSAT-5 is currently scheduled to be launched in 2014. In the satellite Integration and Testing (I&T) phase, the first set of radiometric parameters of the RSI can be accurately measured in a well-controlled laboratory. However, these pre-flight radiometric parameters are inevitably calibrated on-orbit due to effects such as the outgassing phenomenon in the early stage, and on a longer scale by the radiations that effect both the optical transmission and sensor signal in darkness. Therefore, it is necessary to conduct the in-flight radiometric calibration regularly in order to compensate for this. This paper describes the preliminary investigation of in-flight radiometric calibration plan of the RSI onboard FORMOSAT-5, based on the reflectance- and radiance-based vicarious calibration as well as cross-calibration with other sensors.

8866-69, Session PMon

Energetic balance in the precise uniform light source based on optically connected integrating spheres

Leonid A. Mikheenko, Volodymyr N. Borovytsky, National Technical Univ. of Ukraine (Ukraine)

The paper presents the mathematical technique for calculation of the output radiance of the precise uniform light sources which have a form of several or multiple optically connected integrating spheres. The principal advantages of these light sources are high photometric and metrological characteristics. The light source contains several (3 … 11) primary integrating spheres of small diameters which are installed on a secondary integrating sphere of bigger diameter. The initial light sources – halogen lamps or light emitted diodes are installed inside the primary integrating spheres. These spheres are mounted on the secondary integrating sphere. The radiation comes from the primary integrating spheres to the secondary one through diaphragms which diameters can be varied. The secondary integrating sphere has an output aperture where uniform radiance emits. The proposed technique describes how to calculate the fluxes coming from the primary integrating spheres to the secondary one. It takes into account the fluxes multiple times coming from the secondary integrating sphere to the primary ones and again from the primary integrating spheres to the secondary one. This flux exchange introduces the additional part to the output radiance of up to 8 % that is very important for precise calibration. As a result the precise value of the output radiance can be obtained. The proposed light sources can be considered as one of the best candidates for calibration of remote sensing radiometers working in optical range 0.4 – 2.2 mkm.

8866-70, Session PMon

On-orbit spatial characterization of VIIRS using the Moon

Zhipeng Wang, Sigma Space Corp. (United States); Xiaoxiong Xiong, NASA Goddard Space Flight Ctr. (United States)

The moon is a very stable source for on-orbit calibration of the space-borne sensors with regular lunar observation capability, such as MODIS on-board the Terra and Aqua satellites and VIIRS on-board the Suomi NPP satellite. The spectral bands of both sensors are located on multiple focal plane assemblies (FPA) and spatially registered in both along-scan and along-track directions. Any mis-registration, or the band-to-band registration (BBR) shift, can deteriorate the quality of the science data products that are composed from multiple spectral bands. In this paper, the VIIRS spatial performance, mainly focusing on its BBR, is characterized using its lunar observations via an approach developed and modified from MODIS lunar BBR characterization. In this approach, the centroids of the lunar images of various bands are calculated and the BBR is determined from the differences of these centroids. Results show that on-orbit change of the BBR has been small for VIIRS VIS/NIR bands since its launch in Oct. 2011. Similarly to MODIS lunar spatial characterization, the centroids of lunar images of various detectors within a band can be used to study the detector-to-detector registration (DDR) shift. Since the detectors within a band are assembled in the along-track direction, the movement of the moon relative to the sensor, especially in the along-scan direction, during lunar calibration must be compensated to get reliable DDR results. Overall, results from this study demonstrate that the lunar approaches developed and applied to MODIS lunar spatial characterization can be effectively applied to VIIRS.

Trend analysis of the aerosol optical depth over china using fusion of MODIS and MISR aerosol products via adaptive weighted estimate algorithm

Jing Guo, Xingfa Gu, Tao Yu, Institute of Remote Sensing and Digital Earth (China); Tianhai Cheng, Institute of Remote Sensing Applications (China)

Atmospheric aerosol play an important role in the climate change, though direct and indirect processes [1]. To evaluate the effects of aerosols on climate it is necessary to estimate their spatial and temporal distributions [2]. Satellite aerosol remote sensing is a developing new technology that may provide good temporal sampling and superior spatial coverage to study aerosols. Since 2000, the Moderate Resolution Imaging Spectroradiometer (MODIS) and Multi-angle Imaging Spectroradiometer (MISR) have been providing global aerosol products [3]. However, the uncertainties still exist in current satellite aerosol products attributable to the complex surface, cloud contamination, and aerosol models used in the retrieving process [4]. Comparing to AERONET AOD, the larger magnitude and different variation tendency in AOD for both sensors indicate that either individual aerosol product may not be good application over China. Combing multiple sensors is a method to reduce uncertainties and improve observational accuracy. An adaptive weighted estimate algorithm of multi-sensor data fusion was presented, which could adjust the fused sensor's weight in time according to the variation in sensor's variance. The combined AOD product using the fusion method is in better agreement with corresponding AOD from AERONET than single sensor, which illustrate the fusion method performs better applicability in China. The fusion method can reduce uncertainties both sensors and expand the scope of the distribution in AOD. A method of evaluation was applied to detect the significance of the regional aerosol trends. Compared with trend analysis in MODIS and MISR, the combined result is improved by 8.2% and 4.5%, respectively, which is considered as significant with confidence level above 95%. Using the latest ten-year (2002-2011) fusion product, we study the trend analysis of the aerosol optical depth over typical regions in China. The insignificant trend is observed over the whole China. However, AOD regional long-term trends are evident. The increasing trend is found over Jingjintang and Yangtze River Delta, which are highly associated with human activities. The evaluation of trend shows trends are statistically significant with 95% confident level over Jingjintang and Yangtze River Delta.

8866-72, Session PMon

Alternative method for VIIRS Moon in space view process

Kwofu V. Chiang, Sigma Space Corp. (United States); Xiaoxiong Xiong, NASA Goddard Space Flight Ctr. (United States)

The Visible Infrared Imaging Radiometer Suite (VIIRS) onboard the Suomi National Polar-orbiting Partnership (S-NPP) spacecraft was successfully launched on October 28, 2011. Since its nadir aperture door opening on November 21, followed by cryo-cooler door opening on January 18, 2012, the VIIRS instrument has been acquiring the Earth images, both in reflective solar bands (RSB) and thermal emissive bands (TEB). The sensors are calibrated on-orbit by a solar diffuser (SD) and solar diffuser stability monitor (SDSM) system for the RSBs, and a blackbody (BB) for the TEBs. The SDR radiometric calibration is performed by subtracting the detector's space view (SV) dark background digital number (DN) from the Earth view (EV) DN scan by scan. Occasionally, the lunar intrusion into SV will corrupt the true background signals, causing contaminated data if not corrected. The current SDR operational code contains a complex algorithm, due to dual gains and two mirror sides, for background substitution when the Moon appears within the defined space view range. It substitutes SV data by BB view data for RSBs or uses SV data several scans away. The algorithm also leaves the TEBs un-calibrated because the SV data are flagged with fill value. This paper

proposes an alternative method, similar to the one used in MODIS L1B calibration. It utilizes part of the SV data which are useful and valid for background subtraction even when the Moon is in the SV. The SDR test for the code change will be performed and the results presented in the paper.

8866-73, Session PMon

Static concentrator tracking system

Jin-Jie Hsieh, Jong-Woei Allen Whang, National Taiwan Univ. of Science and Technology (Taiwan)

Since the position of the sun will change over time, the light collecting efficiency of the traditional passive concentrator can reach its maximum only in a specific period of time, but it may not be optimal at other time.

In this paper, we propose a Static Concentrator Tracking System. First, the system is to determine when the maximum light collection efficiency of Static Concentrator is. We install a small piece of solar panel on the bottom of the Static Concentrator to collect the light out from the bottom of Static Concentrator because of the reflection of sunlight, and to detect the current value of the transparent solar panels generated by photoelectric conversion through Zigbee to judge the efficiency of light collection. When the value of the current generated by the solar panels becomes higher, it represents Static Concentrator is missing out a lot of sunlight and the light collection efficiency is not high; vice versa.when we detect light collection efficiency is poor, the system searches for the location of the sun through a photo-detector, and Zigbee remote control the Mirror Array to adjust the angle of the sunlight. Static Concentrator is therefore able to achieve its maximum light collection efficiency.

The system has two merits, which is able to achieve maximum light collection efficiency at different times and the power generated by the solar panels can be used for other purposes (Ex: Zigbee power or Nighttime lighting needed).

Optical infrastructure for time and frequency transfer in the Czech Republic

Josef Vojtech, Vladimir Smotlacha, CESNET z.s.p.o. (Czech Republic)

In every country exists a time and frequency laboratory that operates a set of atomic clocks to provide national approximation of UTC time scale. Generally, higher number of these interconnected clocks (Caesium primary standards and Hydrogen masers) improves accuracy and stability of the time scale. The term "interconnection" in this context means that we transfer time scales between them despite of their location at geographically distant places – the common method is a dedicated two-way satellite link or a GPS based system, however utilization of fiber links constantly increases.

Experience with time transfer between Czech and Austrian national time and frequency laboratories, whose regular operation started in August 2011 and achieved better time stability compared with GPS based methods, lead us to design and build national infrastructure for time and frequency transfer – TF-infrastructure.

It will connect six institutes into a star and uses variety of means of transport:

-dark fibers for distances from 0.3km (0.2miles) to 16km (10miles)

-lambdas in single fiber bidirectional transmission system for distance of about 70km (43.5miles)

-lambdas in fiber pair transmission system for distance over 300km (186.5miles)

We achieved passive transmission over single fiber bidirectional system and will verify the stability. Near future plan is to improve time stability (in term of TDEV) in fiber pair transmission system.

8866-12, Session 3

Software engineering processes for class d missions

Ronnie Killough, Debi Rose, Southwest Research Institute (United States)

Software engineering processes are often seen as anathemas; thoughts of CMMI key process areas and NPR 7150.2a compliance matrices can motivate a software developer to consider other career fields. However with adequate definition, common-sense application, and an appropriate level of built-in flexibility, software engineering processes provide a critical framework in which to conduct a successful software development project. One problem is that current models seem to be built around an underlying assumption of "bigness", and assume that all elements of the process are applicable to all software projects regardless of size and tolerance for risk. This is best illustrated in NASA's NPR 7150.2a in which, aside from some special provisions for manned missions, the software processes are to be applied based solely on the criticality of the software to the mission, completely agnostic of the mission class itself. That is, the processes applicable to a Class A mission (high priority, very low risk tolerance, very high national significance) are precisely the same as those applicable to a Class D mission (low priority, high risk tolerance, low national significance). This paper will present real-world examples of efficient software practices, propose changes to NPR 7150.2a, taking mission class into consideration, and discuss how some of these changes are being piloted for a current Class D mission – NASA's 2011 Earth Venture Cyclone Global Navigation Satellite System (CYGNSS) mission.

8866-13, Session 3

Community satellite processing packages for real-time users

HungLung A. Huang, Univ. of Wisconsin-Madison (United States)

In cooperation with the NOAA Suomi NPP/JPSS program, CIMSS/SSEC continues to expand NASA funded International MODIS/AIRS Processing Package (IMAPP) effort, and to facilitate the use of polar orbiter satellite data through the development of a newly conceived Community Satellite Processing Package (CSPP) to support the Suomi NPP and JPSS, and subsequently build up over time, to support GOES-R and other international polar orbiting and geostationary meteorological and environmental satellites for the global direct broadcast user community.

This paper highlights more than 12 years of success of IMAPP, used by ~1,500 users in 70 countries, as a foundation to the continuing development of a freely available software package to transform raw data into products and various weather and environmental applications to support Suomi NPP and subsequently the JPSS missions under the CSPP framework. Summary will be given to report on the current software release and the early operational use of Sensor Data Record (SDR) and Environmental Data Record (EDR) of VIIRS, CrIS and ATMS in National Weather Service (NWS) field offices' daily operation and many other real time users around the world for their time critical applications. research.

8866-14, Session 3

Application study of principal component based physical retrieval algorithm for hyperspectral infrared sensors

Wan Wu, Science Systems and Applications, Inc. (United States); Xu Liu, NASA Langley Research Ctr. (United States); Hui Li, Science Systems and Applications, Inc. (United States); Daniel Zhou, Allen M. Larar, NASA Langley Research Ctr. (United States)

Hyper-spectral remote sensors such as Cross-track Infrared Sounder (CrIS), Atmospheric Infrared Sounder (AIRS), and Infrared Atmospheric Sounding Interferometer (IASI) use Fourier-transform spectrometers to make high resolution thermal emission measurements, providing two orders of magnitude more spectral channels as compared to traditional sounders. Data obtained from these thousands of channels contains rich information about atmospheric temperature, moisture, and trace gas vertical profiles, cloud properties, surface emissivity spectra, and surface skin temperature. To fully utilize information content contained in these high-spectral resolution spectra and meet the real-time data processing requirement, one has to develop fast spectral analysis and inversion algorithm. An ultra-fast principal component based physical retrieval algorithm has been developed at NASA Langley research center. Core part of the algorithm is the principal component based radiative transfer model (PCRTM) which enables a single forward calculation (with Jacobian output) to be done in the milli-second time frame. And the levenberg-marquardt method based inversion algorithm can use climatological background as the first guess and retrieve the geophysical parameters simultaneously. The PCRTM can also simulate the radiative contribution from clouds, given the location of the cloud height and cloud single scattering properties. Work are under way to maximize the application potential of the PCRTM algorithm in order to generate reliable products from hyper-spectral sensor data for climate studies. The algorithm has been tested using synthetic data for various infrared sensors. This paper describes in detail about retrieval sensitivity study carried out for several hyper-spectral infrared sensors using this physical algorithm. The retrieval accuracy obtained using the algorithm for the atmospheric parameters including trace gases of interests is discussed. Its dependence on the sensor system noise and spectral resolution is illustrated by comparing the retrieval performance achieved for different sensors. Practices used to optimize the retrieval system and compensate for the possible system errors will also be addressed.

8866-16, Session 3

Automated identification of voids in three-dimensional point clouds

Katie N. Salvaggio, Carl Salvaggio, Rochester Institute of Technology (United States)

In the construction of three-dimensional (3D) point clouds from multi-view aerial imagery, voids in the point cloud often exist where multiple views of the area were not obtained during collection. A method is presented for identifying these voids. In this work, point clouds are derived from oblique aerial imagery using multi-view techniques from the photogrammetry and computer vision communities. A voxel-based approach is used to partition the 3D space and each voxel is classified as containing or not containing derived points. Using the imagery and the position of the camera, it is possible to analyze what the cameras can and cannot see, thereby making it possible to label the voxels as occupied, free, and non-classified spaces. This method has been tested on high-frame-rate oblique aerial imagery captured over Rochester, NY as well as synthetic data sets. Also presented is a unique synthetic dataset for 3D reconstruction. The data set, created with the Rochester Institute of Technology's Digital Imaging and Remote Sensing Image Generation (DIRSIG) software, provides high-fidelity radiometric data in addition to known 3D locations and surface normals for each pixel location in an image scene. This data set will be made available to the community for use in their related research.

8866-17, Session 4

Intercalibration and concatenation of climate quality infrared cloudy radiances from multiple instruments

Ali Behrangi, Hartmut H. Aumann, Jet Propulsion Lab. (United States)

A change in climate is not likely captured from any single instrument since no instrument has spanned decades of time. Therefore, to detect signals of global climate change, observations from many instruments on different platforms have to be concatenated. This requires careful consideration of multi-instrument relative biases in the spectral brightness temperatures, footprint size, and diurnal cycle of observations. A common basic assumption is that the data quality is independent of the observed scene and therefore can be determined using clear scene data. However, as will be demonstrated, this is not necessarily a valid assumption as the globe is mostly cloudy. In this study we highlight challenges in inter-calibration and concatenation of infrared radiances from multiple instruments. We illustrate this for the evaluation of data quality and to inter-calibrate different instruments for various cloudy conditions using TRMM VIRS to make correction for observational differences in the local time and foot print sizes. In this study we focus on the analysis of deep convective clouds in AIRS and IASI data. However, the approach can be applied retroactively to vintage instruments such as IRIS, AVHRR, and HIRS.

8866-19, Session 4

Scene-based Cross-comparison of SNPP-VIIRS and Aqua-MODIS over Coastal/Oceanic Waters

Nima Pahlevan, Zhongping Lee, Univ. of Massachusetts Boston (United States)

The Visible Infrared Imaging Radiometer Suite (VIIRS) onboard the Suomi National Polar-orbiting Operational Environmental Satellite System (NPOESS) Preparatory Project (SNPP) was launched in October 2011 to continue monitoring the globe in a similar fashion as the heritage sensors, such as the MODerate resolution Imaging Spectroradiometer (MODIS). This paper applies a scene-based technique to examine in-orbit radiometric stability of VIIRS with reference to MODIS. The cross-comparison is made over bodies of waters ranging from clear oceans to coastal/inland waters. This cross-comparison allows for a comprehensive examination of the sensors' radiometric responsivity at low signal levels. The study is further extended for L2/L3 products, including remote sensing reflectance and inherent optical properties (IOPs) of waters under investigation, derived from the top-of-atmosphere (TOA) radiance (L1B). The temporal analyses give insights into the trends in the relative radiometric differences and the resulting discrepancies in the corresponding products.

8866-20, Session 4

An initial assessment of the VIIRS onboard calibration using DCC and desert referenced to the aqua-MODIS calibration

Rajendra Bhatt, Science Systems and Applications, Inc. (United States); David R. Doelling, NASA Langley Research Ctr. (United States); Benjamin R. Scarino, Arun Gopalan, Conor O. Haney, Science Systems and Applications, Inc. (United States)

The CERES observed EBAF 12-year TOA flux dataset are used to monitor the Earth's climate and in validating climate models. The associated cloud properties are retrieved from a fusion of MODIS and geostationary imagers. The quality of these cloud properties relies on the absolute calibration of these imagers. The geostationary imager radiances are calibrated against the Aqua-MODIS calibration reference in order to retrieve uniform cloud properties both spatially and temporally. Any calibration discontinuity or artifact may be interpreted as a climate trend. CERES record will be extended using CERES fluxes onboard NPP. CERES will need to tie the VIIRS with the Aqua-MODIS calibration in order to provide a seamless record of cloud and flux properties.

This paper will present initial assessment results for interconsistency between VIIRS and Aqua-MODIS calibration of matching visible channels. Empirically derived exoatmospheric VIIRS radiance models for deep convective clouds and desert invariant targets are used to assess the initial onboard calibration of VIIRS. The VIIRS models are based on characterizing these invariant targets with Aqua-MODIS as an absolute calibration reference. Correction for spectral band differences in the VIIRS and MODIS channels is performed using the SCIAMACHY hyperspectral data.

8866-21, Session 4

Inter-comparison between Suomi NPP VIIRS, aqua MODIS and NOAA-19 AVHRR using extended simultaneous nadir overpass in the low latitudes for consistent radiometric calibration

Sirish Uprety, National Oceanic and Atmospheric Administration (United States) and Colorado State Univ. (United States); Changyong Cao, National Oceanic and Atmospheric Administration (United States); Slawomir Blonski, Xi Shao, Univ. of Maryland, College Park (United States)

Suomi NPP VIIRS has been undergoing extensive calibration/validation efforts in order to produce high quality weather and climate related satellite data products. VIIRS absolute radiometric accuracy and consistency can be achieved by inter-comparing its measurements with other well calibrated instruments such as AQUA MODIS. This study uses simultaneous nadir overpass extended to low latitudes (SNO-x) for comparing VIIRS with MODIS at more uniform and stable sites such as deserts. VIIRS moderate bands compared with matching MODIS bands at North African desert reveals that the radiometric bias at desert for channels M-1 through M-8 is less than 2% after accounting for spectral differences. VIIRS is a follow on mission for MODIS and AVHRR. In an effort to establish radiometric consistency of VIIRS with multi-decadal global earth observations from AVHRR, this study uses SNO-x approach to inter-compare VNIR channels of NOAA-19 AVHRR measurements with VIIRS at desert. The inter-comparisons are performed at nadir and at off-nadir angles and the impact due to spectral differences are quantified using MODTRAN and hyperspectral measurements from EO-1 Hyperion.

8866-22, Session 4

Inter-comparison of METOP-A and METOP-B AVHRR and on-orbit calibration update

Tiejun Chang, ERT, Inc. (United States); Xiangqian Wu, Fuzhong Weng, National Oceanic and Atmospheric Administration (United States)

Meteorological Operational (METOP)-B spacecraft was launched on September 17, 2012, and the Advanced Very High Resolution Radiometer (AVHRR) visible and near-infrared channels were activated shortly after the launch. After on-orbit verification of the instrument performance, an important task is to update the visible and near-infrared channel calibration coefficients. Due to the lack of on-board calibrator, the post-launch calibration can only be carried out vicariously, and Libyan Desert has been used as reference since 1995.

The seasonal variation of Libyan Desert reflectance has been considered in the calibration, and, for early time of the post-launch, the seasonal variations are derived from previous AVHRR measurements. A new method has been developed using the MetOp-A and MetOp-B inter-comparison with consideration of the BRDF effect, and applied to the calibration update. Since these two satellites are in the same orbit with half orbit time (~50min) apart, it may be possible to use the inter-comparison of the AVHRR measurement on Libyan Desert between the instruments on board of them for MetOp-B calibration. However, the solar zenith angle and sensor zenith angle are not the same for the collocated measurements, and the Bidirectional Reflectance Distribution Function (BRDF) affects the comparison. The zenith angle dependent measurements have been modeled and the comparison of the reflectance with the same solar zenith angle and sensor zenith angle has been derived. The calibrations from these two methods are consistent and the updates are ready for the delivery. This work is also useful to investigate BRDF effect on the inter-comparison.

8866-23, Session 5

Ground viewing radiometer characterization, implementation and calibration applications: a summary after two years of field deployment

Nikolaus J. Anderson, Jeffrey Czapla-Myers, College of Optical Sciences, The Univ. of Arizona (United States)

In 2011, three improved ground-viewing radiometers (GVRs) were built and deployed to support the Radiometric Calibration Test Site (RadCaTS) developed by the Remote Sensing Group (RSG) at the University of Arizona. The GVRs are filter-based radiometers with eight spectral channels covering a wavelength range of 400-1550 nm. They are automated, field-deployable instruments capable of long-term, standalone operation. The radiometers are temperature-controlled and designed for greater stability and lower noise.

This work describes the deployment period of these radiometers with particular attention paid to the in-field performance, reliability, and results from these instruments. Using other RadCaTS inputs including meterological station data and Aerosol Robotic Network (AERONET) Cimel sun photometer data, select vicarious calibration results are presented. With these results, an assessment of the calibration applications of the RadCaTS during new GVR deployment is discussed. In addition, GVR calibration and characterization results, including solar radiation based calibration (SRBC), are presented as another means of assessing the performance of the radiometers over deployment periods.

8866-26, Session 5

Monitoring NPP VIIRS On-Orbit Radiometric Performance from TOA Reflectance Time Series

Aisheng Wu, Sigma Space Corp. (United States); Xiaoxiong Xiong, NASA Goddard Space Flight Ctr. (United States); Changyong Cao, National Oceanic and Atmospheric Administration (United States)

The recently launched (October 28, 2011) Suomi NPP (National Polar-orbiting Partnership) satellite (http://npp.gsfc.nasa.gov/viirs.html) has been operating nominally to daily collect global data. The Visible Infrared Imaging Radiometer Suite (VIIRS) is a key NPP sensor, similar to the heritage sensor MODIS. VIIRS has on-board calibration components including a solar diffuser (SD) and a solar diffuser stability monitor (SDSM) for the reflective solar bands (RSB), a V-groove blackbody for the thermal emissive bands (TEB), and a space view (SV) port for background subtraction. This study examines VIIRS RSB calibration stability and performance using observed top-of-atmosphere (TOA) reflectance time series collected from two approaches. The first is from comparison with a well-calibrated Aqua MODIS and the second is from overpasses over the widely used Liby-4 desert site. The VIIRS and MODIS comparison data is obtained from simultaneous nadir overpasses (SNO) for their spectrally matched bands. The impact due to the band spectral differences between the two instruments is corrected based on MODTRAN5 simulations. The reflectance trends over the Libya-4 site are extracted from 16-day repeatable orbits so each data point has the same viewing geometry relative to the site. Results of this study provide useful information on NPP VIIRS post-launch calibration assessment and preliminary analysis of its calibration stability and consistency for the first 1.5 years.

8866-27, Session 5

Vicarious calibration of Suomi NPP VIIRS day-night band

Joel McCorkel, NASA Goddard Space Flight Ctr. (United States)

The Suomi National Polar-orbiting Partership (NPP) Visible Infrared Imaging Radiometer Suite (VIIRS) is a moderate resolution radiometer that acquires a full earth image every day in 22 spectral channels in the visible to thermal infrared. One of these channels is panchromatic across the solar reflective and called the Day-Night Band (DNB). The DNB has three gain regions and radiometric resolution to provide sensitivity in over seven decades required for imaging the range of dimly illuminated earth-night scenes to typical solar-illuminated scenes. Performance of the DNB since the launch of NPP in October 2011 is excellent having shown capability of detecting the illumination from airglow and starlight. Significant effort went into understanding and characterizing the radiometric calibration of all VIIRS channels pre- and post-launch. This paper provides vicarious calibration results for the DNB to complement these efforts with an independent approach. This work will use imagery of desert sites gathered with sensors with well-known radiometric calibration in combination with lunar and solar databases to provide an absolute radiometric characterization for the VIIRS DNB.

8866-28, Session 5

Early ground-based vicarious calibration results for Landsat 8 OLI

Jeffrey Czapla-Myers, Nikolaus J. Anderson, Stuart F. Biggar, College of Optical Sciences, The Univ. of Arizona (United States)

The Operational Land Imager (OLI) is one of two instruments onboard the Landsat 8 platform, which was launched in February 2013 from Vandenberg Air Force Base in California. The multispectral bands of OLI retain the 30-m spatial resolution of Landsat 5 TM and Landsat 7 ETM+, but improvements to the system include 12-bit radiometric resolution, and nine bands in the VNIR and SWIR spectral regions. The earlier TM and ETM+ sensors use a whiskbroom configuration, while OLI uses a pushbroom configuration, which allows it to have a much larger signal-to-noise ratio than previous Landsat instruments. This also creates challenges in radiometric calibration due to the large number of detectors on the focal plane.

Long-term data continuity is a crucial component of the 40-year Landsat series of satellites, and ground-based vicarious calibration has played an important role in ensuring that these sensors remain on the same radiometric scale. This work presents the early ground-based in-flight radiometric calibration of OLI, which was determined using the traditional and well-understood reflectance-based approach, as well as the Radiometric Calibration Test Site (RadCaTS), which is an automated suite of instruments located in central Nevada.

8866-29, Session 6

Calibration status of the atmospheric infrared sounder after eleven years of operation

Denis A Elliott, Jet Propulsion Lab. (United States); Margie Weiler, ATK Aerospace Systems (United States); Evan M Manning, Jet Propulsion Lab (United States); Thomas S. Pagano, Steven E. Broberg, Hartmut H. Aumann, Jet Propulsion Lab. (United States)

The Atmospheric Infrared Sounder (AIRS) is a grating array infrared hyperspectral sounder with 2378 channels from 3.75 to 15.4 microns with spectral resolution 1200 to 1400 depending on the channel. AIRS was designed as an aid to weather prediction and for atmospheric process studies. It produces profiles of atmospheric temperature and water vapor. Because of its spectral coverage and spectral resolution it is sensitive to a number of trace atmospheric constituents including CO_2, CO, SO_2, O_3, and CH_4. The AIRS sensitivity, stability, and long life have led to its use in climate process studies and climate model validation, both of which place far more stringent requirements on calibration than weather forecasting does. This paper describes results from several special calibration sequences, originally developed for pre-launch testing, that have been used in the last year to monitor the AIRS calibration accuracy, including the handling of instrument polarization, space view response, and channel health.

8866-30, Session 6

Lessons learned from the AIRS pre-flight radiometric calibration

Thomas S. Pagano, Hartmut H. Aumann, Jet Propulsion Lab. (United States); Margie Weiler, ATK Aerospace Systems (United States); Kenneth R. Overoye, BAE Systems (United States)

NASA's Atmospheric Infrared Sounder (AIRS) is a hyperspectral infrared instrument that covers the infrared spectrum from 3.7-15.4 um with 2378 channels and flies on the EOS Aqua spacecraft. AIRS has demonstrated exceptional radiometric accuracy to better than 0.1K for module averages at scene temperatures of 265K (Pagano, SPIE 2008). Several channels and band edges do not perform as well, primarily due to vignetting within the system or polarization effects. While the performance of AIRS is exceptional, small errors in the calibration result particularly at cold scene temperatures from errors in the knowledge of scan mirror polarization. Two methods are explored to improve the calibration of AIRS in the infrared that are applicable to other instruments. The first method uses the intercept of the fit to the linearity test to determine the polarization terms, while the second inverts the calibration equation to improve handling of second order effects of polarization in the calibration. These methods could be applied to other infrared instruments with mirror polarization effects.

8866-31, Session 6

Space view issues for hyperspectral sounders

Evan M. Manning, Hartmut H. Aumann, Jet Propulsion Lab. (United States)

The expectation from hyperspectral sounders is absolute calibration accuracy at the 50 mK level and stability at the < 5 mK/yr level. The AIRS, CrIS, and IASI hyperspectral sounders currently in orbit have been shown to agree well over most of their brightness temperature range. Some larger discrepancies are seen, however, at the coldest scene temperatures, such as those seen in Antarctic winter and deep convective clouds. A key contributor to the calibrated scene radiance uncertainty for cold scenes is the assumption that the effective radiance of the cold space view pertains to the scene views. The spaceview signal is actually the sum of external sources, the instrument thermal emission, the scan mirror, and associated external baffles, all at the spacecraft ambient temperature of about 270 K. Any difference in any of these contributions between spaceviews and scene views will impact the absolute calibration accuracy, especially for cold scenes. Any change over time in these will show up as an apparent trend in calibrated radiances. We use AIRS data to investigate the validity of the spaceview assumption in view of the 50 mK accuracy and 5 mK/yr trend expectations.

8866-32, Session 6

Results from CrIS/ATMS using the AIRS Science Team retrieval methodology

Joel Susskind, NASA Goddard Space Flight Ctr. (United States)

The NPP mission was launched in October 2011 as part of a sequence of Low Earth Orbiting satellite missions under the "Joint Polar Satellite

System" (JPSS). The future JPSS missions, J1 and J2, are currently scheduled for November 2016 and November 2021 launches. The J1 mission will be very similar to NPP, using the same spacecraft and instrument complement. NPP carries CrIS and ATMS, which are advanced infra-red and microwave atmospheric sounders that were designed as follow-ons to the AIRS and AMSU instruments flying on EOS Aqua. We have been conducting research to optimize products derived from CrIS/ATMS observations using a scientific approach analogous to that used by the AIRS Science Team. Results will be shown comparing the quality and spatial coverage of GSFC CrIS/ATMS sounding products to those of NOAA-derived CrIS/ATMS products, as well as those of AIRS/AMSU products derived using the currently operational AIRS Science Team Version-6 retrieval algorithm. The main objective of this work, from the NASA perspective, is to assess whether CrIS/ATMS is an adequate replacement for AIRS/AMSU from the perspective of the generation of long term Climate Data Records, or if improved instruments should be developed for flight on J2.

8866-33, Session 6

Detection of extremes with AIRS, IASI, and CRIS

Hartmut H. Aumann, Jet Propulsion Lab. (United States)

Climate change is expected to be detected first as changes in extreme values rather than in mean values. Since AIRS, IASI and CRIS are producing data at the same time, we can determine if there are significant differences in extreme values. For the analysis of extreme values we analyze the Probability Density Functions (PDF) of the brightness temperatures in the 900 cm-1 atmospheric window channels created from about 2 million spectra collected between April and December 2012 in the tropical oceans. The mean brightness temperatures from the three instruments, 283.6K, agree within 10 mK. This excellent agreement confirms conclusions from tests under more restricted conditions, that on average the calibration of the three instruments is excellent. However, IASI and CRIS both find significantly more extremely hot cases than AIRS. For example the 99.9% of the PDF for IASI is 1.2 K warmer than for AIRS, for CRIS it is 2.4K warmer than for AIRS. Experiments with data quality filters available from the CRIS L1b imaginary component of the radiances confirm that this is an artifact of the CRIS calibration. Similar diagnostic information is not available from the IASI L1c data. Future releases of re-processed CRIS and IASI data may mitigate these effects. As is, we conclude that significant difference in extreme values can be found in the three instruments. If the data from AIRS, IASI and CRIS were interpreted as samples from three different instruments representative of future time periods separated by decades, the observed differences in the extreme value could be misinterpreted as evidence of changes in frequency of extreme cases due to climate change.

8866-34, Session 7

MERIS calibrations: 10 years

Steven Delwart, European Space Agency (Italy); Ludovic Bourg, ACRI-ST (France)

The calibration results from the MEdium Resolution Imaging Spectrometer (MERIS) on board the ENVISAT satellite over its ten years of operation of will be presented.

These will include radiometric and spectral calibration results using the on-board diffusers as well as radiometric validation results from a number of vicarious calibration methods.

8866-35, Session 7

Pleiades-HR 1A&1B image quality commissioning: innovative radiometric calibration methods and results

Vincent Martin, Gwendoline Blanchet, Philippe Kubik, Sophie Lacherade, Christophe Latry, Laurent Lebegue, Florie Lenoir, Florence Porez-Nadal, Ctr. National d'Études Spatiales (France)

PLEIADES is an earth observing system conducted by the French National Space Agency, CNES. It consists of two satellites launched on December 2011 (PHR-1A) and December 2012 (PHR-1B), both designed to provide to civilian and defence users optical push-broom imagery on five spectral bands, with ground sample distance up to 70 cm. During in-flight image quality commissioning, radiometric activities included inter-detector normalization coefficients computation, refocusing operations, MTF assessment and estimation of signal to noise ratios. This paper presents in-flight results for both satellites. It focuses on several innovative methods that were implemented, taking advantage of the satellite platform great agility. These methods are based on processing images obtained through dedicated exotic guidance. In particular, slow-motion steering enables an efficient estimation of the instrumental noise model, since during acquisition each detector has been viewing a stable ground target along different time samples. Conversely, rotated retina guidance is used to guarantee that all different elementary detectors have successively viewed the same set of landscape samples during acquisition. Non-uniformity of detector sensitivities can then be characterized, and on-board coefficients used prior to compression can be calibrated in order to prevent vertical striping effects on operational images. Defocus control and Point Spread Function estimation can be easily obtained through processing acquisitions of stars associated to various spectral characteristics, for different adjustments of the refocusing system. All these methods allow an accurate estimation of radiometric performance on the whole range of specified spectral radiances, while drastically reducing the number of required acquisitions on natural targets.

8866-36, Session 7

Pleiades satellites image quality commissioning

Laurent Lebegue, Daniel Greslou, Gwendoline Blanchet, Christophe Latry, Vincent Martin, Francoise de Lussy, Sébastien Fourest, Ctr. National d'Études Spatiales (France); Sophie Lacherade, Ctr National d'Études Spatiales (France); Jean Marc Delvit, Cecile Dechoz, Virginie Amberg, Florence Porez-Nadal, Florie Lenoir, Philippe Kubik, Ctr. National d'Études Spatiales (France)

PLEIADES is the highest resolution civilian earth observing system ever developed in Europe. This imagery program is conducted by the French National Space Agency, CNES. The first satellite has been launched December 17th 2011, and the second one December 2nd 2012. Each satellite is designed to provide optical images to civilian and defense users. Images are simultaneously acquired in Panchromatic (PA) and multi-spectral (XS) mode, which allows, in nadir acquisition condition, to deliver 20 km wide, false or natural colored scenes with a 70 cm ground sampling distance after PA+XS fusion. Coverage is almost world-wide with a revisit interval of 24 h for the 2 satellites.

The assessment of the image quality and the calibration operation has been performed by CNES Image Quality team during the 6 month commissioning phases that followed each satellite launch. These activities cover many topics such as absolute calibration, the normalization coefficients computation, the refocusing operations, the MTF assessment, the estimation of signal to noise ratio, the geometric model calibration, the assessment of localization accuracy, multi-spectral overlapping, static and dynamic stability, planimetric and altimetric accuracy. These operations required specific control of the payload and dedicated guidance of the satellite platform. The new capabilities offered

by PLEIADES satellites agility allowed to imagine new methods of image calibration and performances assessment.

Starting from an overview of the satellite and instrument characteristics, this paper present all the calibration operations that were conducted during the commissioning phases and also give the main results for every image quality performance.

8866-37, Session 7

Pleiades-HR 1A&1B image quality commissioning: innovative geometric calibration methods and results

Daniel Greslou, Francoise de Lussy, Virginie Amberg, Cecile Dechoz, Jean Marc Delvit, Laurent Lebegue, Ctr. National d'Études Spatiales (France)

PLEIADES is an earth observing system conducted by the French National Space Agency, CNES. It consists of two satellites launched on December 2011 (PHR-1A) and December 2012 (PHR-1B). The system has been designed to provide to civilian and defense users 20 km wide Earth images , on five spectral bands, with ground sample distance up to 70 cm. This constellation allows an almost world-wide coverage with a revisit interval of less than 24 h.

The assessment of the image quality and the calibration operation of the two satellites have been performed by CNES Image Quality team during the called commissioning phase that follows the satellite launch.

The geometric commissioning activities consist in asses and improve the geometric quality of the images in order to meet very demanding specifications as localization accuracy, local coherence, dynamic stability, lengths alteration… This goal has been achieved in particular through the implementation of new methods of calibration and performance assessment. Some of these methods are based on the exploitation of very specific satellite acquisitions that have been achieved thanks to the amazing agility of the Pleiades satellite. Thus, many stars acquisitions and very slow earth pictures have been processed to characterize dynamic phenomena. Similarly, "along-cross track" pairs have been exploited to improve the accuracy of the focal plane description.

This paper deals with these new methods; it describes their accuracy and their operational interest. It concludes with an overview of the main geometric results and performances reached on each satellite.

8866-38, Session 7

In-flight attitude perturbances estimation: application to Pleiades-HR satellites

Virginie Amberg, Cecile Dechoz, Ctr. National d'Études Spatiales (France); Laurent Bernard, Magellium (France); Laurent Lebegue, Francoise de Lussy, Daniel Greslou, Ctr. National d'Études Spatiales (France)

This paper deals with the problem of retrieving attitude perturbances in the framework of in-flight high resolution optical satellites. The objective is to estimate high frequency perturbances, ranging above the gyros cutoff frequency, that could corrupt the image. During the in-flight commissioning period of PLEIADES-HR satellite, this analysis was necessary to choose the optimal rotation speed of gyroscopic actuators in the mean of geometrical image quality. In this context, two methods have been tested and compared. The first one uses the high agility capacity of PLEIADES-HR satellites to acquire stars in an inertial steering mode. The resulting image permits to access directly to the attitude perturbance. The second method exploits the design of the PLEIADES-HR instrument: multi-spectral bands are shifted in the telescope focal plane in the velocity direction. Therefore, acquisitions are not simultaneous in the different spectral bands which means that, for a same ground point, images are not affected by the same attitude perturbance. Thus there are misregistrations between images that can be measured by correlation techniques in order to deduce the platform attitude during the acquisition. Finally, for both methods, perturbation frequencies are estimated thanks to spectral analysis and results are compared.

The first method allows to estimate the attitude perturbances with a high precision in the roll direction. Whereas the second method is less accurate because of correlation process but allows to access to attitude perturbances in both roll and pitch directions. In conclusion, the two methods are complementary.

8866-39, Session 7

METOP-B, the second satellite of the EUMETSAT polar system, in orbit

K. Dieter Klaes, Francois Montagner, European Organisation for the Exploitation of Meteorological Satellites (Germany); Carole Larigauderie, Centre National d'Etudes Spatiales (France)

The EUMETSAT Polar System is EUMETSAT's contribution to the Global Observing System in the polar sun-synchronous orbit and serves, in the frame of the Initial Joint Polar System (IJPS) with the United States, the mid-morning orbit. The space segment is composed of the Metop satellites, of which Metop-A is in orbit since 2006, providing a wealth of Earth Observation data, amongst them data for Atmospheric Sounding, cloud and surface monitoring, ocean observation, including ocean winds, atmospheric composition monitoring. The launch of Metop-B on the 17 September 2012 into the same mid-morning orbit (9:30 LST equator crossing time, descending node, phased 48 min. apart from Metop-A) at 820 km assures the continuity of the system. A third Metop satellite (Metop-C), scheduled for launch early 2018, will assure a mission duration of at least 15 years. This paper will discuss the status of the EUMETSAT Polar System (EPS) and in particular present the results from Metop-B commissioning and the actual status of products. Metop-B will be out of its commissioning at the time of the conference and is planned provide its service together with Metop-A, which is healthy and is planned continue its successful service.

8866-40, Session 8

Characterization of a radiometric monitoring system for NASA code 618's SIRCUS-G

Leibo Ding, John W. Cooper, Aboubakar Traore, Gilbert R. Smith, Sigma Space Corp. (United States); James Butler, NASA Goddard Space Flight Ctr. (United States)

A tunable, intensity-stabilized, quasi-continuous wave (CW) laser system, patterned after the Spectral Irradiance and Radiance Responsivity Calibrations using Uniform Sources (SIRCUS) system at the National Institute of Standards and technology (NIST), has been installed and tested in the NASA Goddard Space Flight Center (GSFC) Code 618 Biospheric Sciences Laboratory's Calibration Facility. This system is referred to as SIRCUS-G (SIRCUS-Goddard). The tunable output of the laser system is fiber fed to a 76.2 cm diameter integrating sphere lined with Spectralon. The uniform radiance light emitted from the integrating sphere is used in system-level radiometric responsivity characterizations and wavelength calibrations of remote sensing instruments. The primary radiance reference standard in the responsivity characterizations is a three-element trap detector calibrated by NIST. This detector is located at the exit port of the Spectralon coated integrating sphere. In addition, a set of detectors are mounted on integrating sphere wall ports to monitor source radiance and to provide real-time sphere radiance data during the calibrations of remote sensing instruments. These monitor detectors provide spectral coverage from 300nm to near 2500nm. This paper presents the results of our characterization of the performance of these monitor detectors. Results are presented and discussed on monitor detector short- and long-term system stability, noise level, and total measurement uncertainty.

8866-41, Session 8

The NIST robotic optical scatter instrument (ROSI) and its application to BRDF measurements of diffuse reflectance standards for remote sensing

Heather J. Patrick, National Institute of Standards and Technology (United States); Clarence J. Zarobila, Jung Research and Development Corp. (United States) and National Institute of Standards and Technology (United States); Thomas A. Germer, National Institute of Standards and Technology (United States)

The Sensor Science Division of the National Institute of Standards and Technology (NIST) is in the process of expanding its facilities for reference measurements of diffuse and specular reflectance of materials, including measurements of bidirectional reflectance distribution factor (BRDF) of diffuse reflectance standards that provide traceability for diffuser plaques used as onboard calibration standards in remote sensing. Currently, BRDF of spectrally neutral diffuse samples is measured in the NIST STARR facility. STARR provides wavelength-resolved BRDF measurements from the ultraviolet to the short-wave infrared (approximately 250 nm – 2500 nm), for a limited range of in-plane incident and scattering angle geometries. However, remote sensing systems often use diffusers in out-of-plane configurations, where the viewing angle is rotated from the incident plane formed by the light source incident angle and the normal to the sample. In order to be able to replicate these out-of-plane measurement geometries, NIST recently took delivery of a robotic-arm based goniometer system, nicknamed “ROSI”, that will enable BRDF measurements to be made at nearly any combination of incident and scattering angles.

In this presentation, we will describe the new robotic goniometer and its use for in-plane and out-of-plane reflectance measurements. We will discuss techniques for verifying and establishing the accuracy of out-of-plane angular motions, methods to compensate for sample thickness and wedge, and the projected range of incident and scattering angles that will be accessible to ROSI. We also plan to show measurements of in-plane and out-of-plane BRDF for nominally Lambertian diffuse reflectors.

8866-42, Session 8

Potential use of two ultraviolent bands sensor on the HY-1C/D satellites

Zhihua Mao, The Second Institute of Oceanography, SOA (China)

China has launched two ocean color satellites and plan to launch the next two satellites HY-1C/D in 2015. HY-1C/D are the two same satellites running together with HY-1C at 10:30 AM and HY-1D at 1:30 PM, to improve the frequency of data coverage. Two sensors of the China Ocean Color and Temperature Sensor (COCTS) and Coastal Zone Imager (CZI) will still be installed on HY-1C/D. A new sensor with two ultraviolent (UV) bands for ocean environmental monitoring will also be installed on the satellites. One important potential use of the UV bands is for the development of a new algorithm of the atmospheric correction for turbid coastal waters. As well known, the standard atmospheric correction method based on the two near-infrared (NIR) bands fails for the turbid waters because the reflectance at NIR bands is much larger than zeros. We found that the reflectance at UV bands is close to zeros from in situ measurements. Therefore, the reflectance at UV bands can be used for a new atmospheric correction algorithm. The new algorithm is validated by simulation data, MODIS and GOCI data. The results show that the accuracy of the atmospheric correction has been improved for turbid waters. This algorithm is a potential method for the atmospheric correction of HY-1C/D data.

8866-43, Session 8

A new airborne Ka-band double-antenna microwave radiometer for cloud liquid water content measurement

Jian Sun, Jilin Univ. (China) and Northeast Institute of Geography and Agroecology (China); Kai Zhao, Tao Jiang, Northeast Institute of Geography and Agroecology (China)

A new type upward-looking airborne double-antenna microwave radiometer (ADAMR) system intended for detecting atmospheric cloud liquid water content (LWC) is developed in this paper. The frequency of this radiometer is 31.65 GHz. For the antenna elevation angle, one is and the other is . In order to detect the signals with low effective noise temperature (<10K) from the LWC, the noise coupling technique is used. Through injecting constant equal noise signal into the two antenna ports respectively, the technique can elevate the small input noise signal power to the detectable range of the square-law detector and thus realize the weak signal detection. Moreover, in order to eliminate the impacts of the system gain fluctuations and obtain a higher sensitivity, an auto-gain compensation method based on the analog-to-digital converter, microcontroller and host computer software techniques is also proposed. Compared with the traditional radiometers, the radiometer topology is greatly simplified and the gain fluctuations can be readily real-time compensated using the compensation method. The laboratory test results show that radiometric sensitivity is better than 0.2 K for 300ms integration time and the instrument is conforming to specifications. Finally, the flight observation experiment results are presented to prove that the designed instrument is able to detect small changes of noise signal in a wide effective range of noise temperature (10-350K) and is a powerful tool for LWC measurement.

8866-101, PL Session

The geostationary remote infrared pollution sounder: measurement of the carbon gases from space

Mark Schoeberl, Hal J. Bloom, Ryan Spackman, Science and Technology Corp. (United States); Chad S. Fish, Space Dynamics Lab., Utah State Univ. Research Foundation (United States); Martin J. McHugh, Larry L. Gordley, GATS, Inc. (United States)

We describe an instrument for the measurement of carbon gases and its earth remote sensing capabilities from geostationary orbit. Carbon gases CO, CH4, and CO2 are key components of climate change and air quality. CO, with the shortest lifetime, is produced by fires and industrial processes. It plays a role in ozone formation and is a surrogate for black carbon aerosols and smoke. CH4 is a powerful greenhouse gas produced by biogenic process, leaks from pipelines and extraction complexes, and fires. CH4 sources and sinks are highly uncertain. CO2 is also a powerful greenhouse gas, but despite years of study, its sinks are still uncertain. Using the combination of these gases, we can fingerprint sources of pollution. Our instrument concept, the Geostationary Remote Infrared Pollution Sounder (GRIPS), will provide rapid temporal and high spatial resolution measurements of these carbon gases from space. The instrument is designed to quantify the concentration, sources, and fluxes of these gases over the extra-polar regions from geostationary orbit. One advantage of the geostationary orbit is that more measurements in cloud-free regions can be made in a few days than can be made in several weeks of low earth orbit measurements. A second advantage is that we can resolve the diurnal component of the gas concentration. This allows better tracking of plumes and identification of sources. Unlike the thermal infrared sensors on AIRS, MOPITT, and IASI, GRIPS uses the near- and short-wave infrared to make measurements in the boundary layer, where the sources and sinks are active.

8866-45, Session 9

Critical CCD and CMOS image sensor technology development and ESA space qualification approach in support ESA Earth observation and science missions

Mustapha Zahir, European Space Research and Technology Ctr. (Netherlands)

Image sensors such as CCDs and CMOS detectors are at the core of most ESA space missions, and in many cases form the basis for the only or the main instrument payload. Although high performance scientific applications are based on CCDs, CMOS image sensors are gaining popularity as a replacement for CCDs, as the technology improves in QE and noise performances. Image sensors, both CCD and CMOS, development are an important strategic elements of the ESA Earth Observation as well as science Programmes, as they are enabling technologies for many space missions.

In this paper, we will provide an overview of ESA development road map for Image sensors technology. We will address, current and future development and qualification programs. ESA and industrial partners are undertaking many development programs to fulfil earth observation and science missions requirements, such as GAIA, Euclid, MTG, GMES.

The paper will also provide ESA approach in space evaluation and qualification of image sensors, based on the international ESCC standards. Currently the ESCC 9020 is the main generic specification addressing CCDs and CMOS image sensors, with plans for developing similar standard for IR detector. Standards for Test methods for CCDs has already been developed while similar standards for CMOS and IR detectors are being developed. The difference between project qualification and ESCC qualification will be explained and lessons learned will be shared.

8866-46, Session 9

A remote sensing optical design for the OpenOrbiter CubeSat

Nicholas Long, Rachael Roberts, Dillon Hasselmann, Atif Mohammad, Jeremy Straub, Joshua Berk, Noah Root, The Univ. of North Dakota (United States)

OpenOrbiter is a 1-U form-factor CubeSat-class spacecraft with a remote sensing payload being developed at the University of North Dakota. It is designed to validate the performance of the Open Prototype for Educational NanoSats (OPEN) framework, which seeks to reduce the cost of small spacecraft development.

This paper presents the OpenOrbiter optical system and evaluates it for use for Earth remote sensing applications. System limitations include the small optical aperture size, the movement of the satellite with respect the ground and atmospheric blurring. The spacecraft size dictates that the optical system fit within a 5 cm x 5 cm x 5 cm compartment within the overall CubeSat size of 10 cm x 10 cm x 11 cm.

The small aperture size means that it will be possible to obtain a maximum spatial resolution of about 150 m, based on a prospective 300 km low-Earth orbit. The satellite's orbital velocity of approximately 7.5 to 8 km/s will cause motion blur during image capture. Light scattering from the atmosphere will further degrade image quality. A constant blurring effect is presumed, for the purposes of resolution specification, based on the assumption that the camera is pointing at nadir. Optical defects will further limit the resolution of the image. Onboard post processing includes mosaicking and super resolution. Thumbnail versions of images are sent to controllers for selection of what images to download over the limited communications bandwidth available. The possibility of various remote-sensing applications is considered, based on all of the aforementioned optical limitations.

8866-47, Session 9

MTG FCI optical design and performances

Julien Ouaknine, Sophie Gode, Bruno Napierala, Thierry Viard, Thales Alenia Space (France); Ute Foerster, Sebastian Fray, Patrick Peacoke, Michael Hartl, Kayser-Threde GmbH (Germany); Pascal Hallibert, European Space Research and Technology Ctr. (Netherlands); Yannig Durand, European Space Agency (Netherlands)

Meteosat Third Generation is the next ESA Program of Earth Observation Satellites dedicated to Weather Forecast from the Geostationary orbit, using a 3 axis stabilized platform. The main payload is called the Flexible Combined Imager, currently under development by Thales Alenia Space.

This instrument will provide full images of the Earth every 10 minutes in 16 spectral channels between 0.44 and 13.3 µm, with a ground resolution ranging from 0.5 km to 2 km.

The FCI is composed of a TMA telescope developed by Kayser-Threde, which includes a Scan mirror enabling to image the Earth, as well as a calibration mechanism with an embedded black body dedicated to accurate in-flight radiometric calibration. The intermediate image produced by the telescope is then split into several spectral groups by a spectral separation assembly with dichroïc beamsplitters. The output beams are collimated to ease the instrument integration, and reach the cold optics which focalize the optical beams onto the detectors. The cold optics and IR detectors are accurately positioned inside a common cryostat to improve coregistration between spectral channels. Spectral filters are integrated on top of the detectors in order to achieve the required spectral selection.

This article will describe the optical design and the main optical performances of the FCI : a good image quality, a very high line-of-sight stability, and an efficient rejection of stray-light thanks to implementation of dedicated baffles and a stringent control of contamination.

The FCI currently under development, is expected to exhibit a significant improvement of performances with respect to Meteosat Second Generation satellites.

8866-48, Session 10

Landsat data continuity mission (LDCM): six months on-orbit

Brian L. Markham, James R. Irons, NASA Goddard Space Flight Ctr. (United States)

The Landsat Data Continuity Mission (LDCM) was launched on February 11, 2013. LDCM is a joint mission between NASA and the United States Geological Survey (USGS). About 3 months after launch the LDCM lead role will transition to the USGS and the mission will be renamed Landsat-8. This presentation will give an update on the mission as of the date of the conference. Other papers have been submitted that will provide more details about the two instruments on LDCM: The Operational Land Imager (OLI) and the Thermal Infrared Sensor (TIRS).

8866-49, Session 10

Early radiometric performance assessment of the Landsat-8 operational land imager (OLI)

Julia A. Barsi, Brian L. Markham, NASA Goddard Space Flight Ctr. (United States)

Landsat-8, the latest in the Landsat series of satellites, was launched on February 11, 2013 and carries on board the Operational Land Imager (OLI) as one of its payloads. The satellite's mission is to continue the long history of operational land imaging of the Landsat program. The OLI follows the highly successful Landsat-5 and Landsat-7 in continuing to populate an archive of earth images that dates back to 1972.

The OLI has significant changes from the Landsat Thematic Mapper instruments: it is the first pushbroom instrument; it includes a cirrus band and an ultra-blue band; and the thermal bands are in a separate instrument.

On-board radiometric calibration devices include a full-aperture shutter for a measure of the dark levels, a solar panel for calibration against the sun, and multiple sets of lamps for short-term stability monitoring. The satellite will regularly perform maneuvers to image the moon for lunar calibrations and turn sideways to in order that all detectors image the same point on the ground. Additionally, the OLI will make use of vicarious calibration campaigns by University of Arizona and South Dakota State University, as well as monitoring large desert targets in the Sahara for long-term stability.

This paper will cover the early results of the calibration and characterization that have been performed since launch.

8866-50, Session 10

Preliminary on-orbit performance of the thermal infrared sensor (TIRS) on board Landsat 8

Matthew Montanaro, Sigma Space Corp. (United States); Dennis Reuter, Brian L. Markham, Allen Lunsford, NASA Goddard Space Flight Ctr. (United States); Zelalem Tesfaye, SGT, Inc. (United States) and NASA Goddard Space Flight Ctr. (United States); Brian Wenny, Sigma Space Corp. (United States); Kurtis Thome, Ramsey Smith, NASA Goddard Space Flight Ctr. (United States)

The Thermal Infrared Sensor (TIRS) on board Landsat 8 continues thermal band measurements of the Earth for the Landsat program. TIRS improves on previous Landsat designs by making use of a pushbroom sensor layout to collect data from the Earth in two spectral channels. To ensure proper radiometric integrity, TIRS was calibrated to a NIST absolute radiometric standard during pre-flight testing and characterization. Calibration methods and algorithms were developed to translate the raw signal from the instrument into an accurate at-aperture spectral radiance. The TIRS instrument also has the ability to view an on-board variable-temperature blackbody and a deep space view port for calibration purposes. The calibration routines were also used to transfer the NIST radiometric knowledge to the TIRS on-board blackbody calibrator.

After TIRS was successfully activated on-orbit, checks were performed on the instrument data to determine its image quality. These checkouts included assessment of the on-board blackbody and deep space views as well as normal Earth scene collects and vicarious calibration sites. The TIRS radiometric performance will be regularly monitored using these methods and updates to the calibration algorithms are implemented as necessary to maintain the radiometric accuracy of the data product. An overview of the radiometric calibration process developed pre-flight is given here along with a summary of early on-orbit checkout activities. In addition, a comparison of the pre-flight and early on-orbit performance is discussed.

8866-51, Session 10

Ghosting and stray-light performance assessment of the Landsat data continuity mission's (LDCM) operational land imager (OLI)

Philip W. Dabney, Raviv Levy, Brian L. Markham, Eugene Waluschka, Lawrence Ong, NASA Goddard Space Flight Ctr. (United States); Frank Grochocki, Michael G. Dittman, Ball Aerospace & Technologies Corp. (United States); Jeffrey A. Pedelty, NASA Goddard Space Flight Ctr. (United States)

The newly launched Operational Land Imager (OLI) aboard the LDCM satellite has stringent requirements to control t ghosting and diffuse stray-light in the reflective bands in order to preserve the radiometric accuracy of high contrast images.. The LDCM project science team working with the instrument teams wrote the requirements such that they were image based, inclusive of all effects that appear to be ghosts or stray-light, and consequently more directly testable. The OLI Instrument Developer, Ball Aerospace & Technologies Corporation, working closely with experts from aerospace, academia, and the NASA/USGS LDCM project were able to identify and mitigate the various contributors to ghosting and stray-light, resulting in an outstanding image performance for a wide field-of-view push-broom imaging sensor.

We will describe the ghosting and stray-light requirements and some of the contributing effects such as the leaky pixels that were seen on the EO-1/ALI. we will also highlight some of the technical challenges encountered and the solution resulting in the substantial reduction of ghosting and straylight which were verified by ground test. We will compare these ground measurements and analytic predictions with Lunar scan data to potentially resolve the question of whether the source of some of the performance outliers was the instrument or the test equipment.

Finally, we will discuss the impacts the pre-launch and image estimated values of each will have on the LDCM radiometric accuracy.

8866-52, Session 10

Intercalibration of Landsat 8 using scaled measurements

Joel McCorkel, Kurt Thome, NASA Goddard Space Flight Ctr. (United States)

The launch of Landsat 8 on 11 February 2012 continues a chain of land surface imaging from space started in 1972 with the launch of Landsat 1. Landsat 8 hosts Operational Land Imager (OLI) with spectral channels in the visible to shortwave infrared and Thermal Infrared Sensor (TIRS) with spectral channels in the thermal infrared. Many of the spectral channels in the OLI and TIRS design were also present in previous Landsat sensors, though not identical. Additionally, Landsat 8 shares spatial resolution and temporal coverage with past sensors enabling continued study of urban growth of cities, health and disturbance of forests, recession of the world's glaciers, and water supply and productivity of agriculture. Critical to establishing a link between the new, existing and past sensors is validating prelaunch radiometric calibration. This work provides early on-orbit calibration results from vicarious methods including intercalibration with other satellite, airborne and ground-based sensors.

8866-54, Session 11

SNPP VIIRS spectral bands co-registration and spatial response characterization

Guoqing Lin, INNOVIM (United States) and NASA Goddard Space Flight Ctr. (United States); James C. Tilton, Robert E. Wolfe, NASA Goddard Space Flight Ctr. (United States); Krishna P. Tewari, INNOVIM (United States) and NASA Goddard Space Flight Ctr. (United States); Masahiro Nishihama, Sigma Space Corp. (United States) and NASA Goddard Space Flight Ctr. (United States)

Spatial response has been quantified in terms of field of view (FOV), modulation transfer function (MTF) or horizontal spatial resolution (HSR) derived from line spread functions (LSFs) measured in the along-track and cross-track directions. Band-to-band co-registration (BBR) has been quantified in terms of pixel overlap from one band to another, with mis-registration of line of sight (LOS) in fractions of specified HSR.

These parameters had been evaluated in the worst case scenario, in the non-aggregation zones near the start and end of scan, for requirement compliance. They have neither been evaluated on-orbit nor in the 2-sample and 3-sample aggregation zones towards the center of scan, which will be presented in this paper. This paper also quantifies spatial response in alternative terms such as ensquared energy (EE) and integrated out-of-pixel (IOOP) response, and BBR based on pre-launch measured values of FOV, HSR and overlapped LSFs between corresponding spectral bands.

8866-55, Session 11

Modeling SNPP VIIRS reflective solar bands optical throughput degradation and its impacts on the relative spectral response

Ning Lei, Zhipeng Wang, Sigma Space Corp. (United States); Xiaoxiong Xiong, NASA Goddard Space Flight Ctr. (United States)

Right after the opening of the NADIR door of the Visible/Infrared Imager/Radiometer Suite (VIIRS) aboard the Suomi National Polar-orbiting Partnership (SNPP) satellite, it has been observed that the detector gains of the near infrared (NIR) bands have decreased much faster than expected. This large decrease is attributed to the mirror reflectance degradation of the Rotating Telescope Assembly (RTA). We have established a physical model to describe the mirror reflectance degradation. In this presentation, we use the physical model to fit the observed data to update the model parameter values and the degradation projection. We have adjusted our original model slightly to address the additional optical throughput degradation for the short wave infrared (SWIR) bands, which occurred right after the spacecraft Sun Point anomaly (orbits 2101-2133). The RTA optical throughput degradation and the additional throughput degradation after the Sun Point anomaly for the SWIR bands are not constant across the optical wavelength and therefore impact on a detector's relative spectral response (RSR). Using the model, we establish the degradation versus wavelength curve at any orbit and use the curve to compute the associated impact on the RSR. We further use this degradation modulated RSR to compute the impact on sensor calibration and the Earth View reflectance at the Sensor Data Record (SDR) level.

8866-56, Session 11

Effect of the SDSM detector relative spectral response in determining the degradation of the SNPP VIIRS solar diffuser reflectance

Ning Lei, Zhipeng Wang, Jon Fulbright, Sigma Space Corp. (United States); Xiaoxiong Xiong, NASA Goddard Space Flight Ctr. (United States)

The Visible/Infrared Imager Radiometer Suite (VIIRS) instrument aboard the Suomi National Polar-orbiting Partnership (SNPP) satellite performs its radiometric calibration in the reflective solar bands wavelength region primarily through observing the sunlight scattered from the onboard Solar Diffuser (SD). The reflectance of the SD degrades over time. The degradation is determined by comparing the irradiance of the sun-lit SD with that of the Sun through the onboard Solar Diffuser Stability Monitor (SDSM). The out-of-band relative spectral response (RSR) of the SDSM detectors, if large enough, can lead to a non-negligible bias to the originally determined SD degradation coefficient. The RSR integrates the photons (scattered from the SD) over a wide range of wavelengths to yield the detector signal. As a result, the SD degradation coefficient is more accurately described by an integral (over wavelength) equation. In this presentation, we establish a methodology to solve this particular type of integral equation and apply the methodology to determine the bias.

8866-57, Session 11

Improving the characterization and performance of the Suomi-NPP/VIIRS solar diffuser stability monitor

Jon Fulbright, Ning Lei, Jeffrey McIntire, Boryana Efremova, Xuexia Chen, Sigma Space Corp. (United States); Xiaoxiong Xiong, NASA Goddard Space Flight Ctr. (United States)

The Visible/Infrared Imager Radiometer Suite (VIIRS) instrument on Suomi-NPP performs its primary radiometric calibration through observations of sunlight reflected off the Solar Diffuser (SD). The optical performance of the SD degrades with exposure to short-wavelength UV light. Therefore, VIIRS includes the Solar Diffuser Stability Monitor (SDSM) to monitor the optical performance of the SD. The SDSM acts as a ratioing radiometer that compares the irradiance observed off the SD to that of direct observations of the Sun simultaneously in eight visible/near-IR (VisNIR) bands. These observations yield the H-factors which are used by the SD algorithm to determine the detector gains of the main VIIRS VisNIR bands. In this paper we evaluate several potential improvements to the algorithm used to determine the H-factor from the SDSM observations. First, we include a correction for the effects of the out-of-band response of the SDSM detectors into the calculation of H-factors. Another possible improvement is an update to the transmission functions for both the Sun view and Solar Diffuser view based on the both the yaw-maneuver data and the nominal mission data. We also consider methodologies to expand the amount of useful data recovered per SDSM event, helping correct for the slight misalignment of SDSM optics. Finally, we continue to track the on-orbit degradation of the SDSM detectors and give an estimate of the long-term performance of the SDSM. For each potential improvement, we report on the net effect of the change on the baseline H-factor trending and the H-factor uncertainty.

8866-58, Session 11

NPP VIIRS on-orbit calibration using the Moon

Junqiang Sun, Jon Fulbright, Zhipeng Wang, Sigma Space Corp. (United States); Xiaoxiong Xiong, NASA Goddard Space Flight Ctr. (United States)

The Visible Infrared Imager Radiometer Suite (VIIRS) on-board the Suomi National Polar-orbiting Partnership (NPP) satellite was launched on October 28, 2011. VIIRS has been scheduled to view the Moon approximately monthly through a spacecraft roll maneuver after the opening of the nadir door on November 21, 2011 through the Space View (SV) port to monitor the long-term radiometric stability of its Reflective Solar Bands (RSB). There are also about four lunar intrusions into VIIRS SV per month in about nine months every year. The lunar irradiance observed by VIIRS depends on the viewing geometry. In each VIIRS lunar observation, the Moon is viewed in multiple scans. The lunar irradiance of a VIIRS RSB can be derived from the response of all of its detectors in one of the scans, each of which fully covers the Moon. It can also be calculated from the response of four adjacent scans or by all detectors in multiple scans. The calculated values of the lunar irradiance from different numbers of scans and different detectors are compared and the uncertainty of the calculated VIIRS lunar irradiance is estimated. The influence of the instrument temperature on the lunar irradiance is corrected. With the geometric effect corrected using the ROLO lunar model's prediction and prelaunch calibration coefficients applied, the calculated lunar irradiance can be used to track on-orbit gain change for VIIRS RSB, the inverse of which is the calibration coefficient, F factor, that can also be derived from the Solar Diffuser (SD) calibration. From the lunar calibrations, the calibration coefficient is derived for each band, detector, and Half-Angle Mirror (HAM) side. In this paper, we report our results using the lunar observations to track the VIIRS RSB gain changes since first lunar observation in January, 2012 and to compare the gain changes derived from both lunar and SD calibrations. It is shown that the gain, the inverse of the calibration coefficient, degrades with time

and the degradation is strongly band (wavelength) dependent. The largest degradation occurs at near infrared bands while visible bands have much smaller degradation. The differences between the calibration coefficients derived from the lunar observations and those obtained from the SD calibration are within 0.5% for most bands and within 2% short wavelength bands.

8866-59, Session 11

A synthesis of VIIRS solar and lunar calibrations

Robert E. Eplee Jr., Kevini R. Turpie, Gerhard Meister, Frederick S. Patt, Gwyn F. Fireman, Bryan A. Franz, Charles R. McClain, NASA Goddard Space Flight Ctr. (United States)

The NASA VIIRS Ocean Science Team (VOST) has developed an independent calibration of the SNPP VIIRS moderate resolution reflective solar bands using solar diffuser observations to date and lunar observations through May 2013. The trends show a divergence between the solar and lunar calibration time series, with a greater sensitivity loss in the blue band lunar trends than in the solar trends. Possible causes of the divergence include uncertainties in the solar diffuser stability monitor trending of the solar diffuser BRDF. Assuming that lunar trending is more reliable than solar trending, the VOST has developed a synthesis approach to the on-orbit calibration of VIIRS that uses band-averaged lunar trends to correct the solar time series. Solar observations continue to provide information regarding detector-to-detector and mirror-side response variations. Solar trending also shows a stronger focal plane temperature dependence than expected from the prelaunch instrument characterization testing, leading the VOST to derive a revised set of focal plane temperature correction coefficients. Implementation of the lunar-corrected, solar-derived calibration in ocean data processing shows ocean surface reflectance trends that are more consistent with MODIS observations than surface reflectances derived from the solar-derived calibration alone.

8866-60, Session 12

Improvements of VIIRS and MODIS solar diffuser and lunar calibration

Xiaoxiong Xiong, James Butler, NASA Goddard Space Flight Ctr. (United States); Ning Lei, Junqiang Sun, Jon Fulbright, Zhipeng Wang, Sigma Space Corp. (United States)

Both S-NPP VIIRS and Terra and Aqua MODIS use solar diffuser (SD) and lunar observations to calibrate their reflective solar bands (RSB). In addition, a similar solar diffuser stability monitor (SDSM) is used to track the SD on-orbit degradation or change of the SD bi-directional reflectance factor (BRF). On-orbit observations have shown similar wavelength-dependent SD degradation (larger at shorter VIS wavelengths) and SDSM detector response degradation (larger at longer NIR wavelengths) for both MODIS and VIIRS instruments. On the contrary, MODIS scan mirror has shown more degradation in the VIS spectral region and the VIIRS rotating telescope assembly (RTA) mirrors have experienced more degradation in the NIR and SWIR spectral region. As a result, the sensor's relative spectral response (RSR), in-band (IB) and out-of-band (OOB) combined, is modulated. Due to differences between the solar and lunar spectral irradiance, the modulated RSR will have different impact on the SD and lunar calibration. In this paper, we identify all the factors that need to be considered for the improvements of current SD and lunar calibration approaches and examine their impact on the RSB calibration quality. Special efforts will be made to characterize the effects due to SD and SDSM attenuation screen transmission (uncertainty), SD BRF (uncertainty), SD degradation modulated solar spectral irradiance, sensor optics degradation modulated RSR, and SDSM detector (response) degradation modulated RSR.

8866-61, Session 12

SNPP VIIRS thermal band spectral radiance performance through 18 months on-orbit

Chris Moeller, David Tobin, Greg Quinn, Univ. of Wisconsin-Madison (United States)

SNPP, carrying the first VIIRS instrument, was launched on October 28, 2011 with first light on November 21, 2011. The passive radiative cooler doors were opened on January 18, 2012 allowing the cold focal planes (S/MWIR and LWIR) to cool to the nominal operating temperature of 80K. After an early on-orbit functional checkout period, an intensive Cal/Val (ICV) phase began in the spring 2012. During the ICV, tasks to evaluate various components of the VIIRS radiometric performance have been in process, with data collection and analysis now approaching a one year milestone.

This paper will provide findings of ICV tasks assigned to the University of Wisconsin, including Sensor Data Record (SDR) spectral radiance performance, out-of-band spectral performance, and the Response vs. Scan (RVS) performance of the VIIRS Half Angle Mirror (HAM). The tasks leverage matchups of SNPP VIIRS thermal band earth scene observations with those of CrIS and Metop-A IASI. VIIRS-CrIS globally distributed matchups exceed 100,000 per day, while VIIRS-IASI SNO matchups are limited to high latitudes in each hemisphere at a rate of a few thousand per year. The matchups, with spatial and spectral dependencies removed, establish the daily baseline performance of all VIIRS TEB relative to the other sensors, as well as provide insight into long term performance trends. The first year of comparisons suggest that VIIRS TEB are performing within or very near specification, and show excellent performance stability over the existing data record.

8866-62, Session 12

VIIRS thermal emissive bands on-orbit calibration coefficient performance using vicarious calibration results

David I. Moyer, The Aerospace Corp. (United States); Chris Moeller, Univ. of Wisconsin-Madison (United States); Frank De Luccia, The Aerospace Corp. (United States)

The Visible-Infrared Imaging Radiometer Suite (VIIRS) a primary sensor on-board the Suomi-National Polar-orbiting Partnership (SNPP) spacecraft was launched October 28, 2011. It has 22 bands: 7 thermal emissive bands (TEBs), 14 reflective solar bands (RSBs) and a Day Night Band (DNB). The TEBs cover the spectral wavelengths between 3.7 to 12 ?m and have two 371m and five 742m spatial resolution bands. A VIIRS Key Performance Parameter (KPP) is the sea surface temperature (SST) which uses bands M12 (3.7?m), M15 (10.8?m) and M16's (12.0?m) calibrated Science Data Records (SDRs). The TEB SDRs rely on prelaunch calibration coefficients which use a quadratic algorithm to convert the detector's response to calibrated radiance. This paper will evaluate the performance of these prelaunch calibration coefficients using vicarious calibration information from the Cross-track Infrared Sounder (CrIS) also on-board the SNPP spacecraft and the Infrared Atmospheric Sounding Interferometer (IASI) which is on-board a Meteorological Operational (MetOp) satellite. Changes to the prelaunch calibration coefficient's offset term c0 to improve the SDR's performance at cold scene temperatures will also be discussed.

8866-63, Session 12

VIIRS day/night band (DNB) stray light characterization and correction

Steve Mills, Stellar Solutions, Inc. (United States) and Northrop Grumman Aerospace Systems (United States); Stephanie Weiss, Calvin Liang, Northrop Grumman Aerospace Systems (United States)

The Day/Night Band (DNB) on the VIIRS sensor is a panchromatic band that can detect very dim nighttime scenes. After launch of Suomi NPP in October 2011 we observed a gray haze in radiance images with offsets up to 5?10-9 W cm-2 sr-1. Overall this impacts about 25% of nighttime scenes. We considered stray light as the likely cause, and studied calibration data from the space view. We concluded that stray light is entering the VIIRS scan cavity through its nadir door and solar diffuser openings. We also studied the darkest earth scenes without any solar, lunar or artificial illumination, and found that the offset is a function of cross-track pixel, solar angle of incidence (AOI) and detector number. We observed a strong detector dependence causing striping. Dividing scenes into 3 or 4 zones in each hemisphere based on solar AOI, we devised an algorithmic correction based on polynomial fits of the medians of the data for each zone. The correction removed almost all the haze and striping and improved dynamic range by 2 orders-of-magnitude, to as low as 1?10-10 Wcm-2 sr-1, but some striping remains in the twilight region due to extrapolation.

8866-64, Session 12

On the potential to enhance the spatial resolution of the day-night band (DNB) channel of the visible and infrared imaging radiometer suite (VIIRS) for the second joint polar satellite system (JPSS-2) and beyond

James K. McCarthy, Stellar Solutions, Inc. (United States); Eric J. Jacobson, Timothy M. Kilduff, Ronald W. Estes, Raytheon Space & Airborne Systems (United States); Peter A. Levine, SRI International Sarnoff (United States); Steve Mills, Stellar Solutions, Inc. (United States); Chris Elvidge, National Oceanic and Atmospheric Administration (United States); Steven D. Miller, Colorado State Univ. (United States)

The VIIRS DNB channel provides a unique state-of-the-art capability to capture panchromatic visible-light images of the earth over a remarkable dynamic range spanning roughly 7 decades in input radiance, with sufficient sensitivity to produce high quality earth imagery at night even under quarter-moon illumination or less. This paper examines the feasibility and potential benefits of enhancing the spatial resolution of the VIIRS DNB channel for the second JPSS mission and beyond, by modifying the on-chip pixel binning recipe used in the DNB CCD to aggregate detector area within the scan swath. Presently the DNB delivers 16 cross-scan samples similar in size to the detectors in the VIIRS Moderate Resolution Bands. The proposed relatively low-cost enhancement would instead bin the DNB CCD pixels into 32 cross-scan samples, each half as large in track and scan, effectively doubling the spatial resolution of DNB to match that of the VIIRS Imaging Bands at nadir. DNB CCD clocking is performed via the Focal Plane Interface Electronics (FPIE) unit on-board VIIRS; to fully implement the proposed DNB spatial resolution enhancement over the entire cross-track scan swath would require design and hardware modifications to the FPIE to increase certain CCD clock frequencies. This paper explores the scope and feasibility of this option, alongside other options that (if constrained to use the existing FPIE design with no changes) would not provide the enhanced DNB spatial resolution all the way out to the edges of the cross-track scan, and the potential impacts on DNB imagery products and applications.

Conference 8867: Infrared Remote Sensing and Instrumentation XXI

Monday - Tuesday 26–27 August 2013

Part of Proceedings of SPIE Vol. 8867 Infrared Remote Sensing and Instrumentation XXI

SPIE Optics+Photonics
Optical Engineering + App.

8867-1, Session 1

Infrared remote sensing of planetary surfaces: overview, outstanding questions, and prospects *(Invited Paper)*

Gabriele E. Arnold, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany)

We own a major part of our knowledge about the surface composition and structure of solid planetary surfaces infrared imaging and Fourier transform spectroscopy. Basing on these methods it succeeds to observe the single planetary objects in a global geo-scientific content. The topic of infrared surface studies are mineralogical composition analyses, measurement of surface temperature, thermal inertia and photometric observation of the surface regolith texture. The comparison of infrared with photogeologic data forms the essential basis for comparative studies in planetology. The present paper summarizes outstanding results by examples of ESA experiments like VIRTIS on Venus Express and Rosetta, and PFS on Mars Express, MERTIS on Bepi Colombo, and provides an outlook for future plans. The instruments are introduced, and the interplay of disciplines like planetology, IR measuring techniques, and space flight engineering is demonstrated. Following this overview the paper summarizes outstanding questions, and prospects in IR remote sensing of planetary surfaces.

Infrared remote sensing provides essential knowledge about the current state of solid planetary surfaces. This allows studying fundamental questions in comparative planetology. The present paper summarizes selected results of spaceborne surface composition analyses, introduces key instruments, and discusses outstanding questions as well as prospects of the infrared method and techniques.

8867-2, Session 1

Pre-launch calibrations of the vis-IR hyperspectral imager (VIHI) onboard BepiColombo, the ESA mission to Mercury *(Invited Paper)*

Fabrizio Capaccioni, Gianrico Filacchione, Giuseppe Piccioni, INAF - IASF Roma (Italy); Michele Dami, Leonardo Tommasi, Iacopo Ficai Veltroni, SELEX Galileo S.p.A. (Italy)

The pre-launch calibration activities of VIHI, the Visible and Infrared Hyperspectral Imager onboard Bepi Colombo/MPO, the ESA cornestone mission to be launched in 2015 to Mercury, are reported here. VIHI (Capaccioni et al., 2010) is one of the three optical channels of the SIMBIO-SYS suite (Spectrometers and Imagers for MPO BepiColombo Integrated Observatory SYStem). The payload, built by an Italy-France consortium, includes also a high spatial resolution and a stereo colour cameras (Flamini et al., 2010). The VIHI imager spectrometer operates in the 0.4-2.0 µm spectral range with a spectral sampling of 6.25 nm/band, covering a FOV of 64 mrad with 256 pixels having each a IFOV of 250 µrad. Since the instrument shall operate in pushbroom mode, these characteristics allow to acquire a 25.6 km-wide swath on ground at 100 m/pixel resolution from a 400 km polar orbit. Before integration in the SIMBIO-SYS suite, the spectrometer undergoes to a cycle of calibration measurements to characterize the spectral, geometrical, spatial and radiometric performances. These calibration activities include also the characterization of the internal calibration unit output which shall be used in flight for the verification of the instrument performances. These activities, currently running in the Selex SE laboratories (Campi Bisenzio, Florence, Italy), are performed using a specific calibration setup, consisting of a dedicated optical bench, which houses different calibration sources, joined to the VIHI pupil. A description of the calibration purposes, setups, measurements and results, will be given.

8867-3, Session 1

MERTIS on BepiColombo: seeing Mercury in a new light *(Invited Paper)*

Jörn Helbert, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany); Harry Hiesinger, Westfaelische Wilhelms Univ. (Germany); Mario D'Amore, Ingo Walter, Thomas Säuberlich, Gisbert Peter, Gabriele E. Arnold, Alessandro Maturilli, Piero D'Incecco, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany)

The MErcury Radiometer and Thermal infrared Imaging Spectrometer (MERTIS) is part of the payload of the Mercury Planetary Orbiter spacecraft of the ESA-JAXA BepiColombo mission. MERTIS's scientific goals are to infer rock-forming minerals, to map surface composition, and to study surface temperature variations on Mercury. To achieve these science goals MERTIS combines a imaging spectrometer covering the wavelength range from 7-14 microns with a radiometer covering the wavelength range from 7-40 microns. MERTIS will map the whole surface of Mercury with a spatial resolution of 500m for the spectrometer channel and 2km for the radiometer channel.

The MERTIS instrument had been proposed long before the NASA MESSENGER mission provided us with new insights into the innermost of the terrestrial planets. The discoveries of the MESSENGER fundamentally changed our view of Mercury. It revealed a surface that has been reshaped by volcanism over large parts of geological history. Volatile elements like sulfur have been detected with unexpectedly high abundances of up to 4%. MESSENGER imagined structures that are most likely formed by pyroclastic eruptions in recent geologic history. Among the most exciting discoveries of MESSENGER are hollows – bright irregularly shaped depressions that show sign of ongoing loss of material.

Despite all this new results the MERTIS dataset remains unique and is now more important than ever. None of the instruments on the NASA MESSENGER mission covers the same spectral range or provides a measurement of the surface temperature. The MERTIS will complement the results of MESSENGER. MERTIS will for example be able to provide spatially resolved compositional information on the hollows and pyroclastic deposits – both among the most exciting discoveries by the MESSENGER mission for which the NASA mission can not provide compositional information.

8867-4, Session 1

Pointing and spectral assignemnt design and control for MERTIS

Ingo Walter, Thomas Säuberlich, Matthias Lieder, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany); Miroslaw Rataj, Space Research Ctr. (Poland); Hans Driescher, Astro- und Feinwerktechnik Adlershof GmbH (Germany); Jörn Helbert, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany); Harry Hiesinger, Westfaelische Wilhelms Univ. (Germany)

The development of MERTIS, a miniaturized thermal infrared imaging spectrometer onboard of ESA's cornerstone mission BepiColombo to Mercury has been completed. Qualification of the design is followed by the calibration of the instrument showing up first results of the technology used.

Based on subsequent viewing of different targets including on-board calibration sources the push-broom instrument will use a 2-dimensional bolometer detector to provide spatial and spectral information.

Here repetition accuracy of pointing and spectral assignment is supported by the design of instrument components under the restriction

of limited resources. Additionally a concept of verification after launch and cruise phase of the mission was developed.

The article describes how this has been implemented and what the results under environment testing are.

8867-5, Session 1

Developing of MERTIS as an advanced process from the study up to the flight model

Gisbert Peter, Ingo Walter, Jörn Helbert, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany); Harry Hiesinger, Institut für Planetologie (Germany); Gariele E. Arnold, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany)

In 2005 a new infrared spectrometer and radiometer for remote sensing of the Mercury has been proposed to ESA, now in 2013 the flight model is integrated, tested and calibrated. The result is a state of the art instrument with better optical performance as required (e.g. SNR (spectrometer) > 500 @ 8µm), lower technical resources as expected (i.e. 3,1kg and <10W), developed on schedule within the required financial budget. A brief description of the instrument design and applied technologies, the operational concept and optical performances are presented. It is shown that an extended model philosophy not only cost but also saves money, especially when almost all components need new technologies for development. An advanced on-board and on-ground software concept speeds up the development process having more time at the end for calibration, which is one of the most important step getting an optimized scientific optical performance (before launch). Furthermore the verification concept by from the designer independent companies helped getting a design with withstands the harsh environmental conditions during launch, thermally in orbit and due to radiation. The paper gives a summary on the development with examples how it was done and what we have learnt.

8867-6, Session 1

Advanced geometrical calibration of the thermal infrared push-broom imaging spectrometer MERTIS based on simulation and testing

Martin Bauer, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany)

The Mercury Radiometer and Thermal Infrared Spectrometer (MERTIS) onboard the BepiColombo Mercury Planetary Orbiter (MPO) is a state of the art instrument for studies of the surface composition of Mercury. MERTIS is the first spaceborne push-broom spectrometer that allows mapping the Mercury's surface mineralogy in the diagnostic mid-infrared range.

A method for MERTIS geometrics parameter determination based on ray tracing simulation, laboratory testing and synthesis of both is described by this paper. At first geometrical calibration theory and its application for MERTIS is presented. In the following a simulation of ideal MERTIS imaging by ray tracing and results of laboratory testing are presented. Than it is shown how simulation and laboratory testing data are connected to the calibration model and results are discussed. The method of coupled simulation and testing gives a feedback during the calibration process itself and finally makes it more reliable.

8867-7, Session 2

Atmospheric chemistry suite (ACS): a set of infrared spectrometers for atmospheric measurements on board ExoMars trace gas orbiter *(Invited Paper)*

Oleg Korablev, Space Research Institute (Russian Federation) and Moscow Institute of Physics and Technology (Russian Federation); Alexei V. Grigoriev, Space Research institute (Russian Federation); Alexander Trokhimovsky, Space Research Institute (Russian Federation) and Moscow Institute of Physics and Technology (Russian Federation); Yurii Ivanov, Main Astronomical Observatory (Ukraine); Boris Moshkin, Space Research Institute (Russian Federation); Alexei Shakun, Space Research Institute (Russian Federation) and Moscow Institute of Physics and Technology (Russian Federation); Imant I. Vinogradov, Ilya Dzuban, Space Research Institute (Russian Federation); Franck Montmessin, Lab. Atmosphères, Milieux, Observations Spatiales (France)

The ACS package for the ExoMars Trace Gas Orbiter is a part of Russian contribution to the ExoMars mission. On the Orbiter in complements NOMAD investigation and is intended to recover in much extent the science lost with the cancellation of NASA MATMOS and EMCS infrared sounders. ACS includes three separate spectrometers, sharing common mechanical and electrical interfaces.

NIR is a versatile spectrometer for the spectral range of 0.7 – 1.7 ?m with resolving power of 20000. It is conceived on the principle of RUSALKA/ISS or SOIR/Venus Express experiments combining an echelle spectrometer and an AOTF (Acousto-Optical Tuneable Filter) for order selection. NIR will be operated principally in nadir, but also in solar occulations, and possibly on the limb.

MIR is a high-resolution echelle instrument exclusively dedicated to solar occultation measurements in the range of 2.2 – 4.4 ?m targeting the resolving power of 50000. The order separation is done by means of a steerable cross-disperser, allowing instantaneous coverage of two 200-nm ranges of the spectrum. MIR is dedicated to sensitive measurements of trace gases, approaching MATMOS detection thresholds for many species.

TIRVIM is a 2-inch double pendulum Fourier-transform spectrometer for the spectral range of 1.7-17 µm, and apodized resolution varying from 0.2 to 1.6 cm-1. TIRVIM is primarily dedicated to monitoring of atmospheric temperature and aerosol state in nadir, and would contribute in solar occultation to detection/reducing of upper limits of some components absorbing beyond 5 ?m, complementing MIR and NOMAD. Additionally, MIR targets the methane mapping in nadir, using separate detector optimized for 3.3-µm range.

The development status and technical implementation of the instrument will be discussed.

8867-8, Session 2

Remote sensing of planetary atmospheres in the thermal IR: Mars and Venus *(Invited Paper)*

Luidmila Zazova, Alexei V. Grigoriev, Space Research Institute (Russian Federation); Gabriele E. Arnold, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany); Rainer Haus, Westfälische Wilhelms-Univ. Münster (Germany)

Remote sensing in the thermal IR is an effective method of the planetary atmospheres investigations. IR spectrum with strong absorption bands gives information about the atmosphere layers in a wide range of latitudes. In the atmospheres of Mars and Venus the 15?m CO2 band is the most outstanding. Our work is devoted to the most significant results of IR spectrometry for Mars and Venus, including IRIS Mariner-9 and PFS

Mars Express for Mars and PMV Venera-15 and VIRTIS VEX. We also discuss shortly a possible future work.

8867-9, Session 2

Search for Martian methane with TES data: development of a dedicated radiative transfer code: first results

Giuliano Liuzzi, Guido Masiello, Carmine Serio, Univ. degli Studi della Basilicata (Italy); Sergio Fonti, Francesca Mancarella, Univ. del Salento (Italy); Ted L. Roush, NASA Ames Research Ctr. (United States)

Since methane was first reported in the Martian atmosphere, in 2004, an extraordinary effort has been undertaken to understand its origin, evolution and removal from the atmosphere, on time scales much less than the UV photodestruction rate of ~350 years. Much of the work, using orbital data, so far has focused on the analysis of the data coming from two instruments: the Planetary Fourier Spectrometer (PFS) on the Mars Express, and the Thermal Emission Spectrometer (TES) on the Mars Global Surveyor. Here we focus on the TES data, because of their abundance (several millions of spectra per Martian year), the more extensive spatial coverage, and better spatial resolution. Unfortunately, the spectral resolution of TES (5 and 10 cm-1) is challenging to the detection of methane using the ?4 band centered at 1306 cm-1. For this reason, an accurate atmospheric model, and a reliable radiative transfer code are required, in order to assess the reliability of the methane column abundance retrieval with TES data, and whether methane exhibits a regular seasonal cycle or not. From this perspective, we have developed a dedicated pseudo-monochromatic radiative transfer model, based on a model developed for the analysis of the Earth atmosphere, whose main advantage is the analytical parameterization of the optical depths layer-by-layer, with the ability to calculate the analytical Jacobians with respect to the gas concentrations and to the state vector.

In the present work, the main theoretical elements of this model and the first results are shown.

8867-10, Session 2

The Venus emissivity mapper instrument concept

Jörn Helbert, Nils T. Mueller, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany); Riccardo Nadalini, Active Space Technologies GmbH (Germany); Suzanne Smrekar, Jet Propulsion Lab. (United States)

The Venus Emissivity Mapper (VEM) is a new instrument concept designed specifically to observe Venus's surface in segments of the near-IR (NIR) spectrum that penetrate the atmosphere with minimal absorption. It builds on experience from analysis of data from Galileo/NIMS, Cassini/VIMS, and especially VIRTIS on Venus Express. Unlike those general-purpose imaging spectrometers, VEM is a hyperspectral mapper focused on observing the surface. It will map the surface in five atmospheric windows between 0.85 and 1.18 microns. In addition, several other bands are used to observe the clouds and water vapor at 0–15 km altitude.

VenusExpress VIRTIS data have already generated significant scientific results about Venus's surface. However, the instrument was not specifically designed for this purpose. The design of VEM will allow imaging Venus with a signal to noise ratio (SNR) at 1.31 ?m that is twice the SNR of 3 sec exposure VIRTIS images. VEM's band-center and width-scatter is roughly 5 times less than VIRTIS.

8867-11, Session 3

In-orbit performance of the AVHRR, HIRS, and AMSU-A instruments onboard the MetOp-A and MetOp-B satellites *(Invited Paper)*

Douglas R. Battles, HE Space Operations GmbH (Germany); Robert W. Lambeck, MEI Technologies, Inc. (United States); Abelardo Perez-Albinana, European Space Research and Technology Ctr. (Netherlands); Helmut Bauch, Telespazio VEGA Deutschland GmbH (Germany); Jörg Ackermann, European Organisation for the Exploitation of Meteorological Satellites (Germany)

The MetOp series of satellites constitute the space segment for the EUMETSAT Polar System (EPS), the European contribution to the Initial Joint Polar System, being developed in co-operation with the National Oceanic and Atmospheric Administration (NOAA) of the USA, to provide meteorological data from the polar orbit.

The first MetOp satellite was launched on 19 October 2006 on a Soyuz launcher from the Baikonur Cosmodrome in Kazakhstan. Following the successful completion of the commissioning campaign, the MetOp-A satellite and its ground segment were declared operational by both agencies, NOAA and EUMETSAT, during the summer of 2007. Now already exceeding its mission lifetime goal of five years in service, the performance trends presented in this paper take on special significance. The MetOp-B satellite was launched on 17 September 2012, so this paper will focus on the long-term performance trends on MetOp-A and draw comparisons with the early performance results on MetOp-B.

The Advanced Very High Resolution Radiometer (AVHRR), the High-resolution Infrared Radiation Sounder (HIRS) and the Advanced Microwave Sounding Unit-A (AMSU-A) instruments constitute the operational meteorological payload provided by NOAA that, in addition to the EUMETSAT provided Microwave Humidity Sounder (MHS), is flown on both the NOAA Polar Orbiting Satellites (POES) and the EUMETSAT MetOp satellites.

It is well known that the varying geometrical relationships between the Sun and the Earth throughout the year affect to some degree the performance of the instruments onboard Earth orbiting satellites. Following the commissioning of MetOp-A, EUMETSAT and NOAA have continued monitoring the long term trends in in-orbit performance of AVHRR, HIRS and AMSU-A. The data acquired since the launch of the satellite has allowed studying how the yearly seasonal variations, as well as aging, have affected the instrument performance. This paper presents the evolution of the performance of the AVHRR, HIRS and AMSU-A for more than six years since the launch of the Metop-A satellite, as well as the early performance results for MetOp-B.

8867-13, Session 3

The SpaceWire-based thermal infrared imager system for asteroid sample return mission HAYABUSA2

Hiroki Hihara, NEC TOSHIBA Space Systems, Ltd. (Japan); Kaori Iwase, Junpei Sano, NEC TOSHIBA Space Systems Ltd (Japan); Hisashi Otake, Tatsuaki Okada, Japan Aerospace Exploration Agency (Japan); Ryu Funase, The Univ. of Tokyo (Japan); Ryoichi Kashikawa, Isamu Higashino, NEC TOSHIBA Space Systems, Ltd. (Japan); Tetsuya Masuda, NEC Corp. (Japan)

Thermal infrared imager system is developed for HAYABUSA2, which is planned to be launched in 2014 and aims at sample-return from a C class near-Earth asteroid 1999JU3 considered to contain organic or hydrated materials. The system consists of a thermal-infrared imager (TIR) and a digital electronics, which is used not only for the scientific investigation of

physical properties of the asteroid surface, but also for the assessment of landing site selection and safe descent operation onto the asteroid surface with in situ measurement.

Since round trip communication time between the asteroid and the Earth is more than thirty minutes, onboard automatic data processing function and high speed data recording capability are provided to exploit the limited downlink capacity which is up to 32kbps.

TIR adopts an uncooled bolometer with 320 x 240 effective pixels. Image operations as multiple images summation, dark image subtraction, and the compensation of dead pixels are processed onboard. A processing module is connected to sensor interfaces through SpaceWire in order to provide deterministic processing time. Data compression is also provided to reduce restriction on storage capacity and operation time, which provides the equivalent compression ratio as JPEG2000 in 1/30 processing time in average. A high speed data recorder is also connected through SpaceWire in 50Mbps in order to record TIR data in parallel with other sensor data.

The modularity of SpaceWire enables to use as built devices for TIR and inherits the same design as the long-wavelength infrared imager developed for the Venus climate orbiter Akatsuki.

8867-14, Session 3

Space-based carbon monitoring by GOSAT and GOSAT-2: towards better accuracy of Xco2 observation

Hiroshi Suto, Akihiko Kuze, Kei Shiomi, Masakatsu Nakajima, Japan Aerospace Exploration Agency (Japan)

To observe the global column concentration of carbon dioxide (CO2) and methane (CH4) from space, the Greenhouse gases Observing SATellite (GOSAT) was launched on January 23, 2009, and has started the operational observation. Thermal and Near Infrared Sensor for Carbon Observation – Fourier Transform Spectrometer (TANSO-FTS) has been continuously measuring CO2 and CH4 distributions globally, and the retrieved column CO2 and CH4 data have been distributed to the public. Over four-years operational periods, the useful scientific data sets and interesting articles for carbon source/sink evaluation were produced and published, and these results have been supporting to well understanding of carbon cycle. Currently, the importance of space-based carbon observation has been approved and desired the continuous observation in toward. Through the TANSO-FTS operation with the radiometric, geometric and spectroscopic characterizations, we learned how to improve the accuracy of XCO2 and XCH4 based on short-wavelength FTS. The correction procedures for micro-vibration from companion components, non-linear response of analogue and digitizing circuit are key role on the current on-board operating TANSO-FTS. On instrumental aspects, the robustness and improvements will be required on the future mission. The retrieval accuracy of XCO2 by GOSAT spectra is around 2 ppm, which is much smaller than 4 ppm of the GOSAT mission target. To elucidate the carbon cycle more precisely, our experiences have to be summarized and applied in the future missions. To continue and improve the space-based carbon monitoring, the conceptual study of follow-on mission has started and will be presented.

8867-15, Session 3

A Doppler-modulated gas correlation approach for measuring neutral temperatures and wind in the upper atmosphere

Larry L. Gordley, Benjamin T. Marshall, GATS, Inc. (United States)

A new approach to measuring wind and temperature is under development that could revolutionize our ability to monitor wind and neutral temperature in the upper atmosphere. Using a Doppler modulated gas filter correlation technique, wind and temperature can be measured simultaneously from low Earth orbit, continuously from 15 km to over 200 km, on one second time intervals, both day and night. A constellation of six of these dual-sided Doppler Wind and Temperature Sensors (DWTS) on small-sat platforms could provide nearly real time global temperature and wind fields. The DWTS technique, measurements and weather forecast benefits are discussed. A microsoft Power-Point tutorial of the technique can be accessed at http://www.gats-inc.com/projects_dwts.htm.

8867-40, Session 3

A two-laser beam technique for improving the sensitivity of low frequency open path tunable diode laser absorption spectrometer (OP-TDLAS) measurements

Israa L. Mohammad, Univ. of Arkansas at Little Rock (United States) and Univ. of Mustansiriyah (Iraq); Gary T. Anderson, Youhua Chen, Univ. of Arkansas at Little Rock (United States)

Open path tunable diode-laser absorption spectroscopy (OP-TDLAS) is a promising technique that is proposed for detecting low concentrations of possible biogenic gases on Mars. This technique determines the concentration of a gas by measuring the amount of laser light absorbed by molecules at a specific wavelength that is characteristic of those molecules. One of the major factors limiting sensitivity in the TDLAS systems operating at low modulation frequencies is 1/f noise. 1/f noise is minimized in many spectroscopy systems by use of high frequency techniques. However, these techniques use complex instruments that include reference cells and other devices for calibration, making them relatively large and bulky. We are building a spectroscopy system for space applications that requires small, low mass and low power instrumentation, making the high frequency techniques unsuitable. This paper explores a new technique using two laser beams to reduce the affect of 1/f noise and increase the signal strength for measurements made at lower frequencies. In this method, two lasers are excited at slightly different frequencies. An algorithm is then used to estimate the noise in the second harmonic from the combined spectra of both lasers. This noise is then subtracted from the signal to give a more accurate measurement of gas concentration. The error in estimation of 1/f noise is negligible as it corresponds to noise level made at much higher frequencies. Simulation results using ammonia gas and two lasers operating at 500 and 510 Hz respectively shows that this technique is able to decrease the error in estimation of gas concentration to 1/6 its normal value.

8867-34, Session PMon

Influence of radiation energy transfer on boundary layer temperature drops

Tomaz B. Kranjc, Joe Peternelj, Univ. of Ljubljana (Slovenia)

The influence of thermal radiation on wall surface temperatures in a typical conjugate heat transfer problem is studied. Free convective heat transfer, accounted for phenomenologically through the introduction of heat transfer coefficients, is supplemented by surface thermal radiation. The calculations, presented for cubical enclosure exposed on two sides to solar radiation, clearly indicate that surface radiation can change significantly the surface temperatures which, in general, are reduced with increasing emissivities of the walls. In particular, in the case of small convection heat transfer coefficients, small thermal transmittances of the walls and high values of emissivities, the temperature difference across the temperature boundary layers adjacent to the walls could even be reversed.

8867-35, Session PMon

Wavefront recovery algorithm in a vectorial shearing interferometer

Beethoven Bravo-Medina, Guillermo Garcia-Torales, Univ. de Guadalajara (Mexico); Ricardo Legarda-Sáenz, Univ. Autónoma de Yucatán (Mexico); Jorge L. Flores-Nuñez, Univ. de Guadalajara (Mexico)

Vectorial shearing interferometer is able to select variable shear and tilt along any wavefront direction. This system is self-referenced and with variable sensibility.

We proposed this instrument to measure a phase object without rotational symmetry. Phase recovery is implemented by a Fourier-based algorithm and spatial unwrapping methods.

We show results emphasizing the advantage in the easier selection of fringe density and orientation of the directional derivative for a specific optical element.

8867-36, Session PMon

Measurement of phase objects by the use of color phase-shifting technique

Oscar E. Castillo, Univ. de Guadalajara (Mexico); Ricardo Legarda, Univ. Autónoma de Yucatán (Mexico); Jorge L. Flores-Nuñez, Guillemo Garcia-Torales, Univ. de Guadalajara (Mexico)

A simple technique for wavefront measurement is presented. This technique is based on the use of a computer display (LCD monitor) to generate color fringe patterns, which are imaged by a single-CCD color camera; whereas a phase object is placed in the ray path for imaging. The ray deflections distort the image of the pattern. By measuring this distortion, the gradients of the phase change caused by the object can be obtained. For the evaluation of the acquired fringe patterns, we use a classical phase-shifting technique encoded in a single color image displayed by the monitor. Therefore, this proposed technique permits real-time object shape measurement. Experiments are presented to demonstrate the success of this technique.

8867-37, Session PMon

Spectral interrogation of several-hundred-years old paintings with a broadband IR camera

Marija Strojnik Scholl, Ctr. de Investigaciones en Óptica, A.C. (Mexico)

We develop a theory to compare the signal-to-noise ratio of detected details with narrow and broad-band IR illumination and detection.

8867-38, Session PMon

Advantages of placing a segmented mirror of the type, the Great Mexican Telescope, on the Moon to detect extrasolar planets

Gonzalo Páez, Marija Strojnik Scholl, Ctr. de Investigaciones en Óptica, A.C. (Mexico)

In the Early nineties, we proposed placing a segmented telescope on the moon to detect the Extra-solar planets. Since that time, we demonstrated that mm region is highly advantageous for planet detection in an inetrferometric configuration. It may even be incorporated on the surface of the Earth, on a high mountain, such as The Great Mexican Telescope, near Puebla, Mexico. We evaluate the performance improvements that may be achieved in the absence of Earth atmosphere.

8867-16, Session 4

ACE-FTS on SCISAT: 10th year on-orbit anniversary *(Invited Paper)*

Marc-André Soucy, Henry L. Buijs, Richard L. Lachance, ABB Analytical Measurement (Canada)

The Atmospheric Chemistry Experiment (ACE) is a mission on-board the Canadian Space Agency's SCISAT-1. ACE consists of a suite of instruments consisting of an infrared Fourier Transform Spectrometer (FTS) coupled with an auxiliary 2-channel visible (525 nm) and near infrared imager (1020 nm). A second instrument, MAESTRO, is a spectrophotometer covering the near ultra-violet to the near infrared. In combination, the instrument payload covers the spectral range from 0.25 to 13.3 ?m. The intent of the ACE mission has been to measure the chemical and dynamical processes that control the distribution of ozone in the upper troposphere and stratosphere. ACE measures the vertical distributions of more trace gases than any other instrument as well as polar stratospheric clouds, aerosols and temperature by solar occultation from low earth orbit. A high inclination (74°), low earth orbit (650 km) provides coverage of tropical, mid-latitude and Polar Regions. Detailed and sensitive vertical distribution of trace gases help to better understand the chemical processes not only for ozone formation and destruction but also other dynamic processes in the atmosphere. The ACE/SCISAT-1 satellite was successfully launched by NASA on August 12, 2003.

This paper presents the heritage and development history of the ACE-FTS instrument. Design challenges and solutions will be related. The actual on-orbit performance is presented, and the health status of the instrument payload is discussed. Potential future follow-on missions are finally introduced. After ten years of fruitful operation in orbit, the SCISAT mission has been the source of over 250 scientific papers.

8867-17, Session 4

Progress in development of tropospheric infrared mapping spectrometers (TIMS): geostationary greenhouse gas (GHG) application *(Invited Paper)*

John B. Kumer, Richard L. Rairden, Aidan E. Roche, Lockheed Martin Space Systems Co. (United States)

We review development of the TIMS beginning in the early part of the decade and up to preliminary results of work in progress. We describe a geostationary application (geoCARB) at near PDR maturity for mapping CO_2, CH_4 and CO column mixing ratios on continental scale areas (e.g., Australia and East Asia) several times per day on contiguous samples with spacing the order 3 km at the sub satellite point. Measurements per footprint are expected to be acquired with median mission SNRs >> 300, 300 and 240 in the traditional spectral regions (e.g., OCO and TANSO-FTS on GOSAT) for CO_2, namely the O_2 A-band, and the weak and strong bands of CO_2 near 1.61 and 2.06 microns; and >> 200 in a region near 2.32 microns for CO and CH_4.The resolving powers are 15000, 15000, 11000 and 11000 in the 4 regions, respectively. Given this performance the median mission retrieval for CO_2, CH_4 and CO column mixing ratio is expected to be considerably better than 0.7, 1.0 and 10.0%, respectively. These measurements over several years would provide a break through reduction in the uncertainty and attribution for the sources of CO_2, CH_4 and CO within the large geostationary field of regard of the geoCARB.

8867-18, Session 4

Determination of technical readiness for an atmospheric carbon imaging spectrometer

Joseph Mobilia, John B. Kumer, Alice L. Palmer, Kevin A. Sawyer, Yalan Mao, Jason A. Mix, Ted C. Nast, Charles S. Clark, Roel W. H. van Bezooijen, Antonio L. Magoncelli, R. Baraze, David L. Chenette, Lockheed Martin Space Systems Co. (United States)

The geoCARB sensor uses a 4-channel slit-scan push broom slit-scan infrared imaging grating spectrometer to measure the absorption spectra of sunlight reflected from the ground in narrow wavelength regions. The instrument is designed for flight at geostationary orbit to provide continual monitoring of greenhouse gas over continental scales, several times per day, with a spatial resolution of a few kilometers. The sensor provides multiple daily maps of column-averaged mixing ratios of CO2, CH4, and CO over the regions of interest, which enables flux determination at unprecedented time, space, and accuracy scales. The geoCARB sensor development is based on our experience in successful implementation of advanced, space deployed optical instruments for remote sensing. A few recent examples include the Atmospheric Imaging Assembly (AIA) and Helioseismic and Magnetic Imager (HMI) on the geostationary Solar Dynamics Observatory (SDO), the Space Based Infrared System (SBIRS GEO-1) and the Interface Region Imaging Spectrograph (IRIS), along with sensors under development, the Near Infared camera (NIRcam) for James Webb, and Global Lightning Mapper (GLM) and Solar UltraViolet Imager (SUVI) for the GOES-R series. The Tropospheric Infrared Mapping Spectrometer (TIMS), developed in part through the NASA Instrument Incubator Program (IIP), provides an important part of the strong technological foundation for geoCARB. The presentation discusses subsystem heritage and technology readiness levels for these subsystems. The system level flight technology readiness and methods used to determine this level are presented along with plans to enhance the level.

8867-19, Session 4

geoCARB design, maturity, and geostationary heritage

Kevin A. Sawyer, Howard C. Holmes, Alice L. Palmer, John B. Kumar, Ted C. Nast, Joseph Mobilia, Scott W. Miller, Lockheed Martin Space Systems Co. (United States)

Our companion paper 'Progress in development of…TIMS: geostationary…GHG application' describes geoCARB performance and science. Here we describe a geoCARB design study leading to near PDR maturity. It is based on our rich heritage (AIA and HMI on SDO, SBIRS Geo-1 and upcoming GLM on GOES-R) of successfully building and deploying optical instruments to geostationary. Heritage includes experience and well developed specifications for near a-thermal carbon fiber honeycomb composite optical benches and optomechanical design forms that utilize a "family" of mounts for nearly any type of optical element. The geoCARB approach utilizes composite optical benches and bipod flexures to fully kinematically mount optics. Tooling for alignment and staking of all elements is integral to the design and is "removed before flight" for mass minimization. GeoCARB requires a cryogenic region for focal planes and spectrometers but front end optics and main structure may run much warmer. A sub-bench with a local cold box attached is used for implementation. A star tracker is used for geoCARB posteriori geolocation including pseudo-diurnal thermal distortion characterization. It is kinematically mounted by low conductance thermal isolators directly on to the low expansion high stiffness composite bench that defines the master optical surfaces including the scanning mirrors. Its camera heads thermal load is routed away from the bench via radiation or heat pipes. Use of kinematic mounting is advantageous for low thermal conduction designs. Honeycomb composites enable the design's low thermal mechanical distortions. Lockheed Martin and the Author have a deep, successful heritage in this design skill.

8867-20, Session 4

The capabilities, performance, and status of the SOFIA first-generation instruments

John W. Miles, B. G. Andersson, Eric E. Becklin, James M. DeBuizer, Universities Space Research Association (United States); Charles D. Dowell, Jet Propulsion Lab. (United States); Edward W. Dunham, Lowell Observatory (United States); Rolf Güsten, Max-Planck-Institut für Radioastronomie (Germany); Doyal Harper, The Univ. of Chicago (United States); Terry L. Herter, Cornell Univ. (United States); Randolf Klein, SOFIA / USRA (United States); Alfred Krabbe, Univ. Stuttgart (Germany); Pamela M. Marcum, NASA Ames Research Ctr. (United States); Ian S. McLean, Univ. of California, Los Angeles (United States); William T. Reach, Universities Space Research Association (United States); Matthew J. Richter, Univ. of California, Davis (United States); Thomas L. Roellig, NASA Ames Research Ctr. (United States); Göran Sandell, Maureen L. Savage, Universities Space Research Association (United States); Erin C. Smith, Pasquale Temi, NASA Ames Research Ctr. (United States); William D. Vacca, Universities Space Research Association (United States); John E. Vaillancourt, SOFIA / USRA (United States); Jeffery E. Van Cleve, Erick T. Young, Universities Space Research Association (United States); Peter T. Zell, NASA Ames Research Ctr. (United States)

The Stratospheric Observatory for Infrared Astronomy (SOFIA) is an airborne observatory, carrying a 2.5 m telescope onboard a heavily modified Boeing 747SP aircraft. SOFIA is optimized for operation in the infrared spectrum, much of which is obscured for ground-based observatories by atmospheric water vapor. The first generation SOFIA instrument complement consists of seven instruments: EXES (Echelon-Cross-Echelle Spectrograph), FIFI-LS (Far-Infrared Field-Imaging Line Spectrometer), FLITECAM (First Light Infrared Test Experiment CAMera), FORCAST (Faint Object InfraRed CAmera for the SOFIA Telescope), GREAT (German Receiver for Astronomy at Terahertz Frequencies), HAWC (High-resolution Airborne Wideband Camera), and HIPO (High-speed Imaging Photometer for Occultations). EXES is a 5 µm-28 µm high-resolution spectrograph, being developed at UC Davis and NASA ARC. FIFI-LS is a 42 µm-210 µm integral field imaging grating spectrometer, being developed at the University of Stuttgart. FLITECAM is a 1 µm-5 µm wide-field imager with grism spectroscopy, developed at UCLA. FORCAST is a 5 µm-40 µm imager with grism spectroscopy, developed at Cornell University. GREAT is a heterodyne spectrometer providing high-resolution spectroscopy in several bands from 60 µm-240 µm, developed at the Max Planck Institute for Radio Astronomy. HAWC is a 50 µm-240 µm imager, developed at the University of Chicago, and undergoing an upgrade at JPL to add polarimetry capability and a substantially larger GSFC detector. HIPO is a 0.3 µm-1.1 µm imager, developed at Lowell Observatory. We describe the capabilities, performance, and status of each instrument, highlighting results obtained using FORCAST, GREAT, and HIPO during SOFIA Early Science observations conducted in 2011.

8867-21, Session 4

Metop-B AVHRR IR channel post-launch calibration and verification tests

Tiejun Chang, ERT, Inc. (United States); Xiangqian Wu, National Oceanic and Atmospheric Administration (United States); Fuzhong Weng, National Environmental Satellite, Data, and Information Service (United States)

Meteorological Operational (METOP)-B spacecraft was launched on September 17, 2012, and the Advanced Very High Resolution Radiometer

(AVHRR) IR channels were activated October 18. AVHRR instrument has been tested and characterized pre-launch under thermal vacuum (TV) condition by the instrument vender. The instrument dynamic range, noise equivalent differential temperature (NEDT), and nonlinear response have been characterized in the test. Basing on the TV test data, the calibration coefficients are generated for post-launch. Currently, a radiance based nonlinear correction algorithm is used for L1B data. The on-orbit verification tests have been performed to verify the instrument response and performance, including the dynamic range, NEDT, on-board blackbody (BB) temperature, linear gain, and instrument status from the telemetry data. The post-launch Cal/Val test is to improve the calibration accuracy and enhance the L1B data quality. These tests include stray light analysis, instrument gain verification, and uncertainty assessment. The stray light impact on the calibration is estimated as 0.2% for 11 um channel, 0.3% for 12 um channel, and 3% for 3.7um channel. Some inter-comparison techniques are applied to verify the radiance and brightness temperature from L1B data. One test is planned to compare AVHRR IR channel radiances with the radiance derived from Infrared Atmospheric Sounding Interferometer (IASI) measurement once IASI data is available. The calibration uncertainty assessment will also be presented, including the impact of BB radiance error induced by the BB temperature uncertainty and non-perfect BB emissivity, and the impact from the calibration coefficient uncertainties.

8867-22, Session 4

Holographic substrate-guided spectrometer for atmospheric sensing

Fedor Dimov, Xiaowei Xia, Jun Ai, Neven Rakuljic, Chris Griffo, Engin Arik, Luminit LLC (United States)

Advances in oxygen A-band spectrometers are particularly important with atmospheric radiation measurements. Both simulations and short-field deployments using the oxygen A-band (at ~770 nm) have demonstrated that the path-length distribution of solar photons respond strongly to variations in the opacity and spatial distribution of clouds in both the vertical and horizontal directions. For field applications, existing low-resolution (3.3 nm to 10 nm) A-band spectrometers with a set of optical filters or prisms are inherently more robust, reliable, and cost-effective than high-resolution grating-based spectrometers (ranging from 2.3 nm for rotating shadow band spectro-radiometers to portions of nanometers), but result in a much lower out-of-band (OOB) rejection ratio, which can affect accuracy. In this paper, we demonstrate a novel holographic A-band multi-channel substrate-guided spectrometer device, based on a novel structure of two reflection substrate-guided-wave based holograms (SGWH) that act as dispersing and imaging elements to enable a sufficient spectral resolution combined with a high OOB rejection ratio. The technology is made very attractive by its significantly lower cost than current similar A-band systems/devices, yet will provide higher light throughput, better OOB rejection ratio, higher resolution at smaller size, and better stability and reliability. The new spectrometer is sensitive to the A-band spectral range from from 757 nm to 775 nm (~18 nm), and has a size 100?50?25 cubic mm. Details of fabrication and experimental testing results (both laboratory and outdoor) will be presented.

8867-23, Session 5

Research on diode pumped acousto-optic Q-switched Tm-doped fiber laser

Qijie Huang, Ting Yu, Yameng Zheng, Jifeng Zu, Weibiao Chen, Shanghai Institute of Optics and Fine Mechanics (China)

Owing to its wide gain spectrum from 1.8 to 2.1 μm, Tm-doped fiber lasers have attracted increasing interests in recent years. Despite its large quantum defect, 790 nm laser diodes directly pumping Tm-doped fiber lasers can have a theoretical 200% quantum efficiency by taking advantage of a highly efficient cross-relaxation process. They have been demonstrated as high-power and highly efficient light sources near 2 μm. High power pulsed Tm-doped fiber lasers are promising sources for many applications, including eye-safe LIDAR, medicine, spectroscopy, remote sensing. In this work, we will report our recent research on the 790 nm laser diodes pumped pulsed Tm-doped fiber lasers. Using an acousto-optic modulator as the Q-switcher, the performance of different pump structure and cavity structure is demonstrated. As short as 29 ns pulse with up to 6.5 kW peak power and 188 μJ pulse energy is obtained at 5 kHz repetition rate by using a short but high doped double-clad fiber. Employing a fiber Bragg grating as reflection coupler, approximately 0.1 nm linewidth pulse with less than 150 ns duration is derived in the further work. The performance of these lasers under different launched pump power and repetition rate is also demonstrated. Such these Q-switched Tm-doped fiber lasers can be potential candidates for applications like LIDAR, medicine or seed of master oscillator power amplification.

8867-26, Session 6

Quantum well, quantum dot, and type-II superlattice infrared detector research at the Jet Propulsion Laboratory *(Invited Paper)*

David Z. Ting, Sir B. Rafol, Sam A. Keo, Alexander Soibel, John K. Liu, Jason M. Mumolo, Cory J. Hill, Arezou Khoshakhlagh, Linda Höglund, Edward M. Luong, Sarath D. Gunapala, Jet Propulsion Lab. (United States)

We present an overview of III-V semiconductor based infrared detector and focal plane array development at the NASA Jet Propulsion Laboratory in recent years. Topics discussed include: (1) The development of broad-band long-wavelength quantum well infrared photodetector (QWIP) for imaging spectrometer applications. (2) The concept and realization of the sub-monolayer quantum dot infrared photodetector (SML-QDIP) as an alternative to the standard QDIP based on Stranski-Krastanov (SK) quantum dots. (3) The mid-wavelength infrared quantum dot barrier infrared detector (QD-BIRD) with extended cutoff wavelength. (4) High-performance type-II superlattice long wavelength infrared detectors based on the complementary barrier infrared detector (CBIRD) architecture.

8867-27, Session 6

High-operating-temperature MWIR detectors using type II superlattices *(Invited Paper)*

Sanjay Krishna, The Univ. of New Mexico (United States)

There is an increasing interest in developing higher operating temperature (HOT) detectors using unipolar barrier structures such as nBn, CBIRD, M-structure, N-structure, pBiBn and cascade structures, to name a few. In this talk, I will review some of the approaches that we have developed in our group nBn, pBiBn and cascade detectors. The performance characteristics of these detectors will be discussed in detail in the presentation.

8867-28, Session 6

Lidar multirange focal plane development for docking to the ISS

Philip M. Mayner, Raytheon Co. (United States)

A multi-range focal plane was developed and delivered by RVS for a docking system that was demonstrated on STS-134. This required state of the art focal plane and electronics synchronization to capture nanosecond length laser pulses to determine ranges with an accuracy of less than 1 inch.

8867-29, Session 6

MTF comparisons between mesa and planar MWIR focal plane detector structures

Mitchell O. Perley, Justin Wehner, David A. Buell, Raytheon Vision Systems (United States); Joseph McCorkle, Mark J. Rehfield, Raytheon Space & Airborne Systems (United States); David Williams, Andrew Dixon, Neil R. Malone, Raytheon Vision Systems (United States)

Raytheon Vision Systems (RVS) has developed scanning, high-speed (>3klps), all digital, with on-chip Analog-to-Digital Conversion (ADC), mid-wave infrared (MWIR 3-5mm) focal plane arrays (FPA) with excellent modulation transfer function (MTF) performance. Using secondary ion mass spectrometry (SIMS) data and detailed models of the mesa geometry, RVS modeled the predicted detector MTF performance of detectors. These detectors have a mesa structure and geometry for improved MTF performance compared to planar HgCdTe and InSb detector structures and other similar detector structures such as nBn. The modeled data is compared to measured MTF data obtained from edge spread measurements and shows good agreement, Figure 1. The measured data was obtained using a custom advanced test set with 1µm precision alignment and automatic data acquisition for report generation in less than five minutes per FPA. The measured MTF values of 83 unique parts, Figure 2, had a standard deviation of 0.0094 and a mean absolute deviation of 0.0066 at half Nyquist frequency, showing excellent process repeatability and a design that supports high MTF with good repeatability.

8867-30, Session 7

Thermal monitoring of transport infrastructures by infrared thermography coupled with inline local atmospheric conditions survey *(Invited Paper)*

Jean Dumoulin, IFSTTAR (France)

One of the two main objectives of ISTIMES project was to evaluate the potentialities offered by the integration of different electromagnetic techniques able to perform non-invasive diagnostics for surveillance and monitoring of critical transport infrastructures. Among the EM methods investigated, long term thermal monitoring by uncooled infrared camera is a promising technique due to its dissemination potential according to its low cost on the market.

Infrared thermography, when it is used in quantitative mode (not in laboratory conditions) and not in qualitative mode (vision applied to survey), requires to process in real time thermal radiative corrections on raw data acquired to take into account influences of natural environment evolution with time. But, camera sensor has to be enough smart to apply in real time calibration law and radiometric corrections in a varying atmosphere. So the work presented hereafter deals with a measurement system studied and developed with low cost infrared cameras available on the market coupled with other sensors to feed simplified radiative models running, in real time, on GPU available on small PC.

In that context, an HMI was developed under Linux using OpenSource and complementary pieces of software developed at IFSTTAR i.e. infrared camera drivers. This new HMI called “IrLaW” has various functionalities that let it compliant to be use in real site for long term monitoring. In particular, a weather station and a Global Positioning System (for timing and localization) are synchronized with the infrared camera to correct inline thermal measurements. The whole system can be remotely controlled in wire or wireless communication mode depending on what is the context of measurement and the degree of accessibility to the system when it is running on real site.

Experiments on real infrastructure were carried out and promising results were obtained thanks to post processing analysis by signal and image approaches.

Finally, Web-enabled capabilities were studied and developed thanks to the adoption of open standards (e.g. OGC SWE, OGC CSW etc.) that allow tasking the system to acquire data, on demand and from anywhere, through a web portal access. These new functionalities will be presented and discussed in the paper.

8867-33, Session 7

Absolute calibration of the reflected sunlight from the Moon

Gerald T. Fraser, Steven W. Brown, Claire E. Cramer, Keith R. Lykke, Ping-Shine Shaw, Allan W. Smith, National Institute of Standards and Technology (United States); Thomas C. Stone, U.S. Geological Survey (United States); John T. Woodward, National Institute of Standards and Technology (United States)

We describe a new method for measuring the spectral irradiance of the Moon at visible wavelengths. Our effort builds upon the highly successful Robotic Lunar Observatory (ROLO), which determined a precise model for the time-dependent irradiance of Moon from six years of observations obtained with an imager equipped with a set of narrow-band filters. The ROLO Irradiance Model allows the Moon to be used as a radiometric reference for tracking changes in the absolute responsivity of near-infrared to visible satellite sensors as a function of time to better than 1 %. The goal of the present effort is to improve the absolute radiometric accuracy of the ROLO model, presently estimated at ~ 10 %, to 1 %. Our approach, which uses an integrating sphere at the focal plane of a telescope to direct light from the integrated lunar disk into a stable spectrograph, also eliminates the dependence of the model on measured optical properties of lunar soil samples, required to interpolate between the 23 visible and near-infrared bands measured by ROLO. The new measurements will allow weather, climate, land-surface, and defense satellites to use the Moon as an absolute calibration reference, potentially reducing the impact of disruptions in continuous long-term climate data records caused by gaps in satellite sensor coverage.

8867-39, Session 7

STORM: sounding and tracking observatory for regional meteorology to launch in 2016 *(Invited Paper)*

Gail E. Bingham, Scott M. Jensen, John Ewell, Joel G. Cardon, Utah State Univ. (United States); David J. Crain, GeoMetWatch Corp. (United States); Allen H.-L. Huang, William L. Smith Jr., Henry E. Revercomb, Univ. of Wisconsin-Madison (United States)

Sounding and Tracking Observatory for Regional Meteorology (STORM), a derivative of the Geosynchronous Imaging Fourier Transform Spectrometer (GIFTS) EDU that was designed, built and tested for NASA by Utah State University (USU) in the early 1990s will be launched on a commercial geostationary satellite in late 2016. STORM combines advanced technologies to observe surface thermal properties and atmospheric weather and chemistry variables in four dimensions.

Large area format Focal Plane detector Arrays (LFPAs) provide near instantaneous large area coverage with high horizontal resolution. A Fourier Transform Spectrometer (FTS) enables atmospheric radiance spectra to be observed simultaneously for all LFPA detector elements, thereby providing high vertical resolution temperature and moisture sounding information. The fourth dimension, time, is provided by the geosynchronous satellite platform, which enables near continuous imaging of the atmosphere's three-dimensional structure. STORM will enhance the polar orbiting imaging and sounding measurements by providing: (1) a direct measure of moisture flux and altitude-resolved water vapor and cloud tracer winds throughout the troposphere, (2) an observation of the time varying atmospheric thermodynamics associated with storm system development, and (3) the transport of tropospheric pollutant gases (i.e., CO and O3).

GMW has entered into a partnership with AsiaSat to host the first STORM sensor on their AsiaSat 9 telecommunications satellite at 122 E over the Asia Pacific area. GMW's business plan is to sell the unique STORM data and data products to countries and companies in the satellite coverage area. GMW plans to place 6 STORM sensors on geostationary telecommunications satellites to provide global hyperspectral sounding and imaging data. Utah State's Advanced Weather Systems Laboratory (AWS) will build the sensors for GMW.

This paper provides an overview of the STORM instrument and the measurement concept. The STORM data will provide data of the same quality as the current LEO satellite sounders (AIRS, CrIS and IASI) but with the ability to track storm development with soundings and images at any desired rate. Wind profiles obtained from a time sequence of STORM water vapor retrieval images will provide additional input to now casting and regional models to supplement synoptic balloon observations.

8868-17, Session PMon

Angle-doppler resolved reflective tomography imaging lidar

Xiaofeng Jin, Luoyang Institute of Electro-Optical Equipment (China); Yi Yan, Luoyang Optoelectro Technology Development Ctr. (China); Peng Zhang, Chunhua Liu, Luoyang Institute of Electro-Optical Equipment (China); Jianfeng Sun, Liren Liu, Shanghai Institute of Optics and Fine Mechanics (China)

Angle-Doppler resolved reflective tomography using single-frequency continuous lasers has been shown to be an image reconstruction, which can be used to recover image information about an object with a non-imaging laser radar system. This paper presents a system of angle-Doppler resolved reflective tomography imaging Lidar. The resulting time-dependent return signal is collected by a non-imaging optical system, which provides a one dimensional signal about the target as a function of Doppler frequency after the short time FFT at each view. The issue between transverse range resolution and the sampling time of single angle is solved. We designed the condition of far-field diffraction in the laboratory, and collected the angle-Doppler reflective projections of the target. Filtered back-projection algorithm was used to reconstruct the cross section of the target. Because of the utilization of coherent detection of coaxial beams, both the imaging S/N ratio and the receiving sensitivity are improved. Due to the simplification in configuration and operations without involving signal phrase processing, this technique has a great potential for applications in extensive Laser radar imaging fields.

8868-20, Session PMon

Imaging resolution analysis using Fourier
slices theorem in reflective tomography laser radar

Yi Sin Yan, Luoyang Optoelectro Technology Development Ctr. (China); Xiaofeng Jin, Luoyang Institute of Electro-Optical Equipment (China); Shuping Zhou, Luoyang Optoelectro Technology Development Ctr. (China); Jianfeng Sun, Liren Liu, Shanghai Institute of Optics and Fine Mechanics (China)

Reflective tomography is one of the most promising high-resolution imaging methods for the remote objects. But in practical application, because of the sampling angle error and limited view of projections in signal collecting process, anisotropic resolution is inevitable and the reconstruction image quality of reflective tomography system degrades. Sampling angle error occurs because the detect angle range is so large that it is difficult to guarantee the consistency of the actual and theory situation, system error and noise can not be excluded. Insufficient projections data problems occur quite frequently because of practical constraints due to the imaging hardware, scanning geometry or target rotation. In this paper, the theoretical imaging resolution derived from Fourier-Slice theorem is presented, computer simulation and experimental verification are also given. Imaging analysis in this paper will make a complement and perfection of the theory in reflective tomography imaging lidar.

8868-1, Session 1

Isolated nanoinjection photodetectors for high-speed and high-sensitivity single-photon detection *(Invited Paper)*

Vala Fathipour, Omer G. Memis, Sung Jun Jang, Robert L. Brown, Iman Hassani Nia, Ryan M. Gelfand, Hooman Mohseni, Northwestern Univ. (United States)

Realization of a large number of emerging technologies such as quantum computing and quantum cryptography have been dependent on the challenging development of highly sensitive single photon detectors (SPDs) with high internal gain, high signal to-noise ratio (SNR) , low jitter, high quantum efficiency and fast response.

Our group has designed and developed a revolutionary new SWIR detector called the nano-injection detector presenting a stable internal amplification while operating at linear regime with low bias voltages. The nano-injector has a high SNR, a stable excess noise factor and exhibits sub-Poissonian noise levels with the Fano noise suppression. In addition, the nano-injector devices can be hybridized into sensitive imagers as they can be formed in high-density arrays and are fully compatible with CMOS technologies due to their low voltage requirements. Furthermore, the high internal amplification of the nano-injection detectors results in high SNR and suppresses later noise contributions such as ROIC noise or preamplifier noise. As such, the nano-injection detectors are viable candidates for SPD and imaging at the short-wave infrared band.

In the first generation of the nano-injector detector, our group developed a high gain low noise SWIR SPD based on a type-II material system at room temperature and bias voltages less than 1 V. We report on a high speed version of the detector that has maintained the excellent gain, low jitter and good noise performance but has significantly enhanced device speed by 5 orders of magnitude. This is achieved by passivating and laterally confining the carrier transportation.

8868-2, Session 1

Comparison of ultimate limits of interband cascade infrared photodetectors and single-absorber detectors

Robert T. Hinkey, Rui Q. Yang, The Univ. of Oklahoma (United States)

Interband cascade infrared photodetectors utilizing multiple discrete stages have been proposed as a means to achieve high performance infrared detectors at high operating temperatures. In this paper, we present a quantitative theoretical comparison of single- and multiple-stage infrared photovoltaic detectors. Specifically, we investigate the ultimate performance limits of infrared detector materials with a given absorption coefficient, diffusion coefficient, and interband generation-recombination properties. We assume detectors with bulk-like absorbers and show how the standard semiconductor transport and recombination equations can be extended to the case of multiple-stage devices. The contribution of both the generation-recombination and diffusion processes to the total current noise is evaluated by using the Ramo-Shockley theorem and the Weiner-Khintchine theorem. This provides a unified noise treatment accounting for both Johnson and shot noise. Using this formalism, we derive analytic expressions for the photocurrent and noise. Comparisons of single- and multiple-stage detectors under several conditions are presented. The magnitude of the improvement possible with the use of multiple stages depends on the number of stages used and the product of the absorption coefficient and minority carrier diffusion length of the absorber material.

8868-3, Session 1

Long-wavelength interband cascade infrared photodetectors with InAs/GaSb superlattice absorbers

Robert T. Hinkey, Lu Li, Hao Ye, Rui Q. Yang, Michael B. Santos, Matthew B. Johnson, The Univ. of Oklahoma (United States)

Improved performance of long-wave infrared (LWIR, 8-12 ?m) detectors may be possible with the use of multiple-stage interband cascade structures. Compared to single-absorber detectors, this type of architecture can achieve higher photon-photocarrier conversion

efficiencies for materials with small absorption coefficients and/or short diffusion lengths. This architecture also increases the diode resistance, thereby making the detectors less susceptible to parasitic noise sources, such as the pre-amplifier.

In this paper, we present our recent study of interband cascade infrared photodetectors capable of detecting in the LWIR region. These structures utilized p-type type-II InAs/GaSb superlattice absorbers, and were grown using molecular beam epitaxy on GaSb substrates. We investigated both two-stage and three-stage devices. In both structures, the first stage had an absorber with a thickness of 570 nm. The subsequent absorber thicknesses were varied across the structures in order to achieve a roughly equal number of absorbed and collected carriers in each stage. At 78 K, the cutoff wavelengths were ~12.8 ?m for the two-stage device and ~11.9 ?m for the three-stage device. The maximum zero-bias responsivities were 0.6 and 0.5 A/W for the two-stage and three-stage devices, respectively. These values are indicative of good carrier collection. However, the ultimate performance of the detectors from both structures was limited by high dark current. We found that despite some mismatch of photocurrent between the stages, the three-stage devices achieved higher values of D* and were able to maintain an observable zero-bias photoresponse for temperatures up to 170 K.

8868-4, Session 1

High-performance SWIR sensing from colloidal quantum dot photodiode arrays

Jay S. Lewis, Ethan J. D. Klem, Chris W. Gregory, Garry B. Cunningham, Dorota S. Temple, RTI International (United States); Arvind I. D’Souza, Ernest W. Robinson, DRS Sensors & Targeting Systems, Inc. (United States); Nibir K. Dhar, Defense Advanced Research Projects Agency (United States); Priyalal S. Wijewarnasuriya, U.S. Army Research Lab. (United States)

While InGaAs-based focal plane arrays (FPAs) provide excellent detectivity and low noise for SWIR imaging applications, wider scale adoption of systems capable of working in this spectral range is limited by high costs, limited spectral response, and costly integration with Si readout integrated circuits (ROICs). RTI has demonstrated a novel photodiode technology based on IR-absorbing solution-processed PbS colloidal quantum dots (CQD) that can overcome these limitations of InGaAs FPAs. The most significant advantage of the CQD technology is ease of fabrication. The devices are fabricated directly onto the ROIC substrate at low temperatures compatible with CMOS, and arrays can be fabricated at wafer scale. Further, device performance is not expected to degrade significantly with reduced pixel size. This combination of high performance, dramatic cost reduction, and multi-band sensitivity is ideally suited to expand the use of SWIR imaging in current applications, as well as to address applications which require a multispectral sensitivity not met by existing technologies.

We will present the results for both passive detectors fabricated on passive Si substrates and on ROICs. We will discuss recent advances in device architecture and processing that resulted in measured dark currents of 3 nA/cm2 at room temperature and sensitivity to ~1.7 µm. We will show other devices with spectral sensitivity that extends from UV to 2.2 µm. We will present D* for the ROIC-integrated devices and discuss the path forward for further performance improvements.

8868-24, Session 1

Advanced imaging systems programs at DARPA/MTO *(Invited Paper)*

Nibir K. Dhar, Defense Advanced Research Projects Agency (United States)

8868-5, Session 2

Effect of electrical contacts on quantum efficiency of near-infrared InGaAs detectors

Xue Li, Heng-jing Tang, Peng Wei, Hai-mei Gong, Tao Li, Shanghai Institute of Technical Physics (China)

InGaAs-based FPAs operated at room temperature are widely used in short wavelength infrared (SWIR) detection systems due to the demand of miniaturization, low cost and high reliability for night vision, spectroscopy, semiconductor wafer inspection, astronomy and military applications. Recently in order to improve the performance and extend wavelength of the detectors, a new type of InGaAs p-i-n photodiodes which consist of a n-type In0.52Al0.48As layer, intrinsic In0.53Ga0.47As absorption layer and p-type In0.52Al0.48As on InP substrate is also studied. I–V characteristics and spectral responses of the detectors were measured and quantum efficiencies of the detectors were investigated by signal and noise measurement system. Quantum efficiency ? of the detector is only 63%. The ideal factor nj and Schottky barrier of the Schottky junction between metals and the p-In0.52Al0.48As capping layer are 1.05 and 0.36eV, respectively, by fitting I-V curve. Schottky-type-like behavior is responsible for the lower quantum efficiency. The ohmic contacts and series resistance of detectors were largely improved by growing the thin p-InGaAs layer on the p-InAlAs layer. Spectral response of detector decreases slightly at the shorter wavelength, which has little effect on the quantum efficiency of the detector. Quantum efficiency of detector reaches up to 90%.

8868-6, Session 2

Embedded plasmonic-enhanced quantum well infrared photodetector

Robert L. Brown, Alireza Bonakdar, Omer G. Memis, Vala Fathipour, Sung Jun Jang, Hooman Mohseni, Northwestern Univ. (United States)

In order to lessen the strain of cooling requirements on mid-infrared detectors, reducing the volume of the detecting medium is one promising solution. It is necessary to augment the absorption (quantum efficiency) lost when shrinking the detector volume. A plasmonic structure has previously been reported on top of a Quantum Well (QWIP) device to improve quantum efficiency. This structure strongly enhanced absorption, but its configuration does not allow for a detector array. Due to the proximity of the plasmonic structure to the detecting medium, bump-bonding from the front would cover the plasmonic structure, and bump-bonding from the back would not allow for any isolation of devices without breaking. To address this issue, we have developed a method based on an embedded surface-plasmonic structure.

We present a QWIP with a plasmonic structure embedded within and around the detection media. Gold surrounds a hexagonal array of cylindrical pillars etched from a stack of QWIP, forming a self-aligned plasmonic-hole array designed for 8µm wavelength with an expected field enhancement of an order of magnitude. A planar dielectric lies on top of this structure, fills in around the pillars and lies nearly flush with the top of the detector stack. With this configuration, a planar top-contact is easily made and array formation with a strong enhancement is possible.

8868-30, Session 2

Photonic and plasmonic carbon nanohybrids for advanced optoelectronics applications *(Invited Paper)*

Judy Z. Wu, The Univ. of Kansas (United States)

Carbon-based nanostructures including nanotubes (CNTs) and graphene have superior electronic, optoelectronic and mechanical properties,

which provide fresh opportunities for designs of novel devices of extraordinary performance in addition to the benefits of low cost, large abundance, and light weight. This work explores a few such examples including type-II CNT/P3HT as well as CNT/graphene heterojunction infrared detectors, aligned ZnO nanowire/graphene hybrid ultraviolet detectors, and ionic-liquid gated plasmonic nanoparticle/graphene hybrid field-effect transistors for photo-detection in a wide spectrum selected by the localized surface plasmonic resonance frequency of the nanoparticles decorated on graphene. Critical to the high performance obtained on these devices are schemes that enable manipulation of photon absorption, exciton dissociation and charge as well as phonon transport at nanoscales. Micro/nanofabrication schemes for scaling up these devices will also be in consideration in order to achieve the compatibility with Si-based readout circuits.

8868-31, Session 2

Improvement in the sensitivity of methane detection using a double fast Fourier transform-based filter

Samira A. Mahdi, Univ. of Arkansas at Little Rock (United States); Edmond W. Wilson Jr., Harding Univ. (United States); Youhua Chen, Gary T. Anderson, Univ. of Arkansas (United States)

A multi-reflection cell has been employed to increase the sensitivity of the detection of methane gas. However, as the requirements of the detection system need to work on a low frequency range, the influence of the 1/f noise will be considered. This paper deal with this problem by investing the signal processing methods using Fast Fourier Transform (FFT) results have been shown an improvements of about 75% in the methane gas readings.

8868-7, Session 3

Optimization of performance for platinum nanowires as subwavelength bolometers

Pauline Renoux, Snorri Ingvarsson, Univ. of Iceland (Iceland); Dorine Charpentier, Institut National des Sciences Appliquées de Toulouse (France)

We fabricated nanoscale bolometers made of platinum wires framed by four contact pads, using e-beam lithography and metal deposition on SiO_2/Si wafers. The thin-film platinum wires have a width of 300 nm and a length of 1 µm. By illuminating the bolometers with light from a ceramic blackbody infrared source (1060 K, peak wavelength at 2.8 µm), we monitor the change in resistance in the structures depending on bias current. The relationship between resistance and temperature is given by : R=R_0 (1+??T)

Where R_0 is a constant and ? is the temperature coefficient of resistance (TCR) of platinum (0.002/K). With this simple equation we are able to characterize accurately the temperature change in the bolometers. From this data we extract two figures of merit for our devices, the responsivity R [V/W] and the detectivity D* [cmHz^{1/2}/W].

In previous works we studied the influence on performance of physical and operating parameters such as oxide thickness, bolometer dimensions or drive current. Lately we have been studying the role of platinum thickness on performance. Samples with a metallic sensing core of thickness between 10 nm and 80 nm were fabricated and characterized. Responsivity increased linearly as the thickness of the film was reduced. Eventually, the responsivity had increased by a factor of 3 for the thinnest sample compared to the thickest one, reaching 3.7x10^4 V/W. However, detectivity stays constant around 2x10^9 cmHz^{1/2}/W. The response time, according to our numerical estimations, of such bolometers is also reduced by a factor of 10 with the thickness decreasing, reaching a minimum value of 0.4 ns.

8868-9, Session 3

Research on multi-alkali cathode photoemission mechanism

Xiaofeng Li, Qian Guo, Qiang Lu, North Night Vision Technology Co., Ltd. (China)

In this paper, the spectral response and fluorescence spectrum of three Na2KSb multi-alkali cathodes without Cs activation, with Cs activation and with both Cs and Cs-Sb activation were measured. The measurement results show that, Na2KSb cathode after Cs activation, the cathode sensitivity was increased, long-wavelength cutoff wavelength was also increased, but the peak wavelength and peak intensity of fluorescence spectrum was essentially unchanged. The increase of long-wavelength cutoff wavelength shows that work function of cathode is reduced, so the Na2KSb cathode after Cs activation, the increase of cathode sensitivity and long-wavelength cutoff wavelength is due to the lower work function. Na2KSb cathode after both Cs activation and Cs-Sb activation, the cathode sensitivity and long-wavelength cutoff wavelength were further increased more substantial, but the peak wavelength and peak intensity of fluorescence spectrum was changed. The peak wavelength was shifted towards the short wavelength and peak fluorescence intensity was increased. The shift of peak wavelength toward short direction showed that energy level of transition electron was increased and increasing of peak intensity of fluorescence spectrum showed that number of transition electron was increased. For Na2KSb cathode with Cs activation and Cs-Sb activation, the increase of transition electrons number and transition electron energy level has a positive effect on the cathode sensitivity. Therefore the reasons of increase for cathode sensitivity and long-wavelength cutoff wavelength of Na2KSb cathode by Cs activation and Cs-Sb activation are the increase in the number of transitions and transition electron energy levels except for surface work function is reduced. Cathode surface electron escape mechanism is not yet conclusive, thus to improve the cathode sensitivity, further research is needed to figure out the objective law of cathode surface activation process. This will help to provide theoretical guidance to further improve cathode production process and to increase cathode sensitivity.

8868-10, Session 3

A measurement of the dielectric, conductance, and pyroelectric properties of MWCNT:PVDF nanocomposite thin films for application in infrared technologies

Matthew E. Edwards, John C. Corda, Michael J. Curley, Manmohan D. Aggarwal, Alabama A&M Univ. (United States)

In this work, we have determined the dielectric and conductance properties of multi-wall carbon nano-tubes (MWCNT) in poly vinylidene fluoride (PVDF) thin film composites as a function of temperature and frequency. The samples, ~ 24 microns in thickness, were measured in a temperature range from 40 to 60 0C and frequencies from 40 Hz to 10 MHz. Our samples were prepared by using the solution casting technique. These measures indicate that at constant temperatures, the real dielectric constant decreases at lower frequencies but rise at higher frequencies. The dielectric loss property, being a particular concern as it is directly proportional to the conductance, also decreases at lower frequencies but rise at higher frequencies with a steeper slope in each case. Additionally, we have measured pyroelectric coefficient in the same temperature range, compared the pyroelectric results with previous measures made on silver nanoparticle in PVDF thin films, and provided preliminary evidence of the causative microscopic mechanism. Our MWCNT:PVDF thin films yield higher figures of merit than that indicated by pure PVDT thin films. The results indicate a usage of MWCNT: PVDF thin films in infrared un-cooled sensors and vidicon technology.

8868-11, Session 3

CMOS compatible IR sensors by cytochrome c protein

Chien Jen Liao, National Taiwan Univ. (Taiwan)

Due to the progression of the semiconductor industry in recent years, the uncooled Infrared sensor, microbolometer, has opened the opportunity of achieving low cost infrared imaging systems for both military and commercial applications. Therefore, various fabrication process and different materials for microbolometers have been developed actively. The cytochrome c (protein) thin film has been reported as high temperature coefficient of resistance (TCR), which is related to the performance of microbolometer directly. The superior TCR value can improve the performance of microbolometer. In this paper, we introduced a novel fabrication process using aluminum which is compatible with the Taiwan Semiconductor Manufacture Company (TSMC) D35 2P4M process as the main structure material. These benefits the device to be integrated with readout integrated circuit (ROIC).The aluminum split structure is suspended by sacrificial layer utilizing the standard photolithography technology and chemical etching. The height and thickness of the structure are carefully considered. Besides, cytochrome c protein is ink-jetted onto the aluminum structure by using the inkjet printer with precise control. In measurement, incident Infrared radiation can be detected and later the heat can be transmitted to adjacent pads to send out the signal. The result showed that the TCR value of cytochrome c thin film exceeded 20% 1/k, ranging from room temperature to forty degrees Celsius. This approach applies an inexpensive and simple fabrication process and makes the device suitable for integration. In addition, the performance can be further improved with low noise readout circuits.

ZnMgO solar blind detectors: from material to systems *(Invited Paper)*

Mehdi F. Anwar, Abdiel Rivera, Anas Mazady, Hung Chi Chou, John W. Zeller, Univ. of Connecticut (United States); Ashok K. Sood, Magnolia Optical Technologies, Inc. (United States)

We will report the growth of ZnMgO nanowires (NW) using low pressure MOCVD. Substrate dependence NW growth will be discussed. We will present the incorporation of Mg up to 30%, on Si-substrate, demonstrating excellent material characteristics as determined by SEM, XRD and PL measurements. Fabrication of detectors arrays along with UV characterization will be reported.

8868-13, Session 4

On-line nonuniformity and temperature compensation of uncooled IRFPAs using embedded digital hardware

Alejandro Wolf, Rodolfo Redlich, Jorge E. Pezoa Nunez, Miguel E. Figueroa, Univ. de Concepción (Chile)

We present a model and a signal-processing scheme for compensating the nonuniformity noise and surrounding temperature self-heating effects on the response of uncooled microbolometer-based infrared cameras. The model for the nonuniformity considers pixelwise gain and offset parameters. The representation for the self-heating dynamics of the camera is an autoregressive moving-average (ARMA) model for camera's internal temperature. The scheme performs initially a two-point calibration at a known surrounding temperature. Next, without modifying the nonuniformity parameters, we dynamically compensate variations in the camera readout using both estimates of the ARMA model and measurements of the surrounding temperature taken by a simple sensor embedded in the camera. Tested on a CEDIP Jade UC33 camera, our system compensates reference black-body images with an error below 0.54 degrees Celsius in scenarios where the room temperature varied up to 14 degrees Celsius. Moreover, the regularity and simplicity of the algorithm enables us to implement it on embedded digital hardware, thereby reducing its cost, size, and power consumption. We implemented the algorithm on a Xilinx XC6SLX45 FPGA using fixed-point arithmetic. The circuit exhibits an arithmetic error of 0.06 degrees compared to a software double-precision implementation. It compensates 320x240-pixel video at up to 1,437 fps and 640x480-pixel video at up to 360 fps, using 1% of the logic resources of the FPGA, and less than 1 mW of dynamic power at 110 MHz. Adding Gigabit Ethernet communication, HDMI display, and a pseudocolor map on the chip uses only 10% of the resources and consumes in total 915 mW.

8868-14, Session 4

Radiation hardness by design for mixed signal infrared readout circuit applications

James Gates, Stephen D. Gaalema, Greg Pauls, Dave Dobyns, Bruce Wall, Black Forest Engineering (United States)

Readout integrated circuits (ROICs) to support space-based infrared detection applications often have severe radiation tolerance requirements.

Radiation hardness-by-design (RHBD) significantly enhances the radiation tolerance of commercially available CMOS and custom radiation hardened fabrication techniques are not required. The combination of application specific design techniques, enclosed gate architecture nFETs and intrinsic thin oxide radiation hardness of 180 nm process node commercial CMOS allows realization of high performance mixed signal circuits. Black Forest Engineering has used RHBD techniques to develop ROICs with integrated A/D conversion that operate over a wide range of temperatures (40K-300K) to support infrared detection. ROIC radiation tolerance capability for 256x256 LWIR area arrays and 1x128 thermopile linear arrays is presented. The use of 130 nm CMOS for future ROIC RHBD applications is discussed.

8868-15, Session 4

Wavelength stabilization of electrostatically actuated micromechanical infrared Fabry-Pérot filters

Jörg R. Schröter, Sebastian Lehmann, Martin Ebermann, Norbert Neumann, InfraTec GmbH (Germany)

It is well known that many gases, fluids and solids yield material specific absorption spectra within the infrared range. Tunable MEMS Fabry-Pérot filters (µFPF) can be applied in miniature sensors, which identify certain substances that are optically active in mid-wavelength infrared. Researchers focus on improving accuracy, sensitivity and robustness of such sensors in order to enable their usage in rough environments as well as in portable devices..

We use bulk micro-machined µFPF with Bragg-reflectors deposited on thick carriers, one fixed and the other suspended by springs. It is actuated electrostatically to tune the reflector distance and hence the filter wavelength. Compared to surface micro-machined devices, this design opens path to higher optical performance due to high parallelism of substrates, but introduces the drawback of acceleration sensitivity because of a moving mass.

To overcome this problem, the filter is driven by a closed-loop control, wherein position feedback is given by an ASIC that directly measures the actuator capacitance, without the need of area-consuming sensing electrodes. We have developed a PI-based controller that adapts to the nonlinear stiffness and damping by recalculating the controller parameters in real-time, depending on the current position. Basic system parameters are derived from optical (FTIR) calibration and step-response measurements. The tuning range was 1300 nm in the mid-wavelength infrared with control voltages up to 35 V. At 5 Hz sinusoidal accelerations of 1 g, we improved the filter wavelength accuracy from ±35 nm in the open-loop case down to ±2 nm in closed-loop operation.

8868-18, Session 5

Modelling of MG-Y laser tuning characteristics

Juraj Poliak, Brno Univ. of Technology (Czech Republic); Hilmar Heininger, Friedemann Mohr, Pforzheim Univ. (Germany); Otakar Wilfert, Brno Univ. of Technology (Czech Republic)

For many years, tuneable lasers were mainly utilized in spectroscopic applications. However, in last years they are becoming employed in other industrial applications as well, e.g. optical fibre sensors for optical remote sensing (distributed fibre optical sensing). Mechanical tuning of lasers decreases their performance, e.g. the tuning speed and the tuning repeatability. Lately, a Modulated Grating Y-branch (MG-Y) laser Syntune S7500 has been introduced using a novel and fully electronic laser tuning with combination of two individually tuned Bragg gratings and tuning of the phase difference. The tuning is carried out by means of changing three currents offering wide tuning range in the whole C band, fast-speed tuning capabilities and high-power output on a single chip.

The MG-Y laser is currently being used solely for telecommunication applications, where the wavelength is chosen from the ITU grid containing 89 channels at 50 GHz spacing by means of tuning three currents listed in a look-up table (LUT). To fully exploit the tuning properties of the device in sensor applications, the tuning step must be as small as possible. This requirement increases the size of the LUT and slowing down the tuning process.

In this paper we propose an analytical approach of describing the tuning properties of the MG-Y laser by means of analytical description of the wavelength dependence of the three tuning currents. The model is based on the theoretical analysis and it was experimentally verified. The results of experiments are included in the second part of the paper. Finally, we conclude with the discussion on the model precision and applications.

8868-19, Session 5

Mechanically induced long-period fiber gratings in Er3+ fiber for structural health monitoring

Maria G. Pulido-Navarro, José A. Alvarez-Chavez, Ctr. de Investigación e Innovación Tecnológica (Mexico); Daniel E. Ceballos-Herrera, Univ. Autónoma de Nuevo León (Mexico); Ponciano J. Escamilla-Ambrosio, SEGOB (Mexico)

This work presents preliminary results on wavelength sensitivity due to mechanically induced long period fiber grating (LPFG) on both standard single-mode and Er-doped fibers. The work presents and compares results for both types of fibers under different torsion conditions. In order to apply the torsion one of the fiber ends is fixed while torsion is performed on the other end. A LPFG whose period is 503 μm is used to press the fiber after the torsion, this will allow for micro curvatures to be formed on the fiber, which will in turn generate a periodical index perturbation on it. Here, it was noted that the rejection band shifts to longer wavelengths for Er-doped fibers. It was detected that for torsion of 6 turns applied to 10 cm doped fiber the wavelength peaks can be moved up to 25 nm, which is longer than similar results reported on standard fibers. Therefore, by using Er-doped fibers this technique will give more sensitive and accurate results on the real conditions of the structure under study. These results can be employed for sensing applications, especially for small to medium size structures, being these structures mechanicals, civil or aeronautical. Theoretical calculations and simulations are compared for experimental results validation and will be included in the presentation.

8868-26, Session 5

Heteroengineering infrared detectors with type II superlattices *(Invited Paper)*

Sanjay Krishna, The Univ. of New Mexico (United States)

Type II superlattices in the InAs/GaSb system provide a lot of band engineering flexibility. A wide variety of unipolar barriers have been investigated in this material system. In this talk, I will review some of our work on unipolar devices and review the fundamental limiting mechanisms for these detectors.

8868-27, Session 5

Development of large-area nanostructured AR coating for EO/IR sensor applications

Ashok K. Sood, Roger E. Welser, Gopal G. Pethuraja, Magnolia Optical Technologies, Inc. (United States); Nibir K. Dhar, Dennis L. Polla, Defense Advanced Research Projects Agency (United States); Priyalal S. Wijewarnasuriya, U.S. Army Research Lab. (United States)

MWIR type-II InAs/GaSb superllatice cascade photodetectors *(Invited Paper)*

A. Kowalewski, W. Pusz, W. Gawron, Military Univ. of Technology (Poland); E. Plis, S. Krishna, The Univ. of New Mexico (United States); A. Rogalski, Military Univ. of Technology (Poland)

Recently, a new strategies used to achieve high operation temperature (HOT) detectors include barrier structures such as nBn, material improvement to lower generation-recombination leakage mechanisms, alternate materials such as superlattices and cascade infrared devices. Another method to reduce detector's dark current is reducing volume of detector material via a concept of photon trapping detector.

In this paper, the performance of a novel HOT detector designs, so called interband cascade type-II MWIR InAs/GaSb superlattice detectors, is presented. Detailed analysis of the detector's performance (such as dark current, RA product, current responsivity, and response time) versus bias voltage and operating temperatures (220 – 400 K) are performed pointing out optimal working conditions. At present stage of technology, the experimentally measured R0A values of interband cascade type-II superlattice detectors at room temperature are higher than those predicted for HgCdTe photodiodes.

Multiscale modeling of photon detectors from the infrared to the ultraviolet *(Invited Paper)*

Enrico Bellotti, The Boston Univ. Photonics Ctr. (United States)

Due to the ever increasing complexity of novel semiconductor systems, it is essential to possess design tools and simulation strategies that include in the macroscopic device models the details of the microscopic physics and their dependence on the macroscopic (continuum) variables. Towards this end, we have developed robust multi-scale modeling capabilities that begin with modeling the intrinsic semiconductor properties. Using techniques such as the empirical pseudopotential method or density functional theory we calculate the band structures of semiconductor alloys and their constituent binary compounds. Then, using the Monte Carlo method we analyze characteristics such as the high field carrier transport, radiative recombination and Auger recombination rates. The models are fully capable of incorporating effects of substrate driven stress/strain and the material quality (dislocations and defects) on microscopic quantities such as the local transport coefficients and non-radiative recombination rate. We then use the microscopic material parameters as an input into device simulations. Using a finite-difference time-domain (FDTD) approach we have analyzed the electromagnetic response of semiconductor devices, computed the carrier generation rate in the device and evaluated the reflectance. We then use the finite element method (FEM) to perform drift-diffusion simulations which use the optical generation rate from the FDTD simulations as an input. In the FEM simulations we simultaneously solve the carrier continuity and Poisson equations on a three-dimensional finite element grid to compute the photo-current and subsequently the quantum efficiency and modulation transfer function. Using this modeling approach we have extensively studied infrared focal plane arrays. Particular emphasis was placed on HgCdTe and InAsSb arrays incorporating photon trapping structures as well as two-color HgCdTe detectors arrays.

Unleashing giant TCR from phase changes in carbon nanotube composites for EO/IR sensor applications *(Invited Paper)*

Gustavo E. Fernandes, Jin Ho Kim, Jimmy Xu, Brown Univ. (United States); Ashok K. Sood, Magnolia Optical Technologies, Inc. (United States)

We review our recent work on carbon nanotube-polymer nanocomposites with a phase-change polymer. This nanocomposite is found to achieve very large temperature coefficient of resistance (TCR), ≈? 10%/ ° C, which is about one order of magnitude larger than the TCR observed in other carbon nanotube materials to date. The giant TCR results from a volume-phase-transition that directly changes the tunneling resistances that electrons experience in moving between nearby carbon nanotubes. We studied the bolometric photoresponses of this new material and found that the bolometric figures of merit, namely the responsivity and time constant, are also strongly affected by the phase transition. The nanocomposite's enhanced responses to temperature and humidity give it strong potential for sensor applications and uncooled infrared detection.

Evapotranspiration analysis based on topography algorithm in the Yellow River Delta

Jicai Ning, Zhiqiang Gao, Yantai Institute of Coastal Zone Research (China); Wei Gao, USDA UV-B Monitoring and Research Program, Natural Resource Ecology Laboratory, CSU (United States)

Remote sensing provides an approach to monitor land surface energy and water balance on regional scale simultaneously, which is very important and useful in researches and applications in global climate change, hydrology, ecology and agriculture etc. Evapotranspiration (ET) may be used as an ecological indicator to address the ecosystem complexity. The accurate measurement of ET is of great significance for studying environmental sustainability, global climate changes, and biodiversity. Remote sensing technologies are capable of monitoring both energy and water fluxes on the surface of the Earth. With this advancement, existing models, such as SEBAL, S SEBI and SEBS, enable us to estimate the regional ET with limited temporal and spatial coverage in the study areas. Exchanges of materials and energy flows were more complex in the Yellow River Delta with the interaction between the land and the ocean. Based on the widely and successfully applied SEBAL model, topography correction (slope, aspect and elevation) for some model parameters, automatically detection the dry and wet pixels and effectively simulated the evapotranspiration (ET) of the water body have been done to establish the regional ET remote sensing model in the context of digital elevation model (DEM), expanding the application of the regional ET remote sensing model. Taking into account the terrain factors, we modified the algorithm of SEBAL model . Results showed that, the modified inversion method of evapotranspiration can better reflect actual evapotranspiration condition. Evapotranspiration changes were consistent with climate and land use change through a multi-phase inversion results.

Monitoring on urbanization of Shanghai in recent fifteen years based on remote sensing

Chong You, East China Normal Univ. (China)

Since 1995,“the land use/land cover change”study plan was internationally put forward,it has become one of the hot topics in global studies.Shanghai is China’s largest city and economic center.For 15 years,it has been through the reform of socialist market economy,Pudong development,population expansion and city building boom.Therefore,the study Shanghai region’s land use change has important sense.
Based on the interpretation of remote sensing data and GIS software support,using Shanghai 1990,2000 and 2005 three issue of interpretation of remote sensing data,I has been working on Shanghai city’s nearest 15 years land use/land cover information extraction and statistical analysis.Methods are including city expansion intensity index,buffer analysis and spatial variation analysis.And I studied Shanghai city land use change rule in recent 15 years,city land spatial pattern change and its driving force. Through the study,the main conclusions are: (1) Shanghai’s urbanized increased from 10.77% in 1990 to 32.96% in 2005,increased 22.19% in total.The main performance is the increase of city construction land,industrial land and traffic land.Among them,the growth rate from 1990 to 2005 is 0.43% and the growth rate from 2000 to 2005 is 1.99%;(2)From the buffer analysis,urbanized area mainly concentrated in the city center district within 12km in 1990,and farmland mainly concentrated out of 12km;In 2000,urbanized area extend to the scope of the 20km;And in 2005,urban land extend to the scope of the 40km,And appeared a peak in the 60km.It shows that the urbanized area of Shanghai is increasing year by year; (3)Spatial growth direction characteristics:in the past 15 years in Shanghai’s urbanized area in different orientations of the expansion differed.Overall, from 1990 to 2005,Shanghai city urbanized area mainly extended to the northeast,Southeast and southwest.(4)Human driving factors such as the economic factors,demographic factors and technical factors and other factors drive significantly on Shanghai city urbanized area change.

Analysis trends of ultraviolet B fluxes in the continental US with USDA and TOMS data

Zhiqiang Gao, Institute of Geographical Sciences and Natural Resources Research (China); Wei Gao, Colorado State Univ. (United States)

Many environmental factors, such as stratospheric ozone, aerosols, and clouds, may affect ultraviolet (UV) irradiance. The aim of this study is to investigate the possible association between ultraviolet B (UVB) radiation and total cloud amount, ozone, and aerosols simultaneously, leading to the assessment of possible impacts of climate change on UVB flux variations in the Continental United States (US). Spatiotemporal correlation analyses are conducted based on data collected from the Total Ozone Mapping Spectrometer (TOMS) and the International Satellite Cloud Climatology Project (ISCCP) with a geographic information system (GIS).

8869-16, Session PMon

Concomitant flow and space variations of evapotranspiration due to changes in LUCC under seawater intrusion in a coastal region

Zhiqiang Gao, Xiaoming Cao, Institute of Geographical Sciences and Natural Resources Research (China); Wei Gao, Colorado State Univ. (United States)

This paper will provides a coherent pattern identification analysis of coastal land use and land cover (LULC) under the impact of seawater intrusion. This study analysis applied the 4-, 3-, and 2-band false color composite Landsat satellite data to characterize the LULC in the study area. The evapotranspiration (ET) and heat fluxes will be estimated by using the SEBAL model with two-time phase thermal infrared band images and regional surface parameters. This will allow for the eventual linkage of seawater intrusion to land use and land cover change (LUCC) and ET variations over time. The spatial distribution pattern and change characteristics of ET will be formed by double driving forces of seawater intrusion and LUCC under the background effects of regional climate.

Keywords: Evapotranspiration, Land use and land cover, Remote sensing, Seawater intrusion.

Assessment of ozone pollution monitoring based on improved regional assimilation meteorology field in the WRF-Chem model

Yan-an Liu, Chaoshun Liu, Wei Gao, Runhe Shi, East China Normal Univ. (China)

Air quality has become a social issue concerned by publics, especially in Shanghai, a city with rapid economic development. The research uses the improved meteorology field provided by regional assimilation system

as the input field of WRF-Chem model, and then compares the forecast ozone data with the observations. The results show that the relationship between the forecast ozone concentration and observations is consistent in whole, and the forecast at 24h is better, but gradually decreases with the increase of forecast time?the model has an outstanding ability on the strong ozone day forecast; the prediction error of ozone also has a high relation with the simulation accuracy of model precipitation; the improved meteorology field obviously reduces the errors of ozone forecast. Therefore, the ozone forecast based on the improved regional meteorology field at the WRF-Chem model will not only provide decision-making data for the sake of building a green city, but also plays an important instructional role in controlling the air pollution and urban smog.

8869-18, Session PMon

Interpolation of XCO2 retrieved from GOSAT in China using fixed rank kriging

Cong Zhou, Runhe Shi, East China Normal Univ. (China)

Greenhouse Gases Observing Satellite (GOSAT) can provide high accuracy column-average dry air mole fractions (XCO2), however, the observations also have large gaps because of the impact by cloud and the observational mode. Kriging interpolation yeilds best linear unbiased predictor, it will be a computational work if the dataset is large. Fixed Rank Kriging (FRK) is based on the Spatial Random Effect (SRE) model, which assumes that the process of interest can be expressed as a linear combi-nation of spatial basis functions, plus a fine-scale-variation component. FRK predictors and standard errors can be computed rapidly. This paper analyzed the FRK prediction of GOSAT Level2 XCO2 data over China. The result shows that FRK prediction is cocurrent with other Kriging methods (e.g. Ordinary Kriging). In addition, the result agrees well with the station measurements at Mt. Waliguan and Shangdianzi.

8869-19, Session PMon

Typhoon observations from multiple satellite imagery

Jingsong Yang, The Second Institute of Oceanography, SOA (China)

MTSAT (Multi-functional Transport SATellite), FY-2 (Fengyun, Chinese meteorological satellite) and EOS MODIS (MODerate-resolution Imaging Spectroradiometer) optical imagery and Envisat ASAR (Advanced Synthetic Aperture Radar) imagery were used to analyze the typhoons in the Western North Pacific from 2005 to 2011. While MTSAT, FY-2 and MODIS observe the cloud-top of typhoons, SAR observes the footprints of typhoons on the sea surface by penetrating the clouds. Several cases of typhoons are used to compare the typhoon eyes observed by SAR (on the sea surface) with optical (on the cloud top) images. Typhoon eyes were retrieved by using wavelet analysis. Furthermore, the best track data from the Joint Typhoon Warning Center (JTWC), Chinese Meteorological Administration (CMA), and the Japan Meteorological Agency (JMA) are used for the calibration and validation. Large horizontal distance between typhoon eyes on the ocean surface and on the cloud top is found.

Research review on observing atmospheric aerosols optical depth by means of multifilter rotating shadowband radiomete

Man Yi Wang, East China Normal Univ. (China)

Atmospheric aerosols play an important role in the transmission of the solar radiation and formation of atmospheric haze,so that the research of aerosol became a focus point. Multifilter rotating shadowband radiometer (MFRSR) has gradually become a more and more widely tool to observe atmospheric aerosols optical depth in the world. It uses automated rotating shadowband technique and excellent diffuse scattering detector to alternatively measure total horizontal and diffuse horizontal irradiances at seven wavelengths simultaneously, and then deduce direct normal irradiance. In this paper, the instrumentation, the different methods of calibration and data processing are introduced. And we also compare the results of MFRSR and AERONET data in order to illuminate the reliability of observed aerosol optical depth with MFRSR. In addition, the reasons of possible error are analysised, and the trend of observing aerosols optical depth by means of MFRSR is discussed.

8869-21, Session PMon

Analyzing the nonstationary space relationship of city greenness degree and social economic conditions in Shanghai, China using OLS and GWR models

Kejing Wang, Yuan Zhang, Youzhi An, Zhuoxin Jing, East China Normal Univ. (China); Wei Gao, East China Normal Univ. (China) and Colorado State Univ. (United States)

The purpose of this research is to explore the non-stationary relationship between socio-economic conditions and greenness across shanghai ,China, using Ordinary Least Squares (OLS) and geographically weighted regression (GWR). The analysis integrates environmental data on vegetation cover, using Normalized Difference Vegetation Index (NDVI) values derived from 2003 Shanghai MODIS imagery to reflect the city green degree level, conducted at the census block group level for shanghai. To explore regional variations in the relationship, City-wide OLS and local GWR models are developed by regressing mean NDVI against three independent variables generated by regressing each of the following socio-economic variables –urban land use, GDP and population density . Research shows that a considerable distinctive spatial variation exists in the relationship for each model and these models indicate that the strength and character of the relationship among the variables varies spatially. Results also indicates that GWR model has superior effect and higher precision than the OLS model at the scale of census block group and should be used for regional scale spatial analysis to account for local effects and geographical variation. From the paper we can see that while urban land use and population density are the impact factors of negative inflience of vegetation vigor in some neighborhoods in shanghai, this relationship changes drastically across the big important chinese city environment.

Application of genetic algorithm in atmospheric carbon dioxide concentration retrieval

Jingyao Li, Runhe Shi, East China Normal Univ. (China); Wei Gao, East Chine Normal Univ. (China) and Colorado State Univ. (United States)

This paper introduced the basic theory and methods of CO2 retrieval whose key step is to search for the optimal solution. Genetic Algorithm is an efficient random search algorithm, which can avoid the local optimization effectively. In this paper, the basic principles of Genetic Algorithm in CO2 retrieval were investigated and the corresponding encoding and decoding method and the fitness function were designed. The Genetic Algorithm is then applied to retrieve atmospheric CO2 concentration from a three years AIRS observations dataset. The retrieval results agreed well with the aircraft measurements with 1.13ppmv RMS errors and clear season cycles.

The differences analysis of UHI character between air temperature and LST

Ke Liu, Xingfa Gu, Institute of Remote Sensing and Digital Earth (China); Wei Gao, East China Normal Univ. (China); Zhiqiang Gao, Institute of Geographical Sciences and Natural Resources Research (China)

Though LST (Land Surface Temperature) show some similar spatial and temporal patterns to UHI (Urban Heat Island) effect for air temperatures, there were significant differences. This paper was based on the 2006 Landsat TM remote sensing images, the 2006 general weather information?include air temperature, precipitation, atmospheric pressure, sunshine and wind power ?of 10 Shanghai meteorological stations four times per day (02:00, 08:00, 14:00, 20:00 (UHT+8)), and the 2006 MODIS LST data of Shanghai region at the nearly same time (01:30, 10:30, 13:30, 22:30 (UHT+8)). First, a 2006 land cover classification of the Shanghai region was derived using Landsat TM image. Second, under calm, clear weather conditions, Contrast and analysis of UHI of air temperatures and LST had been studied, included the analysis of the general characteristics of UHI based on LST and air temperature, the time of day and season of maximum UHI development, the relationship between land use and UHI intensity, the spatial UHI intensity variability by day and season. And in the end, we studied the possible reasons of the relationship between these differences and satellite sensor, observation time, land cover of underlying surface of meteorological stations, and near _surface heat fluxes.

8869-24, Session PMon

Relationships between urban heat island effect and land use around weather stations

Ke Liu, Institute of Remote Sensing and Digital Earth (China); Wei Gao, East China Normal Univ. (China); Xingfa Gu, Institute of Remote Sensing and Digital Earth (China); Zhiqiang Gao, Institute of Geographical Sciences and Natural Resources Research (China)

Based on the relationship between various underlying surfaces intercepted from the different-radius circular buffer zones (the radius is respectively 1, 2, 4, 8km, with 10 Shanghai weather stations as their center) and their corresponding air temperatures (four times per day , 0200, 0800, 1400, 2000(LST)). It is found that a strong positive correlation between construction land and UHI, and a negative correlation between woodland/grassland and UHI. There is a relatively strong positive correlation between water bodies and UHI at night. The influence of different types of underlying surfaces on UHI varies with different hours every day. As far as range of influence is concerned, construction land is within 6 km, woodland/grassland is within 4 km, farmland influence reaches its peak at 4 km, influence of water body is uncertain. At last, it is mainly discussed the possible reasons for how the correlation between different underlying surfaces and UHI can be formed. And based on land use around weather Stations and the population data of town (should be county/district in china), it is discussed the conditions surrounding the normal rural station from which urban effects are to be calculated.

A simple estimation model of aerosol optical thickness based on meteorological station observed atmospheric visibility

Zhu Li, Jianyu Chen, The Second Institute of Oceanography, SOA (China)

Aerosol optical thickness(AOT) and atmospheric visibility are two important weather parameters. AOT reflects the state of the atmosphere and atmospheric visibility is widely used in various aspects of social life. Generally, it is reported in literatures that both of them are effected by Air Pollutants and other meteorological factors, such as surface pressure, ground temperature, wind speed, precipitation. In this paper, a statistic relationship expression is established between AOT and atmospheric visibility on the basis of the point-to-point meteorological observations. Based on observed data provided by the main national meteorological stations throughout China, the relevant analysis has been carried out between the Air Pollution Index(API) and the sunphotometer aerosol optical thickness. In the national region, the correlation between atmospheric visibility and weather factors indicates that the surface pressure has great influence on atmospheric visibility all the year round. And the influence based on precipitation is more obvious in spring and summer, meanwhile wind speed and temperature play important roles in autumn and winter. A significant positive correlation was found between AOT and API. To express the relationship between atmospheric visibility and AOT, some computable models were utilized, including linear function, logarithmic function, cubic curve, power function, inverse function and so on. According to the accuracy analysis, the cubic curve model and the power function model are more accurate. And both R Square of them is higher than 0.47. But the coefficient of cubic curve is more complex in practice. Finally, a simple estimation model of aerosol optical thickness based on meteorological station observed atmospheric visibility was conducted using power function. The Pearson coefficient between calculation of power function and observation is 0.73.

Effect of nitrogen stress on relationship of PRI and LUE during winter wheat growth period

Jianmao Guo, Nanjing Univ. of Information Science & Technology (China)

Light use efficiency (Light-Use Efficiency, LUE) is an important parameter for GPP and and NPP estimation model, cause by the existing model method to estimate the actual LUE is always simple and rough, which may lead to serious bias by GPP and NPP. The photochemical reflectance index (Photochemical remote sensing Reflectance Index, PRI) has great potential for direct estimation the actual LUE. In this paper, wheat in different nitrogen treatments was designed in field trial during Wheat growing period, for obtain photosynthesis and reflective hyperspectral data, and then LUE and PRI was calculated in critical period of wheat growth. The results show that, at different growth stages under three different nitrogen conditions, LUE and PRI value were significantly increased with increasing nitrogen absorption; Last longer, more capable of absorbing nitrogen amount, the correlation between LUE and PRI was better?for example, the correlation coefficient is obviously larger in heading stage than elongation stage for same nitrogen treatment.

Absorption coefficient of CDOM in Zhejiang coastal waters

Guannan Fan, Zhihua Mao, Peng Chen, Haiqing Huang, The Second Institute of Oceanography, SOA (China)

Chromophoric dissolved organic matter (CDOM) exists in all natural waters. Researches on optical properties of CDOM play an important role in ocean color remote sensing retrieval. The optical properties of CDOM in Zhejiang coastal waters were investigated from August 18 ,2009 to June 9 ,2011 covering four seasons. In this paper, CDOM light absorption parameters were researched in Zhejiang province and its adjacent waters to achieve the following objectives: 1) According to CDOM absorption coefficients measurement data of this voyage, the geographical

distribution and its influencing factors of the absorption coefficient values of CDOM were explored; 2)The relations of CDOM absorption values and salinity have been used to reaserch the of mixing behavior of CDOM to explore the behavior of CDOM mixing process of the study area. Based on the measured data, the distribution of the absorption coefficient of CDOM was analyzed. The results showed that absorption coefficient at 440 nm (a(440)) decreased with the offshore direction, and the relatively high value of a(440) was observed generally in the coastal waters and low value in the adjacent waters.The distribution reflected the terrigenous origin characteristics of CDOM .The relationship between salinity and a(440) of the four seasons was discussed. The results demonstrated that a(440) had a significant negative linear relationship with the salinity.That is to say,CDOM took on the conservative behavior in the research region.

A new algorithm based on spectral differences for red tide monitoring in the East China Sea

Xiaohui Xu, South China Sea Institute of Oceanology (China) and Graduate Univ. of the Chinese Academy of Sciences (China); Delu Pan, Zhihua Mao, Bangyi Tao, The Second Institute of Oceanography, SOA (China)

Red tide is an ecological anomaly phenomenon in which phytoplankton, protozoa or bacteria in seawater suddenly proliferate or aggregate under certain environmental conditions and within a period of time, resulting in seawater discoloration. Red tide not only destroys marine fishery production, deteriorates the marine environment but also causes human health problems. In China, the East China Sea has a high incidence of red tide disasters; both the frequency and area of red tides are significantly higher than in other regions. Remote sensing technology has been proven the most effective means of monitoring red tides. Red tide organisms accumulate and cause the water color change, which alters the water spectral characteristics that can be detected by remote sensing. Spectral information of red tide water is therefore an important basis for establishing red tide remote sensing monitoring models. This paper analyzes and compares differences in red tide event spectral curves and multiyear monthly averaged spectral curves, and develops a red tide monitoring algorithm based on the background field, to extract red tide information of the East China Sea. This algorithm is applied to red tide events in that sea, find that the algorithm can effectively determine the location of red tide, with good correspondence to results from an official bulletin. This demonstrates that the algorithm can effectively extract red tide information.

Inversion of water quality parameters in the Hangzhou bay based on the high-resolution satellite HJ-1A/B imagery

Qinghui Meng, Zhihua Mao, Haiqing Huang, Yuzhang Shen, The Second Institute of Oceanography, SOA (China)

HJ-1A/B were two small satellite constellations, that were launched for the environment and disaster monitoring and forecasting on September 6th, 2008. This paper focused on the inversion method of water quality parameters in the dynamic water bodies of the Hangzhou bay with HJ-1A/B satellite imagery. First, the atmospheric correction of HJ-1 A/B CCD imagery was carried out using fast line-of-sight atmospheric analysis of spectral hypercubes (FLAASH) model, in which aerosol optical depth was retrieved from synchronous MODIS-Terra data. Then, the inversion of water quality parameters were performed based on the classical band ratio algorithms, which have been modified in order to be applied to the inversion of the case 2 water. The retrieval algorithm for total suspended particle matter was based on the classical red/green band ratio algorithm and corrected with an exponential term which would give a better result on high suspended matter concentration area. For the chlorophyll-a concentration retrieval algorithm, the blue/green band ratio algorithm is also corrected for the influence of non-pigmented particle to give feasible outcome for the TSM dominated area. As for the Secchi Disk Depth, two band reflectance ratio exponent method is applied. To verify the inversion result, the synchronized in situ data were used. The mean relative errors of the retrieved water quality parameters are less than 40%. Results reveal that the inversion accuracy of water quality parameters in case 2 water can be improved with using HJ-1A / B satellite imagery.

Retrieving rice yield and biomass from Radarsat-2 SAR data with artificial neural network (ANN)

Zhuoxin Jing, Yuan Zhang, East China Normal Univ. (China)

Abstract?Estimating crop yield using remote sensing is a key research and application field in agricultural remote sensing. A practical scheme for estimating rice yield from Radarsat-2 data is presented, which demonstrates that Radarsat-2 data can be an important data source for monitoring rice system and estimating rice yield. Artificial neural network (ANN) method was provided for rice yield estimation based on the relationship between the backscattering coefficients of Radarsat-2 data and rice parameters. The rice backscattering coefficients were extracted from multi-temporal Radarsat-2 images, which were combined with the observed rice parameters at field in Aug. 21 (heading stage) and Sept. 14 (maturing stage) to establish the optimal ANN. The rice yield and biomass in Aug. 21 and Sept.14 were retrieved based on the trained network, respectively. And the spatial distribution maps of rice yield and biomass were produced for each rice pixel. By comparing the retrieved results and the measured data, it showed that rice yield and biomass in Aug. 21 and Sept.14 errors were estimated with the root mean square error (RMSE) at approximate 147.09g/m2?170.49 g/m2?226.03 g/m2, respectively. The result indicates that integration of Radarsat-2 data and ANN method can be applied to efficiently estimate rice yield and biomass with acceptable accuracy.

Extracting desertification in Mongolian Plateau based on NDVI-Ts space

Xiaoming Cao, Juanle Wang, Institute of Geographical Sciences and Natural Resources Research (China); Zhiqiang Gao, Yantai Institute of Coastal Zone Research (China)

Combining the spectral vegetation index with thermal infrared information, the triangular space of NDVI-Ts based on satellite remote sensing data provides and effective method for monitoring. Vegetation-Temperature Condition Index (VTCI) based on the triangular space of MODIS NDVI-Ts is applied to monitoring desertification in Mongolian Plateau from 1990 to 2010. The VTCI is based on satellite derived information only, and therefore the index is potential for operational application. It's found that the space of NDVI-Ts for the whole study area is typically triangular because the monitored area is large enough to make the value of NDVI and soil moisture vary in a very large scope. Then, a linear regression analysis is conducted to get the equations of the dry and wet line from the triangular space for the whole area, and the VTCI for the Mongolian Plateau is extracted. Combined with MODIS land cover product IGBP and frequency distribution of the VTCI, the spatial pattern and temporal evolution of the drought are also analyzed. At last, the ground-measured precipitation data at the same periods are used to validate the drought monitoring measurements.

The results show that the drought widely distributed in spatial scale and is very serious. It is more serious in Mongolia than that in inner-Mongolia. In different periods, there would be some differences between Mongolia and inner-Mongolia. The correlation analysis between VTCI and ground-based measured precipitation indicates that there is a signification linear

correlation between VTCI and total monthly precipitation. The VTCI and cumulative total monthly precipitation are also linearly correlated from the monitoring month to the previous months. Obvious correlation is also found between VTCI and the cumulative percentage of departure from normal monthly precipitation from the monitoring month to the previous months.

Deriving leaf chlorophyll content of green-leafy desert plant (Haloxylon ammodendron) from hyperspectral reflectance

Xiaoming Cao, Institute of Geographical Sciences and Natural Resources Research (China); Zhiqiang Gao, Yantai Institute of Coastal Zone Research (China); Juanle Wang, Institute of Geographical Sciences and Natural Resources Research (China); Xi Chen, Anming Bao, Xinjang Institute of Ecology and Geography (China)

Many fundamental ecosystem properties and dynamics are monitored by plant water status, particularly in arid ecosystem where water is usually limiting. Although plant water status have been widely assessed using field measurements by ecological methods, approaches for remotely sensing plant water status are largely lacking, particularly diurnal water status. In arid ecosystem, water use efficiency (WUE) is likely to be a target of natural selection. WUE is not only an indicator of diurnal and dynamic water status, but also the integrated index of including photosynthesis and transpiration procession. In our study, the experiments were conducted on native dominant desert shrub, Haloxylon ammodendron, in their original habitats on the southern periphery of Gurbantonggut desert, Central Asia. We explored simple and useful spectral indices for estimating diurnal WUE at a leaf scale based on diurnal measurements of spectral reflectance, photosynthesis and micrometeorological variables. According to the statistical analysis of relationships between spectral indices and WUE estimation, SR type index (R2 = 0.60, P<0.000) is the sensitivity index for WUE estimation. Our results provide useful insights for monitoring desert shrubs diurnal and dynamic water status, using a wide range of available spectral data. Further research is extending leaf scale to a large scale for arid ecosystem observations.

The research on the fairness of carbon emissions for Chinese energy based on GIS

Qiuxian Wang, Zhiqiang Gao, Jicai Ning, Yantai Institute of Coastal Zone Research (China)

Mainly using carbon emission inventories of 2006 IPCC, carbon emissions of China's 30 provinces in 2000-2010 are calculated on base of China energy statistical yearbook and China cement Yearbook. The figure of carbon emission showed that there are huge differences between the 30 provinces of China. But the whole trends of the total emission are increasing with the development of the economy. Then according to this result the carbon intensity in China in recent ten years and per capita carbon emissions were made. The result showed that national carbon intensity presented a decreasing trend, and the unit GDP energy consumption was also in a decreasing trend. But there are still some areas with high carbon intensity, mainly in Shanxi, Guizhou, Ningxia, Inner Mongolia and Gansu Province. While the intensity of carbon emission in such provinces with developed economic as Fujian, Guangdong, Beijing, Jiangsu, Zhejiang, Shanghai and other provinces is minimum. Next with the help of GIS method the economic contribution coefficient and ecological carrying capacity coefficient of carbon emissions of each province were analyzed. Finally the fairness of carbon emissions for Chinese provinces was researched by the Gene coefficient.

The study on the changing characteristics and their countermeasures for carbon emissions of China's in 2000-2010

Qiuxian Wang, Zhiqiang Gao, Jicai Ning, Yantai Institute of Coastal Zone Research (China)

Based on the quantitative calculation of 2000-2010 China's 30 provinces of carbon emissions by the method of 2006 IPCC with the data from China energy statistical yearbook and China cement Yearbook, a detailed analysis of the temporal and spatial variation characteristics of carbon emissions in both Chinese level and provinces' level was made. The result showed that most of the provinces of China's carbon emissions presented an increasing trend in the past 11 years, especially in Shandong Province, Hebei Province, Shanxi Province, Liaoning Province, Jiangsu province which is located in the national top five. Then on the basis of quantitative calculation, assuming that the external conditions of Chinese carbon emissions unchanged, the author guessed the carbon emissions for China in 2020. The result showed that a carbon emission of China in 2020 is so large that we must take urge measures to prevent the amount to be reached. According to the speculating result, the author put forward some countermeasures for China, such as speeding up the pace of industrial restructuring, searching for clean energy and other measures to reduce the carbon emissions of china.

Preliminary study of a dust event over Beijing by using satellite data and ground-based measurements

Xianxia Shen, Chaoshun Liu, Runhe Shi, Kaixu Bai, East China Normal Univ. (China); Wei Gao, East China Normal Univ. (China) and Colorado State Univ. (United States); Chao Wang, East China Normal Univ. (China)

The present study focuses on an intense dust storm event from 26th April to 4th May in 2012 over Beijing. Multi-satellite observations and ground-based measurements are used to detect and analyze this event. The ground-based AERosol Robotic Network (AERONET) data at Beijing station show that the AOD550 value peaked at ~2.5 on 1st May during the event. Simultaneously, the Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO) passed by Beijing on 1st May and an intense dust layer has been detected at the altitude of 4 to 4.5 km. The vertical distribution of total attenuated backscatter coefficient (TABC), volume depolarization ratio (VDR) and color ratio (CR) of CALIPSO data are analyzed on that specific day. Result shows a TABC above 0.0045 km-1sr-1in the feature layer as VDR and CR concentrates of 0.1 ~ 0.5 and 0.6-1.4 respectively. Additionally, results from a time series of (MODerate resolution Imaging Spectroradiometer) MODIS data also show an agreement that the AOD reach a peak on 1st May in that time period. Hence, consistency between satellite observations and ground-based measurements can be observed in some ways.

Desertification assessment in the agro-pastoral transitional zone of north China (1982-2006) using GIMMS NDVI data

Youzhi An, East China Normal Univ. (China); Wei Gao, East China Normal Univ. (China) and Colorado State Univ. (United States); Zhiqiang Gao, Yantai Institute of Coastal Zone Research (China); Chaoshun Liu, East China Normal Univ. (China)

The Agro-Pastoral Transitional Zone of North China belongs to the arid/

semi-arid area is the most sensitive area of global climate changes where the environment is very fragile. Pearson correlation analysis of annually integrated GIMMS NDVI (?NDVI) against annual rainfall for the period of 1982–2006 is conducted on a pixel-by-pixel basis. ?NDVI and Rain-use efficiency (RUE; the ratio of vegetation productivity to annual rainfall) dynamic trend during the period were analyzed, with using the Mann-Kendall nonparametric test and linear regression temporal trend analysis. The results showed that Pearson correlation analysis of annual ?NDVI and rainfall for the period in most parts of the study area was no significant correlated. Only a few areas showed a very significant correlation ($p<0.01$).The trend analysis of ?NDVI and RUE by Mann–Kendall test and linear regression temporal analysis methods show that vegetation changes mainly reflect an increasing trend, and a significant decrease trend in a small pixel proportion; The northeast and central parts of the study area are characterized by positive trends in RUE slope values whereas a few parts of the southwest negative. In general, the results of the two methods are consistent with the ?NDVI and RUE. Finally, further examination of the desertification tendency among different rainfall conditions was conducted in the study area. The range of 200-500mm rainfall can be seen a certain trend with increasing rainfall and desertification is less likely to occur and vegetation restoration capacity is also enhanced.

8869-37, Session PMon

Spatial and seasonal variation trends of MODIS aerosol optical depth in East China during 2000-2012

Zhai Tianyong, East China Normal Univ. (China)

Using MODIS/Terra derived Aerosol Optical Depth (AOD) at 0.55um we compare them with AERONET derived level 2.0 AOD including Hefei, Shouxian, Taihu and Hangzhou-ZFU in East China. Results of the validation indicate that MODIS data of all sites falling in expectations errors (±0.05 ±0.15) are larger than 66% reaching NASA design requirements, except for Taihu observation site accounted for 41% due to it is located in the lake area and surface reflectance estimated low leading to AOD values large. On the whole, they have a good consistency and MODIS data can meet the applicability analysis for the study area. MODIS/Terra derived AOD at 0.55um from 2000 to 2012 are used to analyze the spatio-temporal variation of AOD in East China, which indicates AODs are significantly affected by the topographic distribution with AODs are relativity low in high altitude mountainous and large in low-lying plains and basins. In addition to, human activities also have a certain impact on the distribution of AOD. AODs are generally higher in urban area than the surrounding area of the urban area and it is more obvious, especially in urban agglomerations such as the Yangtze River Delta. At the same time, AODs have obvious seasonal variations. AODs are generally high in spring and summer, while low in autumn and winter. According to the distribution of Angstrom exponent, we can conclude that aerosol particulate scale is large mainly affected by coarse particles in spring and winter, because it is easy to the occurrence of dust weather in spring and vegetation density decreases in winter. In summer and autumn, it is mainly affected by small-scale particles due to the abundant precipitation is able to wash away the large particles in air and fine particles generated mainly from human activities.

The study on paddy evapotranspiration based on different models

Juan Du, Chaoshun Liu, East China Normal Univ. (China)

Based on the observed paddy micro-meteorology and crop growth data, the hourly and daily paddy evapotranspiration is estimated by using the Penman-Monteith model, the FAO Penman-Monteith equation, the Shuttleworth-Wallace model and the MICROWEATHER model, respectively. The simulation accuracy, mechanism and sensitivity of each model were compared. After being verified by measured micro-meteorology data, the MICROWEATHER model was taken as a standard, the hourly and daily evapotranspiration estimated by the S-W model was most close to that estimated by MICROWEATHER model. The linear regression coefficient between the S-W model and the MICROWEATHER model is highest and the root mean square error (RMSE) between the two models is lowest. The S-W model has the highest simulation accuracy, followed by FAO formula and the P-M model has the lowest accuracy. The sensitivity analysis of three models to leaf area index shows the P-M model is most sensitive to LAI, then the MICROWEATHER model and the S-W model is not sensitive to LAI. The sensitivity analysis of the FAO formula to the wind speed shows that the FAO formula is not sensitive to the wind speed and because it's calculation is easy and accuracy is high, the FAO formula can be used widely. The sensitivity analysis of the P-M model and the S-W model shows that the P-M model is most sensitive to the aerodynamic resistance ra, then the canopy resistance rc .The S-W model is most sensitive to raa , then rcs , relatively large sensitive to rsa and rss , and not sensitive to rca .

8869-39, Session PMon

NO2 long-term monitoring by satellite in the Pearl River Delta

Long Li, Runhe Shi, Wei Gao, Yuanyuan Chen, East China Normal Univ. (China); Jie Zhang, Foshan Bureau of Meteorology (China)

Recently, the air quality is deteriorating continuously, do serious harm to human health. In order to realize the spatio-temporal characteristics of NO2 and its anthropogenic influences in Pearl River Delta, we have analyzed the long-term NO2 column concentration variation before the 2010 Asian Games and its characteristics during the period of the 2010 Asian Games by using the NO2 product OMNO2e from the Ozone Monitoring Instrument (OMI). It shows that the annual average of the NO2 column concentration in the Pearl River Delta has a significant downward trend from 2005 to 2010: the total column concentration of NO2(TotNO2) in the atmosphere had decreased from 9.207?1015molec/cm2 to 8.173?1015molec/cm2, with an average annual growth rate of -2.247%; while the tropospheric column concentration of NO2(TropNO2) had decreased from6.685?1015molec/cm2 to 5.646?1015 1015molec/cm2, with an average annual growth rate of -3.109%. The ratio TropNO2/TotNO2 which can reflect the amount of NO2 exhausted by human activities also decrease form 0.726 in 2005 to 0.691 in 2010. Durning the 2010 Asian Games, the weekly average of the TropNO2 in Pearl River Delta was maintained at a lower level. The characteristics of NO2 average distribution in the Pearl River Delta is maximum in the geometric center, outwardly smaller, and the high value area of TropNO2 became less and less from 2005 to 2010. Foshan, Jiangmen and Kwangchowan are the most polluted areas durning the Asian Games. But because of linkage air quality guarantee measures in the Pearl River Delta during the 2010 Asian games, the air quality of Pearl River Delta is better than historical periods.

8869-40, Session PMon

Assimilation the observation for improved hydrologic and energy flux estimation using ensemble Kalman filter

Chaoshun Liu, East China Normal Univ. (China)

Hydrologic and heat fluxes from land surface are indispensable parts in the surface energy conversion and hydrological cycle processes. Estimation and prediction for fluxes have immense research significance in fields of environmental protection, agricultural production and climate prediction. Base on Community Land Model (CLM3.0), a hydrologic and energy flux assimilation system was developed for improved sensible and latent heat fluxs by using the Ensemble Kalman Filter (EnKF) algorithm to compromise the continuous solution of model simulation and the accuracy of observation. Data from three flux observatory sites of Ameriflux flux observational network (Chestnut Ridge, ARM SGP

Main and Tonzi Ranch) which standing for three different land surface conditions are engaged in parallel experiments to test the assimilation system. The results showed that regardless the underlying land surface condition, direct assimilation of sensible and latent heat fluxes can improve the estimates of total surface sensible and latent heat fluxes. Furthermore, comparing with mainstream study which focusing on assimilation of surface temperature and humidity to indirectly improve the fluxes prediction, the results of direct assimilation of surface water and heat fluxes is far better than the former. It is noteworthy that whether the estimates of observational error is precise or not will directly affect the assimilation results though errors from initial condition, observation and atmospheric forcing will make contributions simultaneously.

Validation of aerosol optical depth and total ozone column in the ultraviolet retrieved from multifilter rotating shadowband

Chaoshun Liu, East China Normal Univ. (China) and Colorado State Univ. (United States); Maosi Chen, USDA UV-B Monitoring and Research Program, Natural Resource Ecology Laboratory, CSU (United States); Wei Gao, Key Laboratory of Geographical Information Science, Ministry of Education, ECNU (China) and Joint Laboratory for Environmental Remote Sensing and Data Assimilation (China) and USDA UV-B Monitoring and Research Program, Natural Resource Ecology Laboratory, CSU (United States)

Ultraviolet (UV) radiation has great impact on health effects, crop yield accumulation, and climate change. Atmospheric aerosols can help to regulate UV by scattering and absorbing. Analysis of ground-based UV measurements can add valuable understanding of the UV radiation present and its interaction with aerosols. Measurements of Ultraviolet Multifilter Rotating Shadowband Radiometer (UV-MFRSR) network, running by the U.S. Department of Agriculture (USDA) UV-B Monitoring and Research Program (UVMRP) at Colorado State University, were selected to retrieve the aerosol optical depth (AOD) in the UV spectral range, and compared with the Aerosol Robotic Network (AERONET) inversions derived from collocated CIMEL sun photometer. The intercomparison between UV-MFRSR AOD and AERONET AOD shows very good agreement with correlation coefficients on the order of 0.98-0.99, slope range from 0.95 to 1.0, and offsets less than 0.02. The results confirm the quality and accuracy of UV-MFRSR measurements.

Spatial distribution of soil erosion in China coastal zone

Qingshui Lu, Zhiqiang Gao, Yantai Institute of Coastal Zone Research (China); Qiao Chen, Shandong Univ. of Science and Technology (China); Wei Gao, Remote Sensing and Modeling Center for Agricultural Sustainability, USDA UV-B Monitoring and R (United States)

The coastal zone is very important in the world. China coastal zone was granted the first priority of developing economy in the late 1980s. Since then, high population density and rapid economic development hace caused intensive changes of LUCC in this zone. Those changes have lead to land degradation. Besides, China governments launched series of projects and policy to improve such problems. Those will inevitably cause to diverse spatial dynamics of land degradtion. However, the state of land degradation in certain time is still unknown. Soil erosion is an important indicator of land degradation.Therefore, we use RUSLE model anlyze the spatial pattern of soil erosion for 2000. By spatial analysis, we found that soil erosion in China coastal zone is not serious. Widespread soil erosion is only occurred on coastal zones in Shandong, Hainan and werstern Guangdong Province. Although rainfall eosivity factor(R) is higher in southern coastal zone, erosion tends to occur on the slopes with lower LS values in northern coastal zone than southern coastal zone. To improve soil eorosion in those areas, we should let governments put more funds to increase vegetation cover in north. Such study will provide helpful suggestions for governments to prevent soil erosion in coastal zone.

Automatic selection of high-resolution remote sensing images segmentation scales and refinement using a multi-scale approach

Ruijuan Yin, East China Normal Univ. (China)

The advantages of object-based classification over the traditional pixel-based approach are well documented. However, which scale parameter is the appropriate scale is difficult to assess, and the choice of scale parameter is very important and has a great influence on the segmentation effectiveness. To date, the most common method to evaluate the quality of a segmentation method is subjective evaluation, which is a tedious process and lacking in stability and reliability. Thus, an objective and unsupervised method is proposed for selecting suitable parameters for a multi-scale segmentation to ensure best quality results. In this paper, a newly multi-scale method is introduced to improve the segmentation of a high spatial resolution (0.5m) satellite data. First, the weight values of different bands are defined based on the variance of bands themselves and the correlation between them. Secondly, 20 segmentations, with similarity and area thresholds ranging from 20 to 200 scale, step by 5, are created in Definiens Professional 8.7. The global intra-segment and inter-segment heterogeneity indexes are taken into account to identify the optimal segmentation scale. Then, a LSI method, which is evolved by landscape fragmentation index, is performed in every object to select under-segmentation objects and Local Moran's is identified as the whole scene to choose over-segmentation. Finally, the under- and over-segmentation regions are refined by (a) further segmenting under-segmented regions at finer scales, and (b) merging over-segmented regions with spectrally similar neighbors. This process leads to the creation of several three- or two-scale image segmentations. As a result, comparison of single- and multi-scale segmentation indicates that local statistics (Local Moran's and LSI method) can improve global segmentation quality.

8869-44, Session PMon

Analysis of non-point and point source pollution in China: case study in Shima Watershed in Guangdong Province

Huaiyang Fang, South China Institute of Environmental Sciences (China); Qingshui Lu, Yantai Institute of Coastal Zone Research (China) and South China Institute of Environmental Sciences (China); Zhiqiang Gao, Yantai Institute of Coastal Zone Research (China); Wei Gao, USDA UV-B Monitoring and Research Program and Center of Remote Sensing and Modeling for Agricultural (United States)

China economy has been rapidly increased since 1978. Rapid economic growth led to fast growth of fertilizer and pesticide consumption. A significant portion of fertilizers and pesticides entered the water and caused water quality degradation. At the same time, rapid economic growth also caused more and more point source pollution discharge into the water. Eutrophication has become a major threat to the water bodies. Worsening environment problems forced governments to take measures to control water pollution. We extracted land cover from Landsat TM images; calculated point source pollution with export coefficient method; then SWAT model was run to simulate non-point source pollution. We found that the annual TP loads from industry pollution into rivers are

115.0 t in the entire watershed. Average annual TP loads from each sub-basin ranged from 0 to 189.4 ton. Higher TP loads of each basin from livestock and human living mainly occurs in the areas where they are far from large towns or cities and the TP loads from industry are relatively low. Mean annual TP loads that delivered to the streams was 246.4 tons and the highest TP loads occurred in north part of this area, and the lowest TP loads is mainly distributed in middle part. Therefore, point source pollution has much high proportion in this area and governments should take measures to control point source pollution.

8869-1, Session 1

MODIS surface reflectance calibration with AVHRR for vegetation condition monitoring

Zhengwei Yang, Feng Gao, Agricultural Research Service (United States); Genong Yu, George Mason Univ. (United States)

USDA National Agriculture Statistics Services (NASS) used a bi-weekly AVHRR (NOAA-19 satellite) normalized difference vegetation index (NDVI) composite to monitor crop vegetation condition. The AVHRR NDVI maps have been proven valuable in providing a spatially complete view of crop's vegetation condition. However, their relatively low spatial resolution of 1km cannot provide crop specific information. NASS currently is developing a new Web-based vegetation condition monitoring system - VegScape in which MODIS daily gridded Surface Reflectance L2G product MOD09GQ with Bands 1 and 2 at a 250-meter resolution are used to replace the AVHRR NDVI. It was found that NDVI images of AVHRR and MODIS illustrated significant difference if they were displayed in the same legend (color schema). This indicated that AVHRR and MODIS sensors had significant difference in red band and/or IR band surface reflectance responses. To keep the continuity of USDA NASS' vegetation condition monitoring, this paper proposed to calibrate the MODIS surface reflectance based on the AVHRR data product. In this paper, the daily MODIS surface reflectance product MOD09GQ data were first corrected to nadir view reflectance. The corrected time series data were then composed into weekly composite using maximum value composite method. The calibration was performed by correlating corresponding pixels of the same spectral bands of both AVHRR and MODIS data acquired at the same date. Two look-up tables of the spectral reflectance values cross the sensors were established. The preliminary results show that the visual difference between NDVIs from two sensors was effectively minimized.

8869-2, Session 1

Integrating remote sensing data from multiple optical sensors for ecological and crop condition monitoring

Feng Gao, Agricultural Research Service (United States); Peijuan Wang, Agricultural Research Service (United States) and Chinese Academy of Meteorological Sciences (China); Jeffrey G. Masek, NASA Goddard Space Flight Ctr. (United States)

Ecological and crop condition monitoring requires high temporal and spatial resolution remote sensing data. Due to technical limitations and budget constraints, remote sensing instruments trade spatial resolution for swath width. As a result, it is difficult to acquire remotely sensed data with both high spatial resolution and frequent coverage. A synthesized approach fusing multiple types of remote sensing imagery provides a feasible and economical solution for many application areas. In recent years, we have developed a Spatial and Temporal Adaptive Reflectance Fusion Model (STARFM) that allows fusing high spatial resolution data from Landsat (16-day, 30m) with high temporal resolution data from MODIS (daily, 500m). The fused reflectance products can provide synthesized images with MODIS revisit frequency and Landsat spatial details. In this presentation, we will demonstrate an operational data fusion framework based on STARFM for integrating existing MODIS data products and freely available Landsat data for ecological and crop condition monitoring. Improvements of data consistency between Landsat and MODIS will be discussed and demonstrated. Tests focus on a cloudy naturally vegetated area and a crop region. Our initial results show that the detailed spatial and temporal variability of the landscapes can be identified from the fused remote sensing data. Different spectral and temporal patterns for natural vegetation and crops can be found at the field scales in the study areas. The operational data fusion framework provides an alternative solution to build dense time-series images at high temporal and spatial resolution for ecological and crop condition monitoring.

8869-3, Session 1

Wheat growth monitoring with radar vegetation indices

Thomas J. Jackson, U.S. Dept. of Agriculture (United States); Yihyun Kim, Sukyong Hong, Kyoungdo Lee, National Academy of Agricultural Science (Korea, Republic of); Rajat Bindlish, U.S. Dept. of Agriculture (United States)

Microwave remote sensing can help in the monitoring of crop growth. Many experiments have been carried out to investigate the sensitivity of microwave sensors to crop growth parameters. These have clearly shown that canopy structure and water content can greatly affect the measurements. For agricultural crops this suggests that each general type needs evaluation, here we focus on wheat. Ground-based polarimetric scatterometers can be of value in these studies because they can provide continuous crop observations using multi-polarization, multi-frequencies, and various incidence angles. They have been extensively used in a frequency range from L-band to Ka-band. The Radar Vegetation Index (RVI) was proposed as a tool for monitoring crop growth because it was less sensitive to both incidence angle and environmental condition effects than basic polarimetric data. Only a few studies have attempted to relate the RVI to vegetation parameters. In this investigation, we examine the relationship between wheat biophysical variables and RVI based upon polarimetric radar data. Data were obtained using a ground-based multi-frequency polarimetric radar system that provided measurements every 10 minutes over a crop growing season. The results show that L-band RVI can be used to accurately retrieve growth parameters for wheat.

8869-4, Session 1

Measuring vegetation heights from high resolution stereo aerial photography

Ahmed Elaksher, New Mexico State Univ. (United States); Jeffrey Gillan, Jason Karl, Agricultural Research Service (United States); Michael Duniway, U.S. Geological Survey (United States)

In the United States, including Alaska, there are approximately 770 million acres of rangelands, natural landscapes valued for livestock production, biodiversity, and watershed services. Vegetation height and structure are critical indicators for assessing rangeland health with regard to wildlife habitat, estimating forage and browse, and estimating wildfire fuels. Conventional field monitoring methods provide high accuracy for these indicators; however, they are expensive and time consuming particularly for large areas. Moreover, despite the high quality elevation information that is achieved through ranging techniques (e.g., LiDAR), they lack the ability to provide optical information that is indispensable in delineating vegetation in rangeland. On the other hand, recent development in digital photogrammetry has stimulated a great interest in its application in large scale mapping, monitoring, and change detection applications.

This article presents the use of stereo-aerial imagery in mapping rangeland vegetation heights for use in broad-scale monitoring programs. Three overlapping color-infrared aerial images were taken with an UltraCamX sensor at a scale of 1:3200, with a base-to-height ratio of 1/5. Due to the absence of ground control information, three orientation approaches are evaluated and compared. The first approach

was an absolute orientation using the on board GPS and INS systems with fixed inner camera parameters as defined through the camera calibration report. In the second approach camera parameters where defined in a relative manner and the model was scaled using the base distance between the first two images in the model. The third approach determined both exterior and interior camera orientation parameters through a unified least squares process. The calculated sets of orientation parameters were comparable between the three approaches leading to insignificant differences among the generated elevation models. These results suggest that vegetation height indicators can be gathered remotely with limited field visits to collect ground control.

8869-5, Session 1

Comparison of Terra and Aqua MODIS measurements with drought event characterization over the northern United States

Xianjun Hao, John J. Qu, George Mason Univ. (United States); Xiaoxiong Xiong, NASA Goddard Space Flight Ctr. (United States); Di Wu, George Mason Univ. (United States)

Both Terra and Aqua Moderate Resolution Imaging Spectroradiometer (MODIS) instruments have operated successfully over 10 years. Terra and Aqua MODIS calibration consistency over time and spatial regions is very important for accurate production of long-term consistent climate data records, which are invaluable for environmental monitoring and natural hazards detection. Since calibration accuracy, spectral, spatial, temporal and angular differences and other factors may contribute to the disparity between Terra and Aqua MODIS instruments, it is a challenging task to track Terra and Aqua MODIS calibration consistency. But, for climate extreme events, such as severe drought, both Terra and Aqua MODIS data products should demonstrate similar spatial and temporal patterns. In this study, consistency of Terra and Aqua high level data products was investigated, through characterization of drought events in year 2012 over the northern United States. Time series of spectral indices derived from both Terra and Aqua MODIS 8-day surface reflectances were used to characterize the impacts of drought on vegetation. The spatial distribution and temporal development of drought events in year 2012 were identified using time seris of Terra MODIS and Aqua MODIS, respectively. Then, the spatial and temporal patterns of severe drought events from Terra and Aqua MODIS measurements were compared. This approach provides an alternate approach to check the consistency of Terra and Aqua MODIS measurments.The results will be helpful to analyze the impacts of MODIS calibration consistency.

8869-6, Session 2

Integrated data fusion and bio-optical models for monitoring microcystin concentrations in Lake Erie

Ni-Bin Chang, Benjamine Vannash, Univ. of Central Florida (United States)

Blue-green algae or cyanobacteria are photosynthetic bacteria that require little energy for cell maintenance and growth, giving them a distinct advantage over competition. Population growth and agricultural activities have caused an influx of nutrients into Lake Erie, leading to eutrophic zones. These conditions result in the formation of algal blooms, some of which are toxic due to the presence of Microcystis (a cyanobacteria), which produces the hepatotoxin microcystin. Microcystis has a unique advantage over its competition as a result of the invasive zebra mussel population that filters algae out of the water column except for the toxic Microcystis. The toxin threatens human health and the ecosystem, and it is a concern for water treatment plants using the lake as a water source. In this paper, we have proposed an early warning system using integrated data fusion and bio-optical models to determine microcystin concentrations and distribution by measuring the surface reflectance of the water body using satellite sensors. The fine spatial resolution of Landsat is fused with the high temporal resolution of MODIS to create a synthetic image possessing both high temporal and spatial resolution. As a demonstration, the spatiotemporal distribution of microcystin within western Lake Erie is reconstructed using the band data from the fused products and applied machine-learning techniques. The capabilities of two bio-optical models, including two-band and three-band models, to identify the highly nonlinear relationship between microcystin concentration and surface reflectance were analyzed using four statistical indices. The two-band model shows larger potential to estimate microcystin concentrations in the lake.

8869-7, Session 2

Characterization of drought events over Nebraska using time series of MODIS measurements

Xianjun Hao, John J. Qu, Di Wu, George Mason Univ. (United States); Xiaoxiong Xiong, NASA Goddard Space Flight Ctr. (United States)

Agricultural production systems are susceptible to climate extremes, especially drought. It is critical to detect and characterize drought events so as to provide supports for decision makers to mitigate the impacts of potential disasters on agriculture. The Moderate Resolution Imaging Spectroradiometer (MODIS) instrument onboard Terra satellite has successfully operated since December 1999. Time series of Terra MODIS measurements provides the potential towards spatial and temporal characterization of drought events through analysis of the water content and greenness of vegetation. In this study, time series of Normalized Difference Vegetation Index (NDVI), Normalized Difference Water Index (NDWI), and Normalized Difference Infrared Index(NDII) from Terra MODIS measurements were analyzed to investigate the drought events of year 2002 and year 2012 in the United States. Records of normal NDVI, NDWI and NDII values for each pixel, each 8-day period were constructed using MODIS data of time period without drought. Then, anomaly of NDVI, NDII, and NDWI for each of the 8-day period in drought year (2002 and 2012) were analyzed, using the Nebraska state as an example. The results demonstrated the spatial distribution and temporal development of severe drought events in year 2002 and 2012 clearly, thus can provide the capability to characterize drought events at moderate spatial and temporal resolution (500m and 8 days). Further integration of remote sensing measurements with weather observations at ground stations, and crop data will lead to in-depth understanding of drought impacts on crop yield.

8869-8, Session 2

Periodicity analysis for teleconnection signal propagation between sea surface temperature and forest greenness across North America

Ni-Bin Chang, Sanaz Imens, Univ. of Central Florida (United States)

The growth of forest is critically vulnerable to the change in rainfall and radiation than in air temperature. The amount of rainfall and cloudiness in the northeast region of the United States is assumed to be strongly affected by the Atlantic sea surface temperature (SST). The observational investigation of the relation between the greenness of three undisturbed forested areas in the Atlantic region and Atlantic SST is fundamental to understand the response of terrestrial ecosystems to climate change. Such teleconnection signals may also entail the change of natural variability associated with several hydrological parameters such as rainfall and runoff. We conducted short-term environmental change quantification using MODIS satellite images supplemented by Tropical

Rainfall Measuring Mission (TRMM) data. Wavelet analysis was employed to derive climate signals of SST and embedded precipitation patterns over the decadal timescale to illuminate the high frequency propagation effects on climate teleconnection. In this context, the effect of Atlantic and pacific SST on the spatial and temporal changes of the Enhanced Vegetation Index (EVI) in the two selected northeastern and northwestern pristine forest regions of the United States was examined by using MODIS satellite images from 2002 to 2010. Cross wavelet analysis was performed to search for new insight in regard to the influence of long-distance climate teleconnection on seasonality effect of vegetation cover based on EVI variations.

8869-9, Session 2

Microwave monitoring of the soil moisture

Ferdenant A. Mkrtchyan, Vladimir F. Krapivin, Anatoly M. Shutko III, Institute of Radio Engineering and Electronics (Russian Federation)

Interrelations between the characteristics of the microwave emission field of moisted soil and of the soil liquid water content, soil density, temperature and mineralization level of liquid water are the properties studied both theoretically and by field measurements. Both research and field studies show that microwave radiometric measurements permit estimates of 7 to 10 moisture levels in the top 0.1 to 1.0 wavelengths of soil and 3 to 7 grades of the subsurface water level between 0 and 1.5-3.5 m.

The soil moisture is divided on the solidly-united, loosely-united, and free one. United moisture is the water adsorbing by ground particles surface and having the form of film with the thickness equaled no more of 6 to 8 molicular layers. The volume of united moisture in the soil layer is determined by the soil type and is fluctuated in the wide interval from 2-3 per cent for sandy soil to 30-40 per cent for clay and loess soils. United water is unattainable for the plants and do not influence on the salt regime of soil. That is why the monitoring system is to realize that kind of moisture classification in the soil.

The soil moisture is expressed in per cent of dry soil weight. The radiation models of the soil moistering for different types, taking into consideration of soil density, its temperature and salinity, were studied in the details. The data required for solution of the moisture problem can be obtained from the values of brightness temperature contrasts, degree of polarization and spectral characteristics at centimetre and decimetre wavwlengths. Wavelengths 2.25, 18 and 30 cm proved to be the most informative to solve this task. The microwave radiation model describing the land cover emittively under the conditions of heterogeneously moistened layer is based on the existence of vertical heterogeneity in the dielectric permeability coefficient: ??(1+0.5?s)2. The value of ? is informative indicator of the moisture soil variation. As soil moisture begin to grows the ? increases at first slowly, if soil was dry, then it increases more rapidly. Weak dependence of ? on the stage of initial moistening can be explained thereby the tied moisture is characterized by small dielectric permeability. The existence of knowledge base that kind and application of GIMS technology allow to solve the task of water content, Ws(z), diagnostics in the soil layer . Four major types of vertical moisture profiles have been identified from an analysis of the moistening characteristics of the various climatic zones in the Former Soviet Union. In other climatic zones it is necessary to have such identification. As a matter of fact the task is reduced to the function Ws(z) reconstruction when the values Wsi=Ws(zi) are known and the following conditions are satisfied:

?Ws / ?z |z=0 ? C, 0? Ws(z)?Ks(z),

where Ks(z) is the given function.

8869-10, Session 3

Estimation evapotranspiration over the large landscape by using remote sensing data

Jianmao Guo, Nanjing Univ. of Information Science & Technology (China)

Evapotranspiration is the important process of plant physiological and ecological, estimating and monitoring evapotranspiration are very useful for evaluation of the influence on the crop growth situation. Determination evapotranspiration over natural surface, the utilization of satellite remote sensing is indispensable. In this paper, a new method is established based on high resolution remote sensing data(TM/ETM) combination Penman-Monteith regional daily evapotranspiration calculation model. The key of the algorithm is used to calculate the Temperature–Vegetation Dryness Index (TVDI) based on an empirical parameterisation of the relationship between surface temperature (Ts) and vegetation index (NDVI), Ts and NDVI in combination can provide information on vegetation and moisture conditions at the surface. These results

indicate that the method is feasible?and VTCI is a close real—time drought monitoring approach?It is based on satellite derived information and combination with the meteorology data, and the potential for operational application of the method is therefore large.

8869-11, Session 3

Inter-sensor relationship of two-band spectral vegetation index based on soil isoline equation: derivation and numerical validation

Kenta Taniguchi, Aichi Prefectural Univ. (Japan); Kenta Obata, Univ. of Hawai'i (United States); Masayuki Matsuoka, Kochi Univ. (Japan); Hiroki Yoshioka, Aichi Prefectural Univ. (Japan)

Differences in spectral response function among sensors have known to be a source of bias error in derived data products such as spectral vegetation indices (VIs). Numerous studies have been conducted to identify such bias errors by comparing VI data acquired simultaneously by two different sensors. Those attempts clearly indicted two facts: 1) When one tries to model a relationship of two VIs from different sensors by a polynomial function, the coefficients of polynomial depends heavily on region to be studied: 2) Although increase of the degree of polynomial improves the translation accuracies, this improvement is very limited. Those facts imply that a better functional form than a simple polynomial may exist to model the VI relationships, and also that the coefficients of such a relationship can be written as a function of variables other than vegetation biophysical parameters.

This study tries to address those issues by deriving an inter-sensor VI relationship analytically. The derivation has been performed based on a relationship of two reflectances at different wavelengths (bands), called 'soil isoline equation.' The derived VI relationship becomes a form of rational function with the coefficients that depend purely on the soil reflectance spectra. The derived relationship has been demonstrated numerically by a radiative transfer model of canopy, PROSAIL. It is concluded that a rational function is a good candidate to model inter-sensor VI relationship. This study also shows the mechanism of how the coefficients of such a relationship could vary with the soil reflectance underneath the canopy.

8869-14, Session 3

Simulation of regional rice growth by combination remote sensing data and crop model

Jianmao Guo, Nanjing Univ. of Information Science & Technology (China); Yanghua Gao, Chongqing Institute of Meteorological

Science (China)

Remote sensing monitoring the macroscopic vegetation situation and reflecting environmental factors influence the results and the process of crops; Crop growth simulation model using environmental factors simulate the process of crop growth, revealing the cause and essence of the process, both of them have advantages and disadvantages. Thus developing the study of combine remote sensing yield estimation and dynamic crop growth model is essential, it is a significant scientific issue studying the approach and method which can combine these two advanced technologies. In this paper, using multi-temporal remote sensing information and crop model ORYZA2000 combined method realizing the rice growth simulation in pixel scale, after the comparison between simulated result and the actual statistic value, accuracy is high and result is good. The combination of remote sensing information and crop simulation model is a complex issue, its result will be affected by many factors, combined with the field test in this study is a simplification of the actual situation, this will certainly affect the result's accuracy.. This method has great practical significance and at the same time has positive application prospect. It can be used to monitor and evaluate crop growth condition, forecast crop yield and so on, thus can be used in decision support service on different regional scales and guiding agricultural production.

8869-45, Session 3

Spatial discretization of distributed hydrological response units for SWAT

Jicai Ning, Zhiqiang Gao, Yantai Institute of Coastal Zone Research (China); Wenjiang Zhang, State Key Laboratory of Hydraulics and Mountain River Engineering, Sichuan University (China); Wei Gao, USDA UV-B Monitoring and Research Program, Natural Resource Ecology Laboratory, CSU (United States)

The world is experiencing increasingly more serious situation of water resources. The distributed hydrological model (DHM) has become the indispensable means for exploring the influences of climate change and human on hydrological cycles and water resources. With strict mathematical and physical description of hydrological processes, DHM could account the spatial variations of watershed parameters and horizontally relate different HRUs. Therefore, the Digital Terrain Model (DEM) based DHM is one major trend of hydrological modeling. Theoretically, the absolutely physical DHM is built on the strict hydrological processes. However, none of current DHMs can absolutely describe the strict hydrological processes, and most are based on some hypotheses. For the semi-distributed hydrological model, Soil and Water Assessment Tools (SWAT), Hydrological Response Units (HRU) is the basic modeling unit, defined by land use, soil and slope. Land surface patches within one Hydrological Response Units (HRU) should bear identical hydrological properties (including land use, soil, slope and management) and thus have similar hydrological responses. However, it is difficult to determinate the spatial locations and to describe the interactions between different HRUs. This study proposed one schema to discretize HRU for SWAT on the basis of generalized data input. Within a small watershed of Taihu Basin, the data of land use and soil were generalized for discretizing SWAT HRUs. The SWAT model was modified with the discretized HRUs. The resulted showed that the SWAT improved by discretization schema could be more sensitive the runoff lag process and thus achieved better simulation accuracy.

8869-46, Session 3

Using mixture tuned match filtering to estimate fractional vegetation area in an urban desert environment

Christa Brelsford, Arizona State Univ. (United States)

Estimating changes in fractional vegetation area in desert urban environments is necessary to accurately measure the effectiveness of water conservation programs that influence outdoor vegetation. Ground truth for fractional vegetation area was visually coded from one foot per pixel aerial photography for 1000 pixels across 9 LANDSAT images, and compared to the corresponding Mixture Tuned Match Filtering (MTMF) result. MTMF is a biased estimator of fractional vegetation area. Three methods of calibrating the MTMF results to match the mean and distribution of the ground truth results were tested: using logistic regression, OLS regression, and a mean shift transformation. After filtering the results over neighborhoods and calibrating raw MTMF results so that the MTMF mean is the same as the ground truth mean, calibrated MTMF is an acceptable measure of changes in fractional vegetation area in residential parcels in Las Vegas, NV.

8870-1, Session 1

Spectral imager based on Fabry-Perot interferometer for Aalto-1 nanosatellite
(Invited Paper)

Rami Mannila, Antti Näsilä, Kai Viherkanto, Christer Holmlund, Ismo Näkki, Heikki Saari, VTT Technical Research Ctr. of Finland (Finland)

Aalto-1 is a 3U-cubesat project coordinated by Aalto University. The satellite will be mainly built by students as project assignments and thesis works and it will be launched in 2014. VTT Technical Research Centre of Finland is developing the main Earth observation payload, a miniaturized spectral imager, for the satellite. It is a novel miniaturized adjustable spectral imager. Mass of the spectral imager including electronics and mechanics of the spectral imager and visual camera will be 500 grams, and dimensions will be 80 mm x 80 mm x 45 mm. The spectral imager is based on a tunable Fabry-Pérot interferometer (FPI) accompanied by a RGB CMOS image sensor. The FPI consists of two metallic mirrors separated by a tunable air gap. The piezo-actuated FPI uses three piezo-actuators in a closed capacitive feedback loop for air gap tuning. The spectral resolution of the imager is 8 – 15 nm (FWHM) and the spectral range is 500 – 900 nm. Imaging resolution of the spectral imager is 1024x1024 pixels. The focal length of the preliminary optics is 32 mm and F-number is 3.4.

8870-2, Session 1

Alignment results for a high-performance thermal infrared imaging spectrometer for Earth science

William R. Johnson, Simon J. Hook, Steven Shoen, Bjorn T. Eng, Jet Propulsion Lab. (United States)

The Hyperspectral Thermal Emission Spectrometer (HyTES) was developed as part of the risk reduction activities associated with the Hyperspectral Infrared Imager (HyspIRI). Spectral band selection for HyspITIR requires high performance imaging spectroscopy which means minimizing any artifacts caused by the instrument such as smile and keystone distortion. The HyTES pushbroom design has 512 spatial pixels over a 50-degree field of view and 256 contiguous spectral bands between 7.5?m and 12?m in the thermal infrared (TIR) wavelength region. The instrument was flown on a twin otter aircraft during an engineering flight, and the results are promising. This paper describes pre-flight alignment results. The entire optical assemblies (both reflective and refractive components) as well as the focal plane array were held at cryogenic temperatures, so achieving precision optical alignment was extra challenging. A HyTES spectral response function (SRF), across track response function (ARF) and cross-track response function (CRF) were measured and are shown to be held at an acceptable level. The instrument turns out to have very low smile and keystone distortion which is a requirement for science data validity.

8870-4, Session 1

A fast, compact, configurable, thermal-infrared hyperspectral and chemical-specific contrast detection imager

Marsha Fox, Neil Goldstein, Pajo Vujkovic-Cvijin, Brian Gregor, Steven Adler-Golden, Jason Cline, Benjamin St. Peter, Spectral Sciences, Inc. (United States); Mark Wilder, Augustus Lowell, Triple Ring Technologies, Inc. (United States)

A second-generation, micro-electro-mechanical systems (MEMS)-based, hyperspectral imager will extend the previously developed Adaptive Multiplexing Spectrometer[1] breadboard into a compact, fully integrated unit. The system will produce hyperspectral imagery and chemical-specific thermal infrared contrast imagery for visualization, detection, and quantification of chemical species through their characteristic long-wave infrared spectral signatures. The slit spectrometer uses a set of concave gratings, a MEMS digital micro-mirror device (DMD), and a single-pixel Stirling-cooled detector to produce spectrally selective scene imagery. The image field-of-view is scanned by a movable, DMD-synchronized spectrometer slit to provide a second spatial dimension.

The sensor may operate in hyperspectral imaging mode; however its strength lies in producing hyperspectral detection filters in hardware to rapidly generate contrast imagery. This mode is accessed by implementing analog transmission functions with the DMD using grey scales. Thus linear algorithms, including traditional detection methods such as matched filters, orthogonal subspace projection, and principal component analysis, can be implemented in hardware. The firmware DMD programming will enable an operator to rapidly change operating mode and spectral, temporal and spatial resolution. For instance, the system can be programmed to operate on sub-arrays of pixels in order to more rapidly interrogate an area or collect high-resolution spectra.

The opto-mechanical, electronic, software and firmware designs of the new system will be described. Preliminary results, using a combination of first and second generation hardware and software will be presented for field image data collection, including hyperspectral and chemical-specific contrast detection imagery.

[1] Goldstein, N., M. Fox S. Adler-Golden and B. Gregor, “Infrared adaptive spectral imagers for direct detection of spectral signatures and hyperspectral imagery,” Proc. SPIE Vol 8618 (awaiting publication).

8870-5, Session 2

Observing system simulation experiments to evaluate the impact of remotely sensed data on hurricane track and intensity prediction
(Invited Paper)

Robert M. Atlas, National Oceanic and Atmospheric Administration (United States); George D. Emmitt, Simpson Weather Associates, Inc. (United States); Thomas S. Pagano, Jet Propulsion Lab. (United States)

Observing System Simulation Experiments (OSSEs) are an important tool for evaluating the potential impact of proposed new observing systems, as well as for evaluating trade-offs in observing system design, and in developing and assessing improved methodology for assimilating new observations. Extensive OSSEs have been conducted at NASA/ GSFC and NOAA/AOML in collaboration with Simpson Weather Associates and operational data assimilation centers over the last 27 years. These OSSEs determined correctly the quantitative potential for several proposed satellite observing systems to improve weather analysis and prediction prior to their launch, evaluated trade-offs in orbits, coverage and accuracy for space-based wind lidars, and were used in the development of the methodology that led to the first beneficial impacts of satellite surface winds on numerical weather prediction. OSSEs are currently being performed using combinations of global and regional models and data assimilation systems to evaluate the impact of hyperspectral sounders and advanced lidars on hurricane track and intensity prediction.

8870-6, Session 2

Lessons from the first 18 years of hyperspectral infrared sounder data *(Invited Paper)*

Hartmut H. Aumann, Jet Propulsion Lab. (United States)

As of the end of 2013 NASA and EuMetSat have accumulated 11 years of AIRS, 6 years of IASI and almost 2 years of CRIS data. In spite of major differences in key design areas, all three instruments continue to perform extremely well. A lot has been learned from the analysis the data and how some of the good capabilities and some of the performance liens of the three instruments in some cases are related to over- and under specifications of Functional Requirements, and how the use of even moderate size arrays can bring unexpected complications. Over-specification of requirements invariably leads to higher cost. All three instruments were nominally specified to support the National Weather Centers for short term weather forecasting with a five year lifetime. Not mentioned in the Functional Requirements, but now emphasized, are Climate research, Cross-calibration of vintage sounders and minor gas retrievals, although some of these potential capabilities were recognized before the launch of AIRS in 2002. We illustrate these points with specific examples from AIRS, IASI and CRIS. Future sounders from low Earth and geostationary obits are expected to be smaller, cheaper and more capable than the instruments they are intended to replace. We discuss highlights of what we have we learned from AIRS, IASI and CRIS, and how can this help in the Functional Specification and design of future infrared sounders.

As an example, the differences between spatially adjacent pixels in AIRS, IASI and CRIS are interpreted as geophysically significant if they exceed the random noise. Grossly un-physical differences are seen in images as “striping”. Experience with the calibration of arrays as small as 3x2x2 for IASI or 3x3x3 from CRIS, 2378x1 from AIRS shows that at the random noise level the radiometric calibration of each of the array elements over its full dynamic range is unique. The use of spatial differences at the random noise level was not stated explicitly in the functional requirements documents and is very difficult to achieve. Future sounders are expected to increasingly rely on large arrays and therefor have to account for the complications introduced by arrays with additional prelaunch calibration.

8870-7, Session 2

High performance Earth imaging and sounding from space using the hyperspectral MWIR

Thomas S. Pagano, Hartmut H. Aumann, Jet Propulsion Lab. (United States)

NASA’s Atmospheric Infrared Sounder (AIRS) is a hyperspectral infrared instrument that covers the infrared spectrum from 3.7-15.4 um with 2378 channels and flies on the EOS Aqua spacecraft. NASA’s MODIS instrument provides global daily imagery with 36 spectral bands ranging from 0.4-14.4 um at spatial resolutions ranging from 0.25 to 1.0 km at nadir. Both AIRS and MODIS have demonstrated considerable value to Earth science, natural and man-made hazards and disaster management and numerical weather prediction. These instruments have been succeeded by the Cross-track Infrared Sounder (CrIS) and the Visible and Infrared Imaging Radiometer Suite (VIIRS) on NPP and JPSS. While the performance of these systems is exceptional future requirements call for hyperspectral imaging and sounding in a combined observation at nominal spatial resolutions of 1-2 km.

Learning from the AIRS experience, excellent surface and atmospheric temperature and water vapor retrievals can be achived using a spectrometer covering the MWIR spectral range from 1950 cm-1 to 2450 cm-1 with 0.5 cm-1 sampling and 1.0 cm-1 spectral resolution. The MWIR is examined due to the lower cost of optical and detector materials and cooling requirements. The very high spectral resolution has not been examined before and will improve spectral and radiometric calibration accuracy and enable accurate surface temperature measurements using “superwindow” channels. Retrieval performance simulations for key parameters including the vertical resolution of temperature and water vapor profiles is examined and compared to state-of-the art AIRS retrievals. The ability to retrieve surface temperature and emissivity for land and ocean applications is also examined.

8870-8, Session 2

Error budget for a calibration demonstration system for the reflected solar instrument for the climate absolute radiance and refractivity observatory

Kurtis Thome, Joel McCorkel, Brendan McAndrew, NASA Goddard Space Flight Ctr. (United States)

The Climate Absolute Radiance and Refractivity Observatory (CLARREO) mission addresses the need to observe high-accuracy, long-term climate change trends and to use decadal change observations as the most critical method to determine the accuracy of climate change. One of the major objectives of CLARREO is to advance the accuracy of SI traceable absolute calibration at infrared and reflected solar wavelengths. This advance is required to reach the on-orbit absolute accuracy required to allow climate change observations to survive data gaps while remaining sufficiently accurate to observe climate change to within the uncertainty of the limit of natural variability. While these capabilities exist at NIST in the laboratory, there is a need to demonstrate that it can move successfully from NIST to NASA and/or instrument vendor capabilities for future spaceborne instruments.

The current work describes the radiometric calibration error budget for the Solar, Lunar for Absolute Reflectance Imaging Spectroradiometer (SOLARIS) which is the calibration demonstration system (CDS) for the reflected solar portion of CLARREO. The goal of the CDS is to allow the testing and evaluation of calibration approaches, alternate design and/or implementation approaches and components for the CLARREO mission. SOLARIS also provides a test-bed for detector technologies, non-linearity determination and uncertainties, and application of future technology developments and suggested spacecraft instrument design modifications. The resulting SI-traceable error budget for reflectance retrieval using solar irradiance as a reference and methods for laboratory-based, absolute calibration suitable for climate-quality data collections is given. Key components in the error budget are geometry differences between the solar and earth views, knowledge of attenuator behavior when viewing the sun, and sensor behavior such as detector linearity and noise behavior. Methods for demonstrating this error budget are also presented.

8870-9, Session 3

Using a new GUI tool to leverage lidar data to aid in hyperspectral image material detection in the radiance domain on RIT SHARE LiDAR/ HSI Data

Emmett Ientilucci, Rochester Institute of Technology (United States)

This paper looks the hyperspectal and LiDAR component of a new multi-modal (freely available) data set (collected by the Rochester Institute of Technology) that has been designed to analyze the various impacts of illumination change on materials. Similar materials were placed on different backgrounds where spectral signatures were analyzed to determined impacts of background adjacency. Materials were also placed next to tree lines where they were fully illuminated but with the possible impact of tree shine. Hyperspectral, multispectral, and LiDAR modalities were used to image the materials in the above mentioned scenarios. Applications such as material detection with results are used

to assess difficulties with finding such materials. The detection is based on the generation of a forward sensor-reaching radiance model that incorporates parameters for shadowing, illumination angle variation, and in-direct sky loading. The incorporation of LiDAR into the physical models will aid in approximating the correct per-pixel signature to be used in the above mentioned material detection scheme. This technique can help mitigate issues related to varying illumination across a scene, for example. All of the processing (i.e., LiDAR data manipulation, MODTRAN (specific atmospheric model), HSI data and material detection) is performed in a new custom GUI tool which runs in the ENVI software. This makes processing and analysis very quick and efficient.

8870-10, Session 3

Calculation of LRCS of spatial object and its experimental verification

Yunhua Cao, Lu Bai, Haiying Li, Yanhui Li, Xidian Univ. (China)

Bi-directional Reflectance Distribution Function (BRDF) of some artificial satellite used materials such as solar panel, satellite coating material, OSR panel, and white paint at the wavelength of 1.06 micrometers is measured in laboratory. A five-parameter BRDF model is introduced, and BRDF models of these materials are established based on the measured BRDF data and the five-parameter model. With the obtained models, BRDF of these materials at arbitrary incident and reflected angle can be obtained.

A scaled geometrical model of a simple satellite with a cubic body and solar panel wing is established. Then the model is divided into small facets, and each facet is assigned with a known BRDF model. As Laser Radar Cross Section (LRCS) of each visible facet can be calculated with BRDF of the facet, LRCS of the satellite can be obtained by summating LRCS of each visible facet. LRCS of the satellite at different incident and reflected angles are calculated. The result shows that the main influence factors of LRCS of the satellite are the shape and BRDF of the material. The peak of LRCS of the satellite is very high at the specular reflection direction when the laser illuminates at facets with material of solar panel or OSR panel, and the value reduced quickly when the incident and reflected direction is away from the specular reflection direction. When the laser illuminated at facets with material of satellite coating material or white paint, LRCS varies slower.

Measurement system to measure LRCS of the satellite is established. The system mainly consists of laser emission unit, laser collimation and expending units, optical receiving units, signal processing unit, and signal display unit. LRCS of the scaled satellite model is measured with the measurement system. The measured data and calculated data are compared and show good consistency.

8870-11, Session 3

Imaging FTIR emissivity measurement method

Edward M. Burdette, C. Spencer Nichols, Sarah Lane, Keith Prussing, J. Michael Cathcart, Georgia Tech Research Institute (United States)

Though many materials behave approximately as greybodies across the long-wave infrared (LWIR) waveband, certain important infrared (IR) scene modeling materials such as brick and galvanized steel exhibit more complex optical properties. Accurately describing how non-greybody materials interact relies critically on the accurate incorporation of the emissive and reflective properties of the in-scene materials. Typically, measured values are obtained and used.

When measured using a non-imaging spectrometer, a given material's spectral emissivity requires more than one collection episode, as both the sample under test and a standard must be measured separately. In the interval between episodes changes in environment degrade emissivity measurement accuracy. While repeating and averaging measurements of the standard and sample helps mitigate such effects, a simultaneous measurement of both can ensure identical environmental conditions during the measurement process, thus reducing inaccuracies and delivering a temporally accurate determination of background or 'down-welling' radiation.

We report on a method for minimizing temporal inaccuracies in sample emissivity measurements. Using a LWIR hyperspectral imager, a Telops Hypercam, an approach permitting hundreds of simultaneous, calibrated spectral radiance measurements of the sample under test as well as a diffuse gold standard is described. In addition, we describe the data reduction technique to exploit these measurements.

Following development of the reported method, spectral reflectance data from 10 samples of various materials of interest were collected. These data are presented along with comments on how such data will enhance the fidelity of computer models of IR scenes.

8870-12, Session 3

Spectral reconstruction using spectrally tunable LED illumination

Meng-Chieh Lin, National Chiao-Tung Univ. (Taiwan)

Spectral imaging provides digital images with far more spectral information for each pixel than traditional color cameras. The raw data output is often visualized as a datacube. This can be thought of as a stack of tens to hundreds of pictures with each successive image representing its own specific color (spectral band), or equivalently, as a detailed spectral curve for each pixel.

Estimating the spectral reflectance of an object through low dimensional images require both image acquisition and a post spectral numerical estimation analysis. In this study, we implemented a system using a homemade cluster of LED light sources with different spectra to illuminate the scene and a conventional color CCD to acquire images. Also, integrating sphere supplies a stable and uniform lighting environment. We used principal component analysis and pseudo inverse transformation to reconstruct the image reflectance. Macbeth Color Checker was chosen to be the training target of our system, and the validity of spectral estimation of Macbeth Color Checker was preliminarily demonstrated.

The results of analyses were incorporated into the estimation transformation matrix. Optimal LED spectra used in the multichannel acquisition system were also designed. Through computer simulations, we confirmed that the estimation technique that incorporates PCA improves computation efficiency without expense of estimation accuracy.

8870-28, Session PMon

Spatial characteristics of Taiwan Banks with HJ-1A/1B imagery and multibeam sonar sounding data

Huaguo Zhang, The Second Institute of Oceanography, SOA (China)

The sun glitter is caused by the direct reflection of the Sun light from the sea surface and it is an intensive interference factor in extraction of accurate oceanic information in conventional optical remote sensing of the oceans. However, as a strong signal, sun glitter has a high value in researches of ocean hydrodynamics or submarine bottom topographic remote sensing. For example, sand waves within the Taiwan Banks, a shoal lies the southern the Taiwan Strait, are frequently imaged by optical satellite sensors which contain sun glitter signals, because the water depths are shallow enough and the sand waves are high enough in this region.

Sun glitter is related to the sea surface roughness, and variations in the sea surface roughness due to submarine topography can result in modulation of the radiance intensity in optical imageries. So submarine topographic features are frequently observed in optical satellite images. The image features of sand wave ridges in the optical remote sensing images are of light and dark stripes.The sand wave and its ridge line can readily be identified and drawn from optical images with the help of image processing software, such as the ArcGIS platform.

In this paper, HJ-1A/1B imagery was used to observe the Taiwan Banks, a sea area between the East China Sea and the South China Sea. Cloud free HJ-1A/1B optical images with sun glitter signals received from 2009 to 2011 were selected and further processed. Based on the image features of sand waves , the spatial distributions of the Taiwan Banks were mapped. The wavelength and direction of sand waves were verified with multi-beam sonar sounding data, then the wavelength and direction of sand waves were measured and statistically analyzed. Results show that the Taiwan Banks lies in 117°14'-119°26'E, 22° 32.5'-23°49'N with an area of 16400 km2, and its length from east to west is up to 228 km, and its width in north-south direction is about 145 km. Statistics results also illustrate that the Taiwan Bank can be divide into three regions, the western region, middle region and eastern region according to their regional spatial characteristics of sand waves. The wavelength of sand waves in the western Taiwan Bank is in the range of 900~1200 m, 500~800 m in the middle, and 350~650 m in the eastern. In term of the direction, the western Taiwan Bank is northeast-southwest, while the middle and east regions of the Taiwan Bank are almost north-south.

8870-29, Session PMon

Effects of band selection on the hyperspectral classification

Charoula Andreou, Vassilia Karathanassi, Gerorgia Diamantopoulou, National Technical Univ. of Athens (Greece)

In the hyperspectral theory, data reduction techniques play an important role in the classification processing as hyperspectral imagery contains an immense amount of data posing many challenging problems such as data storage, computational efficiency, and the curse of dimensionality. Hyperspectral band selection technique is a well-known dimensionality reduction approach which retains the physical meaning of the data. It selects a set of bands from the input hyperspectral dataset which comprises the information needed for subsequent hyperspectral image spectroscopy. The majority of the existing state-of-the-art dimensionality reduction methods set criteria to the spectral information which is derived by the whole wavelength in order to define the optimum spectral subspace. These criteria are not associated with the particular classification task but with the data statistics, such as correlation and entropy values. However, each spectral signature of a particular material has spectral characteristics which contribute to distinguish it from other spectral signatures at specific sequential wavelengths. This paper focuses on investigating the effects of band selection on the classification by exploiting the information of sequential bands. More precisely, it is explored 1) whether classification can be optimized when different set of initial bands is selected per category; 2) whether there is an optimum subset of sequential bands which lead to more accurate classification results. Experiments comprise application of a well-known classification method, the support vector machine (SVM), on real hyperspectral dataset using all the possible subsets of p sequential bands, where p is equal to the dimensionality of the signal subspace. Evaluation of the classification accuracy leads to remarkable conclusions.

8870-13, Session 4

Band selection for hyperspectral remote sensing data through correlation matrix to improve image clustering

Hamed Gholizadeh, Indiana Univ. (United States)

Hyperspectral remote sensing is capable of providing large numbers of spectral bands. The vast amount of data volume presents challenging problems for information processing, such as heavy computational burden. In this paper, the impact of dimension reduction (band selection) on hyperspectral data clustering is investigated from two viewpoints: 1) computational complexity; and 2) clustering performance. Clustering algorithms are built to solve the site labeling problem without the need for training samples. Therefore, clustering is one of the most useful tasks in data mining process for discovering groups and identifying interesting distributions and patterns in the data, and it has been subject of wide research since it arises in many application domains in engineering. So, investigating the impact of band selection on hyperspectral data clustering is justifiable. The proposed band selection method is based on thresholding the band correlation matrix and selecting the least correlated bands. Selected bands are then used to cluster the hyperspectral image. The number of clusters in this method is set equal to the signal subspace dimension inferred by the HFC method. Experimental results on a real-world hyperspectral remote sensing data proved that the proposed dimension reduction method will decrease computational complexity and lead to better clustering results compared to those of K-Means and Fuzzy c-Means in terms of the Calinski-Harabasz and Davies-Bouldin indices.

8870-14, Session 4

Behavioral model and simulator for a multi-slit optimized spectrometer (MOS)

Nicholas Tufillaro, Curtiss O. Davis, Oregon State Univ. (United States); Tim Valle, Michelle Stephens, Peter Spuhler, Ball Aerospace & Technologies Corp. (United States)

The Multi-Slit Optimized Spectrometer (MOS) is a NASA funded Instrument Incubator Program (IIP) to advance an innovative dispersive spectrometer concept in support of the GEO-CAPE ocean science mission. As part of the instrument's design and testing, we have constructed a 'behavioral model' of the instruments optical engine which allows an end-to-end simulation from input radiances to final product maps. The MOS SIMulator (MOS-SIM): (1) Allows the co-design of the instrument assembly and calibration test, (2) permits quantitative exploration of design trade-offs not just in terms of focal plane design metrics (e.g. optical distortions), but also the impact of design trade-offs on final product errors (e.g. remote sensing reflectances or chlorophyll concentration maps), and (3) enables the computation and tracking of `uncertainties' (means and standard deviations) at all stages of the image chain. We describe both the (behavioral) input-output map used for a rapid, but realistic, simulation of the MOS optical engine, as well as illustrative examples of quantitatively tracking errors in the imaging chain from input radiances to bounds on final product errors.

8870-15, Session 4

Simulation of imaging spectrometers degraded by satellite vibrations with pseudo cross-correlation theory

Li-Jun Zhang, Ministry of Education of China (China) and Beijing Insititute of technology (China); Yi Tang, Key Lab. of Photo-electronic Imaging Technology and System (China) and Beijing Insititute of Technology (China); Yue'e Chang, Yibing Nan, Ministry of Education of China (China) and Beijing Insititute of Technology (China)

During the spectral imaging course of imaging spectrometers, satellite platform's instability will bring serious impact on the imaging quality. The degradation mechanism of interferential and dispersive imaging spectrometers caused by satellite vibrations is studied in this paper. A simulation algorithm of degradation based on differential dynamic spectral imaging, and the theory of eight neighborhoods mixing pixels are put forward considering the affect of complex forms of vibration with high-order and multimode. Thus,we can get the point spread matrix, and build the relationship between the parameters of satellite vibration and the influences on spectral imaging using the pseudo cross-correlation theory. A spectral degradation method based on transforming the mixing matrix and a method based on pseudo cross-correlation theory are put

forward. Spectral degradation results are simulated by taking the spectral imaging data and the RGB color surface feature maps of remote sensing satellite as the ideal original data with the two methods separately. Simulation result shows that the degradation of the two methods are effective, reliable and coincident. The different application characters of the two methods are illuminated.

8870-16, Session 5

sCMOS detector for imaging VNIR spectrometry

Andreas Eckardt, Ralf Reulke, Horst H. Schwarzer, Holger Venus, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany); Christian Neumann, Kayser-Threde GmbH (Germany)

The facility Optical Information Systems (OS) at the Robotics and Mechatronics Center of the German Aerospace Center (DLR) has more than 30 years experience with high-resolution imaging technology. This paper shows the scientific results of the institute of leading edge instruments and focal plane designs for EnMAP VIS/NIR spectrograph. EnMAP (Environmental Mapping and Analysis Program) is one of the selected proposals for the national German Space Program. The EnMAP project includes the technological design of the hyperspectral spaceborne instrument and the algorithms development of the classification. The EnMAP project is a joint response of German Earth observation research institutions, value-added resellers and the German space industry like Kayser-Threde GmbH (KT) and others to the increasing demand on information about the status of our environment. The Geo Forschungs Zentrum (GFZ) Potsdam is the Principal Investigator of EnMAP.

DLR OS and KT were driving the technology of new detectors and the FPA design for this project, new manufacturing accuracy and on-chip processing capability in order to keep pace with the ambitious scientific and user requirements. In combination with the engineering research, the current generations of space borne sensor systems are focusing on VIS/NIR high spectral resolution to meet the requirements on earth and planetary observation systems. The combination of large swath and high spectral resolution with intelligent synchronization control, fast-readout ADC chains and new focal-plane concepts open the door to new remote-sensing and smart deep space instruments.

The paper gives an overview over the detector verification program at DLR on FPA level, new control possibilities for sCMOS detectors in global shutter mode and key parameters like PRNU, DSNU, MTF, SNR, Linearity, Spectral Response, Quantum Efficiency, Flatness and Radiation Tolerance will be discussed in detail.

8870-17, Session 5

Fabrication of low straylight holographic gratings for space applications

Reinhard Steiner, Alexander Pesch, Lars H. Erdmann, Matthias Burkhardt, Carl Zeiss Jena GmbH (Germany); Robert Wipf, Carl Zeiss Microscopy, LLC (Germany); Torsten Diehl, Carl Zeiss Jena GmbH (Germany); H. J. P. Vink, Technisch Physische Dienst-TNO (Netherlands); B. G. van den Bosch, TNO (Netherlands); Alexandre Gatto, Carl Zeiss Jena GmbH (Germany)

The main challenges of fabricating diffraction gratings for use in earth monitoring spectrometers are given by the requirements for low straylight, high diffraction efficiency and a low polarization sensitivity. Low straylight gratings are the key component of imaging spectrometers with a high signal to noise ratio. Furthermore the use in space also requires a high environmental stability of these gratings.

We found that holography in combination with ion beam plasma etching provides a way to obtain monolithic, robust fused silica gratings which are able to meet the above mentioned requirements for space applications. Holography accompanied by plasma etching allows the fabrication of a wide range of different grating profiles to optimize the efficiency including the polarization behavior according to a wealth of applications. Typical profile shapes feasible are blazed gratings, sinusoidal profiles and binary profiles and this allows to tailor the efficiency and polarization requirements exactly to the spectral range of the special application. Holographic gratings can be fabricated on plane and also on curved substrates as core components of imaging spectrometers.

In this paper we present our grating fabrication flow for the example of plane blazed gratings and we relate the efficiency and straylight measurement results to certain steps of the process. The holographic setup was optimized to minimize straylight and ghosting recorded by the photoresist during the exposure. Low wavefront deviations require the use of highly accurate grating substrates and high precision optics in the holographic exposure.

8870-18, Session 5

Multislit optimized spectrometer for ocean color remote sensing: fabrication and assembly update

Tim Valle, Chuck Hardesty, Ball Aerospace & Technologies Corp. (United States); Curtiss O. Davis, Nicholas Tufillaro, Oregon State Univ. (United States); William S. Good, Chris Seckar, Peter Spuhler, Ball Aerospace & Technologies Corp. (United States)

The NASA ESTO funded Multislit Optimized Spectrometer (MOS) Instrument Incubator Program will advance a spatial multiplexing spectrometer for coastal ocean remote sensing from lab demonstration to flight-like environment testing. Vibration testing to meet the GEVS requirements for a geostationary orbit launch will be performed. The multiple slit design reduces the required telescope aperture leading to mass and volume reductions over conventional spectrometers when applied to the GEO-CAPE oceans mission. The MOS program is entering year 3 of the 3-year program where assembly and test activities will demonstrate the performance of the MOS concept. This paper discusses the instrument design, fabrication and assembly. It outlines the test plan to realize a technology readiness level of 6. Testing focuses on characterizing radiometric impacts of the multiple slit images multiplexed onto a common focal plane, and assesses the resulting uncertainties imparted to the ocean color data products. The MOS instrument implementation for GEO-CAPE provides system benefits that can lead to cost savings and risk reduction while meeting the science objectives of understanding the dynamic coastal ocean environment.

8870-19, Session 5

The CHROMA focal plane array: a large-format, low-noise detector optimized for imaging spectroscopy

Richard T. Demers, Robert B. Bailey, James Beletic, Steven G. Bernd, Sidharth Bhargava, Jason Herring, Jianmei Pan, Anders K. Petersen, Eric C. Piquette, Brian Starr, Matthew F. Yamamoto, Teledyne Imaging Sensors (United States)

The CHROMA (Configurable Hyperspectral Readout for Multiple Applications) is an advanced Focal Plane Array (FPA) designed for visible-infrared imaging spectroscopy. CHROMA has been integrated into a remote sensing, spectral imaging instrument. Using Teledyne's latest substrate-removed HgCdTe detector, the CHROMA FPA has very low dark current, low readout noise and stable quantum efficiency from the deep blue (390nm) to near the cutoff wavelength. CHROMA has a pixel pitch of 30 microns and is available in array formats ranging from 320?480 to 1600?480 pixels. Users generally disperse spectra over the 480 pixel-length columns and image spatially over the n?160 pixel-length rows, where n=2,4,8,10. The CHROMA Readout Integrated Circuit (ROIC) has Correlated Double Sampling (CDS) in pixel and generates its own internal bias signals and clocks. This paper presents the measured performance of the CHROMA FPA with 2.5 micron cutoff wavelength including the characterization of noise versus pixel gain, power dissipation and wavelength dependent quantum efficiency.

8870-20, Session 6

Hyperspectral imaging of rivers and estuaries *(Invited Paper)*

Curtiss O. Davis, Nicholas Tufillaro, Oregon State Univ. (United States)

The Hyperspectral Imager for the Coastal Ocean (HICO) is the first spaceborne imaging spectrometer designed to sample the coastal ocean. HICO samples selected coastal regions at 92 m ground sample distance with full spectral coverage (88 channels covering 400 to 900 nm) and a high signal-to-noise ratio to resolve the complexity of the coastal ocean. HICO has been operating on the International Space Station since October 2009 and collected over 7000 scenes for more than 50 users. We have been using HICO data to study major rivers and estuaries in the US and Asia. Our results show the advantages of HICO's additional spectral channels and higher spatial resolution for studying these complex coastal waters. We use this data to suggest requirements for spatial and spectral sampling for future ocean color sensors.

8870-21, Session 6

Overview of hyperspectral remote sensing for mapping marine benthic habitats from airborne and underwater sensors *(Invited Paper)*

Heidi M. Dierssen, Univ. of Connecticut Health Ctr. (United States)

The seafloor, with its diverse and dynamic benthic habitats varying on meter to centimeter scales, is difficult to accurately monitor with traditional techniques. The technology used to build imaging spectrometers has rapidly advanced in recent years with the advent of smaller sensors and better signal-to-noise capabilities that has facilitated their use in mapping fine-scale benthic features. Here, the use of such sensors for hyperspectral remote sensing of the seafloor from both airborne and underwater platforms is discussed. Benthic constituents provide a so-called optical fingerprint with spectral properties that are often too subtle to be discerned with simple color photographs or multi-channel spectrometers. Applications include the recent field validation of the airborne Portable Remote Imaging SpectroMeter (PRISM), a new imaging sensor package optimized for coastal ocean processes in Elkorn Slough California. In these turbid sediment-laden waters, only subtle spectral differences differentiate seafloor with sediment from that with eelgrass. Another example is the use of imaging spectrometers coupled with light sources on autonomous underwater vehicles for imaging deep water habitats of ecological significance. Here, results from the use of hyperspectral remote sensing to monitor white and orange cold corals in Norwegian waters are presented. The ultimate goal is to provide robust radiometric approaches that accurately consider light attenuation by the water column and are able to be applied to diverse habitats without considerable foreknowledge.

8870-22, Session 6

Investigating coral hyperspectral properties across coral species and coral state using hyperspectral imaging

Mehrube Mehrübeoglu, Texas A&M Univ. Corpus Christi (United States); Kevin B. Strychar, Grand Valley State Univ. (United States); Dustin K. Smith, Shane W. Smith, Texas A&M Univ. Corpus Christi (United States)

Coral reefs are one of the most diverse and threatened ecosystems in the world. Corals worldwide are at risk, and in many instances, dying due to factors that affect their environment resulting in deteriorating environmental conditions. Because corals respond quickly to the quality of the environment that surrounds them, corals have been identified as bioindicators of water quality and marine environmental health. The hyperspectral imaging system is proposed as a non-invasive tool to monitor different species of corals as well as coral state over time. This in turn can be used as a quick and non-invasive method to monitor environmental health that can later be extended to climate conditions. In this project, a laboratory-based hyperspectral imaging system is used to collect spectral and spatial information of corals. In the work presented here, MATLAB and ENVI software tools are used to view and process spatial information and spectral signature of to identify differences among the coral data. The results support the hypothesis that hyperspectral properties of corals vary among different coral species, and coral state over time, and hyperspectral imaging can be a used as a tool to document changes in coral species and state.

8870-23, Session 6

On the demands on imaging spectrometry for the monitoring of global vegetation fluorescence from space

Stefan Kraft, Umberto Del Bello, Matthias Drusch, Antonio Gabriele, Bernd Harnisch, European Space Research and Technology Ctr. (Netherlands); Jose Moreno, Univ. de València (Spain)

Vegetation fluorescence when measured from space contributes only a tiny fraction of the signal coming on top of the reflected radiance of the Earth. As a consequence, imaging spectrometers have to provide sufficient throughput and radiometric accuracy to enable accurate global monitoring of the daily to seasonal variations of the Earth's vegetation breath, which is particularly challenging if ground resolutions of a few hundred meters are targeted. Since fluorescence retrieval algorithms have to make corrections for atmospheric effects, it is necessary to provide sufficient spectral resolution, so that signal alterations due to the main parameters such as atmospheric pressure, temperature, aerosol density and height, and water vapour content can be accurately modelled. ESA's Earth Explorer 8 candidate mission FLEX carries a Fluorescence Imaging Spectrometer (FLORIS), which has been designed and optimised to enable such measurement. The spectrometer will measure in a spectral range between 500 and 780 nm and provide high spectral resolution of 0.3 nm in particular at the Oxygen A and B bands. It will also cover the photochemical reflection features between 500 and 600 nm, the Chlorophyll absorption band between 600 and 677 nm, and the red-edge in the region of 697 to 755 nm. FLEX will fly in formation with Sentinel 3 in order to further enhance the spectral coverage from measurements made by the Sentinel 3 instruments OLCI and SLSTR. We will report on the current status of the Phase A/B1 studies, and present the mission configuration and the identified instrument concepts.

8870-24, Session 6

Investigating oyster shell thickness and strength using three imaging modalities: hyperspectral imaging, thermal imaging and digital photography

Mehrube Mehrübeoglu, Delbert L. Smee, Petru-Aurelian Simionescu, Dustin K. Smith, Shane W. Smith, Texas A&M Univ. Corpus Christi (United States)

A comparative study of three imaging technologies has been conducted to non-invasively assess the thickness and strength of oyster shells

grown in various environmental conditions. Oyster shell thickness and strength are expected to be dependent on the harshness of the oyster's environment as well as other factors. Oysters have been grown in environments with and without predators, and within and out of tidal zones. Hyperspectral imaging has been used to detect possible differences in hyperspectral properties among oysters from each of the four environments. Thermal Imaging has been utilized to identify hot spots in the shells based on the principles of heat capacitance, indicating density or thickness of the shells. Finally, a visible-range digital photographic camera has been used to obtain digital images. The three technologies are compared to evaluate the effectiveness of each technology in identifying oyster shell thickness and strength. Although oyster shell thickness and strength are related, they may not be exactly correlated. The local thickness of the oyster shells have been measured with a micro caliper for stress measurement to establish a baseline and ground truth. The preliminary results from the three methods demonstrate that thermal imaging correlates the best with the invasive stress test results.

8870-25, Session 7

Extended hyperspectral imaging system modeling and implementation for subpixel target detection

Bo Ding, John Kerekes, Rochester Institute of Technology (United States)

In support of hyperspectral imaging system design and parameter trade-off research, an analytical end-to-end model to simulate the remote sensing system pipeline and forecast remote sensing system performance has been developed and made available to the remote sensing community through an RIT-hosted website. Users are able to forecast hyperspectral imaging system performance by defining an observational scenario along with imaging system parameters. For system modeling the implemented analytical model includes scene, sensor and target characteristics as well as atmospheric features, background spectral reflectance statistics, sensor specifications and target class reflectance statistics. For target detection applications, common data processing algorithms are also implemented. Predicted system performance has been verified by comparing the forecast results to ones obtained using real world data collected during the RIT SHARE 2012 collection. In this paper, a web-based application to model a remote sensing system is implemented and a typical application introduced. Sensor modeling has been extended to include the airborne ProspecTIR instrument. Subpixel target spectral radiance statistics are predicted by this model with given scene information, pre-measured background, target spectral reflectance statistics, and also the atmospheric radiative transfer model MODTRAN. The predicted spectral radiance statistics are transformed into a feature space and used with target detection algorithms to generate probability of detection versus false alarm curves to evaluate system performance and parameter trade-offs. The validation data from the SHARE 2012 collection show consistency with the simulated result. Also, some examples of parameter trade-offs are given and analyzed to explain the utility of this model for hyperspectral imaging system design and research.

8870-26, Session 7

Automated endmember determination and adaptive spectral mixture analysis using kernel methods

Robert S. Rand, National Geospatial-Intelligence Agency (United States); Amit Banerjee, Joshua B. Broadwater, Johns Hopkins Univ. Applied Physics Lab. (United States)

Various phenomena occur in geographic regions that cause pixels of a scene to contain spectrally mixed pixels. The mixtures may be linear or nonlinear. It could simply be that the pixel size of a sensor is too large so many pixels contain patches of different materials within them (linear), or there could be microscopic mixtures and multiple scattering occurring within pixels (non-linear). Often enough, scenes may contain cases of both linear and non-linear mixing on a pixel-by-pixel basis. Furthermore, appropriate endmembers in a scene are not always easy to determine. A reference spectral library of materials may or may not be available, yet, even if a library is available, using it directly for spectral unmixing may not always be fruitful. This study investigates a kernel-based fully-constrained method for spectral unmixing that attempts to determine if each pixel in a scene is linear or non-linear, and adapts to compute a mixture model at each pixel accordingly. The effort also investigates a kernel-based support vector method for determining spectral endmembers in a scene. Various scenes of hyperspectral imagery calibrated to reflectance are used to validate the methods.

8870-27, Session 7

Spatial heterodyne spectrometer: modeling and interferogram processing for calibrated spectral radiance measurements

Cara P. Perkins, John Kerekes, Michael Gartley, Rochester Institute of Technology (United States)

We present a model of spatial heterodyne spectrometer (SHS) and a corresponding interferogram-processing algorithm for the calculation of calibrated spectral radiance measurements. The SHS relies on Fourier Transform Spectroscopy (FTS) principles, and shares design similarities with the Michelson Interferometer. The advantages of the SHS design, including the lack of moving parts, high throughput, and instantaneous spectral measurements, make it suitable as a field-deployable instrument. Our SHS model takes into account the instrument's entrance optics, interferometer, exit optics, and detection scheme to output realistic, interferometric data. The model serves as a tool to find the optimal SHS diffraction grating and Littrow parameters for the desired design specifications and application. It also assists in the data analysis and system characterization. The interferogram-processing algorithm performs flat-fielding and phase corrections as well as apodization before recovering the measured spectral radiance via the Inverse Fourier Transform (IFT). The model and processing algorithm are tested with spectra generated by both MODTRAN and the Rochester Institute of Technology (RIT) micro-DIRSIG software as well as spectra recorded with a Designs & Prototypes Model 102 FTIR non-imaging spectrometer. The model and processing algorithm results shown are for a long-wave infrared (LWIR) SHS design. Operating in the thermal infrared, the SHS design presented provides the capability of performing chemical detection based on spectral signatures.

Hyperspectral data compression using a Wiener filter predictor

Pierre V. Villeneuve, Scott G. Beaven, Alan D. Stocker, Space Computer Corp. (United States)

Application of compression methods to hyperspectral image (HSI) data is a significant technical challenge. A primary bottleneck in disseminating data products to the tactical user community is the limited communication bandwidth between the airborne sensor and the ground station receiver. This report summarizes a newly-developed algorithm (named “Z-Chrome”) for lossless compression of HSI data. This form of data is inherently highly correlated across spectral bands. Modern target detection algorithms typically exploit this correlation as a means to dramatically reduce false-alarm rates from scene clutter.

This algorithm is based on the assumption that compression of spatial information is separable from compression of spectral information. The Z-Chrome algorithm iterates over a sequence of band images from a data cube. At each step a Wiener filter predictor is constructed from the global spectral statistics between the current band and the already-processed data. The model prediction is subtracted from the current band, with the residual band image having spatial content that is now completely decorrelated spectrally from the residual data computed from all other bands. Existing image compression algorithms do a fantastic job at accounting for spatially-correlated image features. Z-Chrome is essentially a spectral-only predictor wrapped around state-of-the-art lossless image compression algorithms.

Z-Chrome algorithm performance is demonstrated by application to many hundreds of HSI data cubes collected by AVIRIS, Hyperion and CAP-ARCHER sensors over a variety of terrains. Quantitative lossless compression performance is measured at the cube level as the average number of bits per pixel. Relative compression performance is reported as the ratio of the compressed file size to the original file size.

8871-2, Session 1

An encoder rate control method for unidirectional distributed video coding

Juan Song, Peiyi Shen, Liang Zhang, Keyan Wang, Xidian Univ. (China)

Due to its good tradeoff between complexity and compression performance, distributed video coding (DVC) is widely used in video surveillance, wireless sensor network and etc. Most of DVC architectures available use a feedback channel to determine the required parity rate for decoding Wyner-Ziv frames. Therefore this kind of DVC architectures with feedback channel is called bidirectional DVC. However, a feedback channel is not always available for some applications or feedback cannot be used due to realtime demand, e.g. offline storage, realtime video streaming, and etc. To make DVC more practical, unidirectional DVC without feedback channel is presented, in which encoder rate control (ERC) is implemented to determine the required parity rate at the encoder. And to maintain low complexity at the encoder, the ERC module should be as simple as possible.

The ERC solutions in the literature either have quite poor performance or high encoder complexity. In this paper an efficient and low-complexity encoder rate control method is proposed. In our proposed method a low-complexity motion estimation method is first presented to create estimated side information at the encoder, in which the motion consistency between frames is utilized to reduce the search range and obtain accurate motion vectors. The motion search in the current frame is implemented based on the motion vectors in the previous frame. Then the created side information is used to estimate correlation noise and conditional entropy of each bitplane at the encoder. The inter-bitplane correlation of conditional entropy is utilized to simplify entropy computation. Finally the conditional entropy is adjusted as the estimated parity rate.

Experimental results show that our proposed encoder rate control method could estimate the required parity rate accurately with much lower complexity. And our ERC based unidirectional DVC system has comparable compression performance with bidirectional DVC.

8871-3, Session 1

Performance analysis of 2D asynchronous hard-limiting optical code-division multiple access system through atmospheric scattering channel

Yaqin Zhao, Xin Zhong, Di Wu, Ye Zhang, Guanghui Ren, Zhilu Wu, Harbin Institute of Technology (China)

Optical code-division multiple access (OCDMA) systems usually allocate orthogonal or quasi-orthogonal codes to the active users. When transmitting through atmospheric scattering channel, the coding pulses are broadened and the orthogonality of the codes is worsened. In truly asynchronous case, namely both the chips and the bits are asynchronous among each active user, the pulse broadening affects the system performance a lot.

In this paper, we evaluate the performance of a 2-D asynchronous hard-limiting wireless OCDMA system through atmospheric scattering channel. The distribution of multiple access interference (MAI) in truly asynchronous case is given. The BER decreases as the ratio of the chip period to the channel delay spread root mean square increases and the channel limits the bit rate to different levels when the chip period varies.

8871-4, Session 1

Lossless compression of multispectral images using adaptive edge-based prediction

Keyan Wang, Liping Wang, Juan Song, Yunsong Li, Rufei Cheng, Xidian Univ. (China)

Prediction-based coding approaches, owing to their high compression ratio and low complexity, are most popular methods for multispectral images lossless compression. However the existing methods did not fully exploit the edge information of the images. In this paper, we propose an algorithm for lossless compression of multispectral images with an adaptive edge-based prediction. The algorithm has two modes in prediction: intra-band and inter-band prediction. A similar median predictor (MP) is adopted In intra-band prediction, while in inter-band prediction a novel edge-based predictor (EP) is utilized. The EP applies an edge detection first to the reference band, and estimates the edge structure of the current band due to the strong inter-band structral similarity. After an edge-based analysis for the pixels within the context, the current pixel is predicted with the edge information from the context by least-squares optimization. All the predicted residuals are finally entropy coded. Experimental results show that the proposed edge-based prediction improves the lossless compression ratio by fully exploiting the high correlation of the pixels along the edges.

8871-5, Session 1

Improving multispectral satellite image compression using onboard subpixel registration

Mathieu Albinet, Roberto Camarero, Ctr. National d'Études Spatiales (France); Maxime Isnard, Thales Services (France); Christophe Poulet, Jokin Perret, EREMS (France)

Future CNES earth observation missions will have to deal with an ever increasing telemetry data rate due to improvement in resolution and addition of spectral bands. Current CNES image compressors implements a discrete wavelet transform followed by a bit plane encoding but only on a mono spectral basis and do not profit from the multispectral redundancy of the observed scenes. Recent CNES studies have proved a substantial gain on the achievable compression ratio, +20% to +40% on selected scenarios, by implementing a multispectral compression scheme based on a Karhunen Loeve transform followed by the classical DWT+BPE. But such results can be achieved only on perfectly registered bands and a deregistration as low as 0.5 pixel ruins all the benefits of multispectral compression.

In this work, we first study the possibility to implement a multi-bands subpixel onboard registration based on a registration grid generated on-the-fly by the satellite attitude control system and simplified registration and interpolation techniques. Indeed bands registration is usually performed on ground using sophisticated techniques too computationally expensive for onboard use. This fully quantized algorithm is tuned to meet acceptable registration performances within stringent image quality criteria and with the objective of onboard real-time processing. In a second part, we describe a FPGA implementation developed to evaluate the design complexity and, by extrapolation, the data rate achievable on a space-qualified ASIC. Finally, we present the impact of this approach on the processing chain onboard but also on ground and the impacts on the design of the instrument.

8871-6, Session 2

Fast implementation of neural network classification

Guiwon Seo, Jiheon Ok, Chulhee Lee, Yonsei Univ. (Korea, Republic of)

Most artificial neural networks use a nonlinear activation function that includes sigmoid and hyperbolic tangent functions. Most artificial networks employ nonlinear functions such as these sigmoid and hyperbolic tangent functions, which incur high complexity costs, particularly during hardware implementation. In this paper, we propose new polynomial approximation methods for nonlinear activation functions that can substantially reduce complexity without sacrificing performance. The proposed approximation methods were applied to pattern classification problems. Experimental results show that the processing time was reduced by up to 50% without any performance degradations in terms of computer simulation.

8871-7, Session 2

An efficient classification by signal subspace projection and partial filtering for hyperspectral images

Lena Chang, Zay-Shing Tang, National Taiwan Ocean Univ. (Taiwan)

Recently, some subspace-based techniques for hyperspectral image classification have received great attention, such as the orthogonal subspace projection (OSP), noise subspace projection (NSP) and signal subspace projection (SSP) methods. In this study, to reduce the computation complexity of hyperspectral data processing, we exploit high degree correlations in spectral and spatial domains, and propose an efficient classification method which combines SSP and partial filtering technique for hyperspectral images.

The SSP-based filters can be designed to extract target information using the signal subspace components corresponding to the image correlation matrix without a priori knowledge of background. Although SSP has been validated less sensitive to an inaccurate desired signature vector, it requires performing eigen-decomposition of image correlation matrix. To reduce computation complexity of SSP, we first examine the correlations between hyperspectral image bands and partition the original image bands into several groups by Maximum Correlation Band Clustering (MCBC) method. According to the spectrum correlations of ground truth data such as vegetation, cane or soil, each class is divided into corresponding band groups during training process. Instead of using all bands simultaneously, we design partial filter for each band group by SSP approach. Finally, the SSP-based partial filters (SSPPF) are combined using corresponding weights for each class. For real image classification, simulations validate the proposed SSPPF can achieve the performance of OSP and SSP with less computation complexity. Generally, the proposed method requires only 1/K^2 computations of SSP, if image is partitioned into K groups.

8871-8, Session 2

Fisher criterion based nearest feature line approach to land cover classification using multi source data fusion

Yang-Lang Chang, Yi-Shiang Fu, Tung-Ju Hsieh, National Taipei Univ. of Technology (Taiwan); Lena Chang, National Taiwan Ocean Univ. (Taiwan); Chin-Chuan Han, National United Univ. (Taiwan); Bormin Huang, Univ. of Wisconsin-Madison (United States)

In this paper a novel technique, known as nearest feature line (NFL) approach, is proposed for supervised classification of multisource images for the purpose of landslide hazard assessment. This approach presents a framework for data fusion of multisource remotely sensed images, which consists of two approaches, referred to as band generation process (BGP) and Fisher criterion based NFL classifier. It is developed for land cover classification based on the fusion of remotely sensed images of the same scene collected from multiple sources. Compared to the original NFL, we propose an improve NFL classifier which uses the Fisher criterion of between-class and within-class discrimination to enhance the original one. In the training phase the labeled samples are discriminated by the Fisher criterion, which can be treated as a pre-processing of NFL. The classification results can be obtained by NFL algorithm. In order for the proposed NFL to be effective for multispectral images, a multiple adaptation BGP is introduced to create a new set of additional bands especially accommodated to landslide classes. Experimental results demonstrate the proposed BGP/NFL approach is suitable for land cover classification in earth remote sensing and improves the precision of image classification.

8871-9, Session 2

Saline-alkali land classification using MODIS data In Western Jilin Province, China

Lingjia Gu, Ruizhi Ren, Jilin Univ. (China); Junsheng Cao, Changchun Institute of Optics, Fine Mechanics and Physics (China); Jian Sun, Jilin Univ. (China)

As an environmental disaster, soil salinization leads to a significant land degradation, furthermore, reduces or destroys soil productivity, which decreases food production in agricultural areas and makes serious threats to the sustainable development of ecology and national economy. Remote sensing technology can obtain useful information of observation

areas, and provide reliable data for ground monitoring, which is widely used in dynamic monitoring and resources research of saline-alkali land. The level of salt accumulation in saline soil directly causes different changes in spectral remote sensing image, which can be used to distinguish the image characteristics of normal soils from saline-alkali lands. Furthermore, the salinization degree can be induced from the spectral characteristics of saline-alkali land. Considering that the spectral reflection of saline-alkali land changes seasonally, it needs integrated experiences and pre-knowledge in order to reduce the classification error and statistical error. In this study, western Jilin Province, China selected as the observation area has a lot of typical characteristics of saline-alkali land. Firstly, the geographical location of the saline-alkali land was roughly determined according to the colors and shapes of MODIS image. Through obtaining and analyzing of the spectral characteristics of saline-alkali soil types, the relationship between the spectral characteristics of saline-alkali soil types and saline-alkali land classification was further established based on the existing empirical knowledge. The research results demonstrated that the saline-alkali lands located in Western Jilin Province, China can be effectively classified based on the spectral characteristics of MODIS data.

8871-10, Session 3

Multi-watermarking scheme for copyright protection and content authentication of DubaiSat-1 satellite imagery

Saeed H. Al-Mansoori, Emirates Institution for Advanced Science and Technology (United Arab Emirates); Alavi Kunhu, Khalifa Univ. of Science, Technology and Research (United Arab Emirates)

This paper exams applying watermarking scheme based on invisible frequency domain approach, called “Discrete Cosine Transform” (DCT), on satellite imagery. This technique emerged as a result of new challenges with piracy of remote sensing imagery ownership. This led researchers to look for different means to secure the ownership of satellite images and preventing the illegal use of these resources. Therefore, Emirates Institution for Advanced Science and Technology (EIAST) proposed utilizing existing data security concept by embedding a digital signature, “watermark”, into DubaiSat-1 satellite images. In this study a gray scale EIAST logo is embedded into DubaiSat-1 satellite imagery, which would protect the organization’s intellectual property against different image processing manipulation (i.e. attacks) attempts. Two criteria’s were set to evaluate the proposed algorithm: the quality of the watermarked image and the robustness of the technique against attacks. Image processing manipulations were used to generate numerous attacks such as lossy compression (JPEG), rotation, flipping , and noise addition (Salt & Pepper and Gaussian).

8871-11, Session 3

Anomaly-specified virtual dimensionality

Chein-I Chang, Shih-Yu Chen, Drew Paylor, Univ. of Maryland, Baltimore County (United States)

Virtual dimensionality (VD) has received considerable interest with its use in specifying the number of spectral distinct signatures, denoted by p. Unfortunately, no specific definition is provided by VD for what a spectrally distinct signature is. This paper presents a new concept, referred to as anomaly-specified VD (AS-VD) which determines the number of anomalies of interest present in the data. Specifically, two types of anomaly detection algorithms are of particular interest, sample covariance matrix K-based anomaly detector developed by Reed and Yu, referred to as K-RXD and sample correlation matrix R-based RXD, referred to as R-RXD. Since K-RXD is only determined by 2nd order statistics compared to R-RXD which is specified by statistics of the first two orders including sample mean as the first order statistics, the values determined by K-RXD and R-RXD will be different. Experiments are conducted in comparison with widely used eigen-based approaches.

8871-13, Session 3

Spatial corrlations constrained sparse unmixing of hyperspectral image using Markov random fields

Jiaojiao Li, Xianyun Wu, Yunsong Li, Keyan Wang, Xidian Univ. (China)

Spectral unmixing is an important research hotspot for remote sensing hyperspectral image. The unmixing process is comprised of the extraction of spectrally pure signatures(also called endmembers) and the determination of the abundance fractions of endmebers. Due to the inconspicuous signatures of pure spectra and the challenge of inadequate spatial resolution, sparse regression(SR) techniques are adopted in solving the linear spectral unmixing problem. However, these SR-based solutions failed to make full use of the spatial information. In this paper, we describe the classic sparse regression formulation firstly and then propose a new unmixing algorithm which involving in more complete spatial information on sparse unmixing formulation for hyperspectral image. The new algorithm integrates the spectral and spatial information in a Bayesian framework which is introduced to exploit the spatial-contextual information effectively. Moreover, the Markov Random Fields(MRF) can model the spatial correlation efficiently, the new method employ a MRF based on the Bayesian framework. Compared with other SR-based linear unmixing methods, our experimental results showed that the method proposed in this paper not only improves the characterization of mixed pixels but also obtains better accauracy in hyperspectral image unmixing.

8871-14, Session 3

Early warning of malaria at Bikaner, Rajasthan in India using AVHRR-based satellite data

Leonid Roytman, Nizamuddin Mohammad, The City College of New York (United States); Kawsar A. Akhand, The City Univ. of New York (United States); Felix Kogan, National Environmental Satellite, Data, and Information Service (United States); Mitchell Goldberg, National Oceanic and Atmospheric Administration (United States)

A better understanding of the relationship between satellites observed vegetation health, and malaria epidemics could help mitigate the worldwide increase in incidence of mosquito-transmitted diseases. This research investigates last 17-years association between vegetation health (condition) index and malaria transmission in Bikaner, Rajasthan in India an arid and hot summer area. The vegetation health (condition) index, derived from a combination of Advanced Very High Resolution Radiometer (AVHRR) based Normalized Difference Vegetation Index (NDVI) and 10-?m to 11-?m thermal radiances, was designed for monitoring moisture and thermal impacts on vegetation health. We demonstrate that thermal condition is more sensitive to malaria transmission with different seasonal malaria activities. The weekly VH indices were correlated with the epidemiological data. A good correlation was found between malaria cases and Temperature Condition Index (TCI) one at least two months earlier than the malaria transmission season. Following the results of correlation analysis, Principal Component Regression (PCR) method was used to construct a model of less than 10% error to predict malaria as a function of the TCI.

8871-15, Session 4

GPU-based parallel design of vertex component analysis for hyperspectral unmixing

Liang Chen, Yong Fang, Northwest A&F Univ. (China); Bormin Huang, Univ. of Wisconsin-Madison (United States); Antonio J. Plaza, Univ. de Extremadura (Spain)

The vertex component analysis (VCA) algorithm is one of the most popular methods for spectral unmixing of hyperspectral data. This unsupervised algorithm is based on the geometry of convex sets. Compared with several existing state-of-the-art methods for endmember unmixing, such as pixel purity index (PPI) and N-FINDR, VCA genrally shows superior performance. Experiments with real hyperspectral data show that this algorithm is an effective tool to unmix linear mixtures of endmember spectra from hyperspectral data. In recent years, graphics processing units (GPUs) have become a widely used technology for general-purpose parallel computing. Massively parallel computations using GPUs have been applied in different areas. Considering the matrix/vector operations and computationally expensive calculations involved in the VCA algorithm, we can conclude that this method is suitable to be implemented on GPUs. In this work, we propose a parallel version of VCA on GPUs which is based on the Compute Unified Device Architecture (CUDA). We choose CUDA as our research platform as it is a well-established scheme in many applications. Different experiments are conducted with our parallel version in order to find its optimal implementation. After applying the algorithm to real hyperspectral data, our GPU implementation shows a speedup of 24.65x with regards to an optimized serial version of the algorithm.

8871-16, Session 4

Parallel acceleration for neural networks algorithms in hyperspectral image unmixing

Xianyun Wu, Jiaojiao Li, Yunsong Li, Keyan Wang, Xidian Univ. (China)

In hyperspectral imagery, mixed pixels are a mixture of distinct substances with linear or nonlinear interactions. Spectral unmixing aims at decomposing the mixed spectral signature into a collection spectrally pure constituent spectra which called endmembers and estimating the abundances of each endmember present in the mixture. Several algorithms have been proposed for spectral unmixing. Neural networks algorithms have shown good capabilities in solving nonlinear inversion problems in hyperspectral image unmixing. In NN-based unmixing algorithms, the Multi-Layer Perceptron(MLP) neural network scheme is trained for the pixel-based classfication algorithm. For the output response, "winner-takes-all" rule is replaced by a soft interpretation to give the percentage with each land cover classes. Compared with Linear Spectral Unmixing(LSU), the NN-based algorithm can obtain better performance. However, NN-based algorithm are usually highly time-consuming and hard for on-board or real-time processing. In this study, we use Graphic Processing Units(GPU) for faster parallel computing. We use Compute Unified Device Architecture(CUDA) language for efficient implementation of NN. For MLP scheme, each layer is independent with others and the learning process for each layer is identical with others. In the same layer, each note is also independent with other notes which make NN very suitable for parallel computing. Our implementation are deep optimized by using shared memory. Experimental results showed that our implementation achieve a very high speedup and identical results compared with single-thread CPU implementation.

8871-17, Session 4

An FPGA implemented bridge over water recognition for an image evaluation on-board of satellites

Sebastian Beulig, Maria von Schönermark, Felix Huber, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany)

In the present study, a novel approach for an automatic bridge over water recognition is introduced.

The method requires no a-priory knowledge about the scene, is applicable to optical gray value satellite image data and is implemented in a small reconfigurable micro chip, a Field Programmable Gate Array (FPGA).

Due to the low power consumption of the FPGA and the autonomous performance of the algorithm the implementation is suitable for an application on-board of satellites.

Since the captured satellite image data can be evaluated within a few seconds, useful information about the infrastructure, which is e.g. desired by the disaster management in case of a natural hazard, can be provided in a short time.

The proposed method is robust and recognizes the whole bridge deck area, which yields additional information about the bridge and allows a detailed analysis of the site. At first a binary water mask is derived from the satellite image data and all islands, hollow spaces in the water areas, are labeled.

Then all potential bridge regions are extracted by morphological operations. Because this step produces also a lot of false detections, a final analysis is carried out to separate real bridges from false ones. The result is a map of marked bridge deck areas.

The hardware implementation, in a Xilinx Spartan 3E FPGA, was tested with 40 panchromatic and near-infrared images with a spatial resolution of 5m, and showed promising results.

Hence, this method seems a reasonable tool for an image evaluation on-board of satellites.

8871-18, Session 4

Massively parallel computation of soil surface roughness parameters on a GPU

Xiaojie Li, Northeast Institute of Geography and Agroecology (China); Changhe Song, Xidian Univ. (China); Bormin Huang, Univ. of Wisconsin-Madison (United States)

Surface roughness is description of the surface micro topography of randomness or irregular. The standard deviation of surface height and the surface correlation length describe the statistical variation for the random component of a surface height relative to a reference surface. In the observation of the earth using microwave radiometers, surface roughness is an important factor to soil microwave radiation. When the number of data points is large, calculation of surface roughness parameters is time-consuming. With the advent of Graphics Processing Unit (GPU) architectures, inherently parallel problem can be effectively solved using GPUs. In this paper we propose a GPU-based massively parallel computing method for 2D soil surface roughness estimation. In this paper we develop a GPU-based high performance computing on the study of soil surface roughness parameters with total data points of 47,958. We reach a speedup of 115? as compared to a single threaded CPU version when I/O transfer is taken into account. The result can be used to IEM (Integrated Equation Model), and the soil backward scattering coefficient will be obtained.

8871-19, Session 4

A novel VLSI architecture for pixel purity index algorithm

Fang Yi, Jie Guo, Yunsong LI, Xidian Univ. (China)

In hyperspectral remote sensing, a single pixel of usually covers several different materials, and its observed spectrum can be expressed as a linear combination of a few pure spectral signatures called “endmembers”. One of the most popular endmember extraction algorithms is the Pixel Purity Index (PPI) which is time-consuming and hard to meet the on-board demands.

In this paper, we present a novel architecture for PPI algorithm on Field Programmable Gate Arrays (FPGA) to meet the on-board demands. The parallel architecture and pipelining technique enhance the processing capacity significantly. We also overcome a burden of huge I/O communication by optimizing the matrix multiplying strategy. Additionally, high-level synthesis tool is used. Based on above methods, our implementation is significantly time saving than other architectures in the same hardware device.

Our system architecture can be easily transplanted to different FPGAs by doing some configurations. In this paper, we implemented it on a System-on-Chip platform and a Virtex-4 XC4VFX60 FPGA. However, we recommend System-on-Chip platform due to its low-weight and low-power features for an entire remote data processing system.

We evaluated our algorithm using the well-known “Cuprite” image and take a comparison with ENvironment for Visualizing Images (ENVI) software. The U.S. Geological Survey library (USGS) is used to assess the accuracy of endmembers we extracted. It demonstrates that our hardware implementation can get equivalent or better accuracy in few seconds while the software runs more than one thousand seconds in a typical computer. This processing speed can meet the on-board demands.

8871-20, Session 4

Parallel processing of point cloud registration

Wen-Han Hsu, Tung-Ju Hsieh, Yang-Lang Chang, National Taipei Univ. of Technology (Taiwan); Bormin Huang, Univ. of Wisconsin-Madison (United States)

Recently, researchers use linear mode to set up a scanner to scan the landscape. It has been proven that the rotation along the z-axis has minimum effect on the accuracy of point cloud registration. In this study, we perform point cloud registration of two set of point cloud measured from different locations. The first set of point cloud remained unmoved. We perform point registration by introducing offsets along the x, y, and z direction to the second set of point cloud. The following steps are performed: First, we use RiSCAN PRO software to manually perform coarse registration by selecting matching points in two sets of point cloud. Second, we perform feature extraction and undergo sequential enumeration method to match point cloud pairs by introducing offsets to the second set of point cloud. Third, we perform sequential combination to fully enumerate offsets to find the optimal. We use Compute Unified Device Architecture (CUDA) to program GPU to achieve parallel computing and achieve a speedup factor of 90x.

8871-21, Session 5

Data fusion of hyperspectral and multispectral remote sensing data for near real-time monitoring of microcystin distribution in Lake Erie

Ni-Bin Chang, Univ. of Central Florida (United States)

Urban growth and agricultural production have caused an influx of nutrients into Lake Erie, leading to eutrophic zones. These conditions result in the formation of algal blooms, some of which are toxic due to the presence of Microcystis (a cyanobacteria), which produces the hepatotoxin microcystin. Microcystis has a unique advantage over its competition as a result of the invasive zebra mussel population that filters algae out of the water column except for the toxic Microcystis. The toxin threatens human health and the ecosystem, and it is a concern for water treatment plants using the lake water as a tap water source. This paper demonstrates the prototype of a near real-time early warning system using Integrated Data Fusion techniques with the aid of both hyperspectral (MERIS) and multispectral (MODIS) remote sensing data to determine spatiotemporal microcystin concentrations. The finer spatial and temporal resolution of MODIS is fused with the high spectral resolution of MERIS to create a synthetic images on a daily basis. As a demonstration, the spatiotemporal distributions of microcystin within western Lake Erie is reconstructed using the band data from the fused products and applied machine-learning techniques. Analysis of the results through statistical indices confirmed that the this type of algorithm has better potential to accurately estimating microcystin concentrations in the lake, which is better than all current 2-band and 3-band models and other computational intelligence models.

8871-22, Session 5

Enhancing DubaiSat-1 satellite imagery using a single image super-resolution

Saeed H. Al-Mansoori, Emirates Institution for Advanced Science and Technology (United Arab Emirates); Alavi Kunhu, Khalifa Univ. of Science, Technology and Research (United Arab Emirates)

DubaiSat-1 (DS1) captures multispectral images, which consist of three visible channels and one NIR with 5-meter resolution and a panchromatic channel with 2.5-meter resolution. Considering these resolutions, some important details might appear blurry on the image. Therefore, the concept of “Super Resolution” has been introduced to reconstruct the image in a way to overcome the inherent resolution limitations of imaging sensors. The aim of this study is to enhance the quality of the image by artificially increasing the number of pixels within the image to sharpen out-of-focus details or smooth rough edges in DubaiSat-1 images that have been enlarged using a general up-scaling process. Usually, images received from satellites go through many image processing and enhancement steps to increase the quality of these images. Many studies have been conducted in this field, and different techniques were suggested to improve the enhancement procedure. Studies were done to combine low resolution images of the same area to come up with an image with a high resolution and better quality. Image enhancement refers to operations used to get image features such edges, boundaries, or contrast in order to make a digital image more useful for display and analysis. In this paper , three common super-resolution techniques (i.e. Bi-linear Interpolation, Bi-Cubic Interpolation, Sparse Representation) are implemented on a single low resolution image and analysed when applying a specific sharpening filter.

8871-23, Session 5

High-resolution satellite image recovery by MTF compensation method using phase congruency estimation

Xiaopeng Shao, Zhenhua Jin, Juan Du, Xidian Univ. (China); Hong Chang, Weihai Vocational College (China)

Satellite imagery always has low-resolution causing poor application in practice because the serious degradation in imaging is resulted in many factors such as atmospheric turbulence, cloud, and aberration of optical system. To reconstruct the degraded remote sensing images with a high quality, we designed an algorithm to estimate the system modular transfer function(MTF) accurately. Phase congruency is employed to detect the edges and corners of the image first, then the significant edges, which are utilized to estimate the edge spread function(ESF) using inclined edge method, are picked up from above features through a certain line detection measurement. An image restoration algorithm based on total variation(TV) is introduced to deconvolute the degraded image with the estimated MTF which is derived from the ESF. The experiments show that this method is adaptive and efficient to recover the remote sensing images taken from a Chinese Satellite. The restored images with a higher resolution and higher signal-to-noise ratio(SNR) will improve the applications greatly.

8871-24, Session 5

Progressive band processing of anomaly detection

Chein-I Chang, Shih-Yu Chen, Robert C. Schultz, Yulei Wang, Univ. of Maryland, Baltimore County (United States); Chunhong Liu, South China Agriculture Univ. (China)

Band selection (BS) has advantages over data dimensionality in satellite communication and data transmission in the sense that the spectral bands can be tuned by users at their discretion for data analysis, while preserving data fidelity. However, to materialize BS in such practical applications several issues need to be addressed. One is how many bands required for BS. Another is how to select appropriate bands. A third one is how to take advantage of previously selected bands without re-implementing BS. Finally and most important one is how to tune bands to be selected in real time as number of bands varies. This paper presents an application to progressive band processing of anomaly detection, which can be carried out in a real time and progressive fashion with data updated recursively band by band in the same way that data is processed by a Kalman filter.

8871-25, Session 5

Quality control of satellite-derived sea surface temperature

Tu Qianguang, Delu Pan, Zengzhou Hao, Haiqing Huang, Fang Gong, The Second Institute of Oceanography, SOA (China)

The individual satellite-derived SST datasets are usually blended together to provide a regular SST analysis with good quality and high resolution in oceanic and atmospheric researches. Data Quality Control (QC) is a preliminary requirement for blending Satellite SSTs. Satellite SST data quality is generally validated by in situ SST. However, in situ data are sparse and not available globally in near real time (NRT), especially in the China Seas and their adjacent seas (CSAS). This paper proposes a complementary quality control procedure, which use the Operational SST and Sea Ice Analysis (OSTIA) system's SST analysis as a reference standard (TR) to identify outliers in infrared Satellite SST (TS) in CSAS. Firstly, we apply a time evolution check. The pixel Ts must lie between SSTmin and SSTmax. The SSTmin and SSTmax are defined relative to TR of the previous 10 days. Secondly, we perform statistical analyses of the differences (ΔSST) between the TS and the TR of the previous day. Outliers are handled using robust statistics, and the Gaussian parameters are trended in time series to monitor SST products for stability and consistency. Finally, cross-check between infrared and microwave SST is also applied to removes the residual cloud and aerosol contaminated SSTs. After all these QC procedures are applied, most of the satellite SST outliers have effectively removed in NRT and the remaining observation errors are mainly due to diurnal variability, which should be focused on in the future study.

8871-26, Session 6

A fast forward/backward semi-blind channel estimation for MIMO STC-OFDM systems

Lena Chang, National Taiwan Ocean Univ. (Taiwan); Ching-Min Cheng, Chunghwa Telecom Co., Ltd. (Taiwan); Z. S. Tang, National Taiwan Ocean Univ. (Taiwan)

Recently, wireless communication techniques have been rapidly developed and it becomes essential to provide a communication system with higher capacity and faster transmission data rate. Multiple-input–multiple-output (MIMO) space-time-coding (STC) and orthogonal-frequency-division-multiplexing (OFDM) techniques are considered as the major techniques in the fourth-generation(4G) communications. It has been investigated that the combination of STC, OFDM and MIMO can provide a good performance for the multiuser scenarios with a small number of pilots.

In the study, we develop a fast subspace estimation for MIMO-STC-OFDM systems. We first analyze the symmetric structure of the correlation matrix corresponding to the received signals of MIMO-STC-OFDM systems. By utilizing the symmetric property, we proved that the forward-backward estimation (FBE) method which combines the forward and backward received signals can get a better estimation of sample correlation matrix and improve the accuracy of channel estimation. Then, we examined the structure of correlation matrix corresponding to the FBE and found the symmetric property of the associated eigenvector. Utilizing the property, we proposed the fast forward-backward estimation (FFB) method. The proposed FFB calculates the noise subspace of the correlation matrix by performing eigen-decomposition on two half-dimensionality matrices which obtained from the correlation matrix of FBE, individually. The FFB has the same performance as the FBE, but the computation complexity of FFB is one-fourth of FBE. Computer simulations demonstrate the effectiveness and accuracy in channel estimation of the proposed FFB which alleviates the computation complexity and improve the convergence rate of the existing semi-blind channel estimation methods based on subspace-decomposition.

8871-28, Session 6

Hyperspectral image compression and target detection using nonlinear principal component analysis

Qian Du, Wei Wei, Ben Ma, Nicolas H. Younan, Mississippi State Univ. (United States)

A hyperspectral image cube contains hundreds of correlated spectral bands. One approach of reducing its dimensionality is to transform the data onto a low-dimensional space. For instance, principal component analysis (PCA) is a commonly used approach. Because of atmospheric compensation and sensor-level degradation, there exists nonlinear correlation between different bands. Therefore, in addition to the widely used linear methods, the performance of nonlinear dimensionality reduction methods should be investigated.

Here, a nonlinear PCA (NLPCA) using auto-associative neural network is considered, which includes three layers: input, hidden, output. The numbers of neurons in the input and output layers are identical, equaling the number of original bands. The number of neurons in the hidden layer is much lower, resulting in data compression or dimensionality reduction. We compare its rate-distortion performance with PCA-based compression, which is comparable. However, in our research, the extracted principal components are used for target detection, which is of great interest in real application of hyperspectral remote sensing. The experimental results show that NLPCA can perform much better than the linear PCA in target detection or kernelized nonlinear detectors using the original data. Therefore, we integrate hyperspectral image compression and target detection in a unified fashion. To facilitate its practical application, the overall system is implemented in parallel using a graphics processing unit (GPU), which shows excellent speed-up performance.

8871-29, Session 6

A normal laser warning system model based on Hadamard transform

Liu Fei, Shao Xiaopeng, Han Pingli, Xidian Univ. (China); Chang Hong, Weihai Vocational College (China)

A normal laser warning system is designed as laser warning taking a great role in laser countermeasure, it is very important to extract useful information from weak laser signal with low signal to noise ratio (SNR) which is obtained in complex battlefield environment. Since the SNR of signal received by laser warning system is very low in real battlefield, the weak signal merging in heavy noise becomes too difficult to detect. Traditional signal processing methods to removal this kind of noise which is detected by laser warning system, that only mean filter or wiener filter are used; perform poorly in improving the SNR. A modified matrix Hadamard transform based on the weighting theory, overcame the disadvantages of matrices that are commonly used to cope with weak signal with low SNR. The modified matrix generating method of Hadamard transform is introduced in detail, and then theory analysis, calculations and simulations on the modified matrix Hadamard transform are presented. The SNR of signal increased about 7 times when using the modified matrix Hadamard transform to processed, so the other results showed that this kind of Hadamard transform performs excellently in increasing detection probability and decreasing False Alarm Ratio (FAR) of the laser warning system.

8871-30, Session PMon

Digital transceiver design for two-way AF-MIMO relay systems with imperfect CSI

Chia-Chang Hu, Yu-Fei Chou, Kui-He Chen, National Chung Cheng Univ. (Taiwan)

In the paper, combined optimization of the terminal precoders/equalizers and single-relay precoder is proposed for an amplify-and-forward (AF) multiple-input multiple-output (MIMO) two-way single-relay system with correlated channel uncertainties. Both terminal transceivers and relay precoding matrix are designed based on the minimum mean square error (MMSE) criterion when terminals are unable to erase completely self-interference due to imperfect correlated channel state information (CSI). This robust joint optimization problem of beamforming and precoding matrices under power constraints belongs to neither concave nor convex so that a nonlinear matrix-form conjugate gradient (MCG) algorithm is applied to explore local optimal solutions. Simulation results show that the robust transceiver design is able to overcome effectively the loss of bit-error-rate (BER) due to inclusion of correlated channel uncertainties and residual self-interference.

Conference 8872:
Lidar Remote Sensing for Environmental Monitoring XIV

Sunday - Monday 25–26 August 2013

Part of Proceedings of SPIE Vol. 8872 Lidar Remote Sensing for Environmental Monitoring XIV

SPIE Optics+Photonics
Optical Engineering + App.

8872-1, Session 1

Technology readiness levels and the Earth Venture Class Missions *(Keynote Presentation)*

George J. Komar, NASA Headquarters (United States)

NASA's Earth Venture (EV) class of missions are low-to-moderate cost Earth Science missions that include full orbital missions (EVF) and instruments for orbital missions of opportunity (EVI). As part of the Earth System Science Pathfinder (ESSP) program, these missions are designed to encourage the development of innovative approaches to Earth Science research by providing periodic, competitively selected opportunities to accommodate new and emergent scientific priorities. ESSP Projects are developmental, high-return Earth Science missions including advanced remote sensing instrument based missions. Due to the limited funding available for EV class missions, an increasingly common requirement is that the proposed instrument be at a Technology Readiness Level 6.

From space-borne instruments and components to data systems and modeling, the NASA Earth Science Technology Office (ESTO) funds and develops a broad range of technologies for the scientific observation and measurement of Earth. A key goal in the funding strategy of ESTO is to provide the resources needed to transition low TRL technologies to the TRL-6 level, thus enabling them to be used in EV class and other Earth Science missions.

The formal NASA definition of TRL-6: "System/subsystem model or prototyping demonstration in a relevant end-to-end environment (ground or space): Prototyping implementations on full-scale realistic problems. Partially integrated with existing systems. Limited documentation available. Engineering feasibility fully demonstrated in actual system application." provides high level guidance but is difficult to fully interpret without a detailed understanding of the platform on which the proposed instrument is to be based. At the proposal stage, the level of design detail needed for a full Technology Readiness Level evaluation is frequently not available. The goal of this presentation is to provide an ESTO perspective and begin a dialog on how proposers and reviewers for EV class missions might approach the TRL-6 requirement.

8872-2, Session 2

Approach to space-qualification of the ICESat-2 laser transmitter *(Invited Paper)*

Floyd E. Hovis, Nick W. Sawruk, Fibertek, Inc. (United States); Mark A. Stephen, NASA Goddard Space Flight Ctr. (United States); Joel Edelman, Slava Litvinovitch, Ryan Edwards, Joe Rudd, Jim Bautch, Elias Fakhoury, Fibertek, Inc. (United States)

A key element in the development of space-flight hardware is demonstrating the design meets the requirements of the intended mission. The areas of concern include an opto-mechanical structure that can survive the launch environment, a thermo-mechanical system that can adequately dissipate heat primarily through conduction and radiation, operational lifetimes in a vacuum environment that meet mission requirements with margin, and radiation hardness relative to the orbit of interest. NASA programs generally consider the design ready for flight when it is deemed to be at a Technology Readiness Level of 6 (TRL 6). A key component in the TRL-6 definition is a "prototyping demonstration in a relevant end-to-end environment". At the proposal and early hardware build phases the "relevant environment" is frequently not well defined, especially for the launch loads the hardware will experience.

The approach taken to defining the relevant environment for the ICESat-2 laser was to require that it be tested to the qualification levels defined in the General Environmental Verification Standard (GEVS, GSFC-STD-7000). The random vibration qualification levels in GEVS are high enough in both amplitude and frequency content (acceleration spectral density of 0.16 g2/Hz from 50 Hz to 800 Hz) to ensure that major resonances in the laser structure would be excited. Our approach to dealing with these high levels was to develop a flexure mounted design that filtered the high frequency content of the GEVS random vibration spectrum. In our talk we will discuss the program and system level implications of this design approach.

8872-3, Session 2

Space-qualification program for the laser diode module on the NASA ICESat-2 Mission

Nick W. Sawruk, Fibertek, Inc. (United States); Mark A. Stephen, NASA Goddard Space Flight Ctr. (United States); Kevin Bruce, nLIGHT Corp. (United States); Floyd E. Hovis, Fibertek, Inc. (United States)

A laser diode module (LDM) space qualification program was developed for the NASA Ice, Cloud and land Elevation Satellite-2, ICESat-2, mission. The ICESat-2 laser transmitter is a high performance diode-pumped solid state laser which requires high reliability, high efficiency and high brightness, fiber coupled laser diode modules. The test centric LDM space qualification program consists of several key phases including a technology plausibility study, component and module pedigree reviews, environmental acceptance and qualification testing, and extensive life testing. The intent of the plausibility study is to analytically and experimentally demonstrate the COTS module design is capable of being space-qualified. A pedigree review of the diode emitter population is conducted to screen out-of-family emitter from the population. The emitter pedigree review is a statistical analysis of several emitter performance metrics (efficiency, threshold current, etc.) with outliers being screened out. All completed modules undergo environmental acceptance testing including vibration, thermal cycling and an extended burn-in. The primary purpose of the acceptance testing is to surface internal workmanship issues. The pedigrees of the acceptance tested modules are subsequently reviewed in terms of the module performance data through the acceptance testing phase, with passing modules being certified as flight-qualified. A sub-set of the flight-qualified modules were exposed to environmental qualification testing and subsequently tested to failure to determine the LDM capability. Multiple units are being life tested and show no signs of degradation with run times approaching 20,000 hours. The details of the laser diode module space-qualification program are presented.

8872-4, Session 2

Development of a TRL-5 conductively cooled 2-micron laser for wind lidar

Timothy Shuman, Floyd E. Hovis, Fibertek, Inc. (United States); Upendra N. Singh, Mulugeta Petros, Jirong Yu, NASA Langley Research Ctr. (United States)

A coherent Doppler wind lidar system operating at 2 μm has the potential to be a key element of the 3-D Winds mission proposed in the NRC Decadal Survey of potential space-based earth science missions. The key performance parameters of the 2 μm laser transmitter needed for such a lidar system are: 250 mJ/pulse at 10 Hz; Pulsewidth > 100 ns and fully conductively cooled system. Under NASA Earth Science Technology Office (ESTO) funded Advanced Component Technology (ACT) Program, Fibertek and NASA Langley have been partnering to develop an engineering version of a Ho,Tm:LuLF based master oscillator/power amplifier (MOPA) that can be demonstrated by test to be at Technology Readiness Level 5 (TRL-5). Achieving TRL-5 has particular challenges for this technology due to its unique requirements. The cold operating temperature required to maximize the efficiency of the Ho,Tm:LuLF gain medium and the long resonator required to generate >100 ns pulsewidths make stabilizing the laser particularly challenging. At this time we have developed, thermally modeled and tested the required conductively cooled laser heads using heat pipe technology. We are in the process of finalizing the opto-mechanical design of the full laser system and will report on our progress in this area.

8872-5, Session 3

2-?m coherent lidar for CO2 and wind measurements *(Invited Paper)*

Shoken Ishii, Kohei Mizutani, Philippe Baron, Hironori Iwai, Toshikazu Itabe, National Institute of Information and Communications Technology (Japan); Hirotake Fukuoka, Hamamatsu Photonics K.K. (Japan); Takahiro Ishikawa, Nippon Aleph Corp. (Japan); Atsushi Sato, Kazuhiro Asai, Tohoku Institute of Technology (Japan)

The National Institute of Information and Communications Technology (NICT) has made efforts in order to develop a 2-?m coherent lidar for measuring CO2 concentration and line-of-sight (LOS) wind speed. A 2-?m conductively-cooled laser-diode-pumped single-frequency Q-switched solid-state laser was developed at the NICT. The 2-?m laser power of 2.4 W (80 mJ, 30 Hz) were obtained. A wavelength is set at 2051.250 nm for the LOS wind measurement and t wo wavelength (on- and off-line laser) are setting at 2051.250 nm and 2051.034 (2051.058) nm for the CO2 measurement. The two wavelengths correspond to the far-wing and wing of the R30 absorption line of CO2, respectively. Receiving components of the 2-?m coherent lidar are a Mersenne off-axis telescope with a 10-cm aperture, a two-axis scanner, two heterodyne detectors, fiber optics, and signal processing devices. Experimental wind measurements were carried out to evaluate the performance of wind profiling. The LOS wind measurements were made for ranges up to about 20 km. The wind speeds derived from the zero-wind-speed returns achieved a bias-free and high precision of 0.12 m/s. Experimental horizontal CO2 measurements were made to examine the detection sensitivity of the 2-?m coherent lidar in April and May, 2008, and October, 2009. Experimental vertical CO2 measurements were made for the Greenhouse gas Observing SATellite (GOSAT) data products validation in February 2010 and in January and February 2011. In the paper, we present overview of our 2-?m coherent lidar and experimental results.

8872-6, Session 3

Lab demonstration of the hybrid Doppler wind lidar (HDWL) transceiver

Catherine T. Marx, NASA Goddard Space Flight Ctr. (United States)

No Abstract Available

8872-7, Session 3

Two-component wind fields from scanning aerosol lidar and motion estimation algorithms

Shane D. Mayor, Pierre Dérian, Christopher Mauzey, Masaki Hamada, California State Univ., Chico (United States)

In 2007, the Raman-shifted Eye-safe Aerosol Lidar (REAL) was operated almost continuously for 3-months in Dixon, California, as part of the Canopy Horizontal Array Turbulence Study (CHATS). Two-component wind vectors were derived from the nearly-horizontal scans by applying a cross-correlation algorithm. The components of the vectors were compared with wind components measured by tower-mounted sonic anemometer at a range of 1.6 km from the lidar. Time series comparisons reveal the best correlation between the anemometer and lidar-derived velocities occurs at night when winds are light and the atmosphere tends to be stable. Stronger winds and turbulence, as typically occurs during the day, reduces the correlation between the two forms of measurement.

In late 2012, the CSU Chico lidar research group began implementing an entirely new method for deriving two-component wind vectors from the aerosol image sequences. The technique is known as “wavelet-based optical flow”. During the summer of 2013, we plan to compute wind vectors from the REAL data in real-time (using both cross-correlation and wavelet-based optical flow) and compare them with wind measurements from a nearby compact Doppler lidar. This work will be conducted in Chico, California, starting in early June. Therefore, new experimental results should be available for this presentation if all goes as planned.

In addition to the above, we are also generating synthetic aerosol images and synthetic wind fields and advecting the aerosol features by the synthetic wind field to develop a more comprehensive understanding of the behavior and performance of these algorithms.

8872-8, Session 4

Development of a pulsed 2-micron integrated path differential absorption lidar for CO2 measurement *(Invited Paper)*

Upendra N. Singh, Jirong Yu, Mulugeta Petros, NASA Langley Research Ctr. (United States); Karl D. Reithmaier, Science Systems and Applications, Inc. (United States)

A 2-micron pulsed, Integrated Path Differential Absorption (IPDA) lidar instrument for ground and airborne atmospheric CO2 concentration measurements via direct detection method is being developed at NASA Langley Research Center. This instrument will provide an alternate approach to measure atmospheric CO2 concentrations with significant advantages. A high energy pulsed approach provides high-precision measurement capability by having high signal-to-noise level and unambiguously eliminates the contamination from aerosols and clouds that can bias the IPDA measurement.

8872-9, Session 4

Efficient 1.6 micron laser source for methane DIAL

Timothy Shuman, Fibertek, Inc. (United States); Amin R. Nehrir, Syed Ismail, NASA Langley Research Ctr. (United States); Ralph L. Burnham, Fibertek, Inc. (United States); Johnathan W. Hair, NASA Langley Research Ctr. (United States)

Methane is a potent greenhouse gas that on a per molecule basis has a warming influence 72 times that of carbon dioxide over a 20 year horizon. Monitoring of the long term concentration changes of this environmentally important species could be accomplished by a combination of airborne and space-based differential absorption lidar (DIAL) systems operating in the 1.6 µm region. These DIAL systems require the development of a narrow-line laser source capable of being tuned to be on or off of a methane absorption line. We have developed the required narrow-line 1.6 µm laser using an efficient nonlinear conversion scheme. By combining a single-frequency 1064 nm pump source and a seeded KTP OPO, more than 5 mJ of 1.6 µm pulse energy is achieved with a conversion efficiency in excess of 20%. The measured linewidth of the resulting 1.6 µm output was <50 pm, limited by the optical spectrum analyzer used to perform the measurement. Tuning of the OPO output over a 400 pm range via tuning of the seed wavelength verified the ability of this OPO to operate on the two wavelengths required by a DIAL instrument. The next step in the development of this laser source for use in a fieldable methane DIAL system will be the development of a ruggedized version of the laser technology.

8872-10, Session 5

Recent improvements to the Raman-shifted eye-safe aerosol lidar (REAL) *(Invited Paper)*

Shane D. Mayor, California State Univ.,Chico (United States); Denton Scott, Anna Petrova-Mayor, California State Univ., Chico (United States); Bruce M. Morley, National Ctr. for Atmospheric Research (United States); Richard W. Wortley, Hextek Corp. (United States)

One potential application of the Raman-shifted Eye-safe Aerosol Lidar (REAL) is to conduct offshore wind energy assessments. The lidar could be deployed on terra firma near the shore and scan horizontally over the ocean to obtain image sequences of the moving aerosol distribution. Numerical motion estimation algorithms can be applied to the image sequences to derive the two-component vector wind field from the displacement of aerosol features from frame to frame. The technique has several advantages, of which the largest is likely the unique ability to measure two wind components from a single instrument. (Two components are necessary to determine wind speed.) However, to be viable, the instrument must operate stably for long periods of time and unattended in order to build offshore wind climatologies. This presentation will describe recent hardware and software improvements that were made to the original NSF/NCAR REAL in an effort to move toward that goal. The improvements include modifications to the transmitter component configuration, development of a control system, new high-performance beam steering unit mirrors, and integration of gravity-referenced tiltmeters to sense platform pitch and roll to <0.0001 degree.

8872-11, Session 5

CELiS (compact eyesafe lidar system): a portable 1.5 ?m elastic lidar system for rapid aerosol concentration measurement *(Invited Paper)*

Michael D. Wojcik, Space Dynamics Lab. (United States); Alan Bird, Jason Wooden, Utah State Univ. (United States)

CELiS (Compact Eyesafe Lidar System) is a tactical elastic lidar system commissioned by the Strategic Environmental Research and Development Program (SERDP) for the purpose of air quality environmental compliance issues surrounding the offroad use of wheeled and tracked vehicles. A complete CELiS instrument weighs less than 300 lbs., is less than 2 cubic meters in volume and uses 700 W of 120V AC power. CELiS has a working range of better than 2km and a range resolution of 5m. Results of field tests will be presented.

8872-12, Session 5

Airborne elastic lidar observation of gravity wave in stable arctic lower troposphere

Iwona S. Stachlewska, Karol Wolek, Jacek Kopec, Konrad Bajer, Univ. of Warsaw (Poland); Roland Neuber, Christoph Ritter, Alfred-Wegener-Institut für Polar- und Meeresforschung (Germany)

A gravity wave was captured in the signals of the Airborne Mobile Aerosol Lidar (AMALi) on 28 May 2004 during Arctic Study of Tropospheric Aerosols (ASTAR) campaign conducted on Svalbard. The airborne elastic-depolarization lidar took observations in the nadir-pointing configuration at 532nm (parallel and orthogonal) and 1064nm wavlengths just outside of Isfiord. The orographic gravity wave was discerned from the backscatter ratio profiles obtained along the flight path despite their very low values (1.2-1.55). The wave was present at an altitude of about 2175m, had an amplitude of about 150m and oscillation period of about 14min, and was spatially persistent for at least an hour. An approach to model this wave's propagation with altitude by using the software developed for clear-air turbulence (CAT) prediction in upper troposphere was facilitated. The vertical wind and temperature profiles were obtained from radiosoundings launched at Ny-Alesund (the AWIPEV Base) at the time close to the airborne measuerement. The gravity wave characteristics, estimated based on the AMALi backscatter ratio profiles and the radiosounding profiles, was applied to a modified version of Scorer's equations to determine the vertical variability of the wave amplitude. This amplitude profile can then supply information on CAT occurence in upper troposphere by using the new CAT predictor.

8872-13, Session 5

A new lidar equation for laser pulses backscattered from optically thick media such as clouds, dense aerosol plumes, sea ice, and turbid coastal water

Anthony B. Davis, California Institute of Technology (United States)

The base of boundary-layer stratus clouds can be so low that it is not detectable by a space-based millimeter radar due to insufficient vertical resolution, yet it is key to the atmosphere's thermodynamic profile, hence to climate dynamics. Moreover, the smallest amount of drizzle swamps the radar reflectivity, normally targeting droplets, which matter the most for the radiation budget and hydrological cycle. Aerosol remote sensing techniques, both active and passive, fail for dense plumes near sources: fires, volcanoes, dust storms, etc. Sea ice thickness is a key property that is hard to determine by any means. Laser bathymetry breaks down in highly turbid waters where the two-way transmitted pulse is all but extinguished by the opaque medium. All of these remote sensing challenges have, at least in principle, a common solution: multiple scattering lidar, both ground- and space-based, or airborne.

I will survey several field demonstrations and feasibility studies, published or not, that collectively show what opportunities open up when the conventional lidar equation (based on a single back-scattering and two-way transmission) is abandoned in favor of multiple-scattering solutions of the full time-dependent 3D radiative transfer problem for pulsed laser sources, a.k.a. space-time Green functions of optical media. Closed-form expressions derived in the asymptotic limit of small mean-free-paths (a.k.a. diffusion theory) are particularly useful for mining the highly-scattered returns for physical information content. That form of analysis will be applied to the above-listed problems in remote sensing of the environment, and technical implementation challenges will be discussed.

8872-14, Session 5

Profiling the optical parameters of the atmosphere with lidar: measurement or a simulation based on past observations?

Vladimir A. Kovalev, Cyle Wold, Alexander Petkov, Wei-Min Hao, U.S. Forest Service (United States)

The distortions of the inverted lidar signals can be caused by (i) the constant offset that remains in the backscatter signal after removing the background component, (ii) the multiplicative distortion component, which level is related with the lidar signal intensity, and (iii) the signal noise in the wide wavelength spectra; the latter includes low-frequency components, which do not obey common random-noise statistics. These distortions, even minor, may yield significant distortions in the retrieved outputs obtained by the inversion of the lidar signal. Implicit and explicit premises and assumptions required for any solution of the lidar equation are additional sources of the uncertainty in the inversion results. There is no reliable way for checking whether used assumptions are valid, therefore, the lidar signal inversion can yield significantly biased results.

As a result, instead some statistically mean profile of the atmospheric parameter of interest with the corresponding probability function, one obtains some qualitative estimate of the profile with unknown uncertainty, which depends on the validity of used assumptions. It means that lidar profiling is not a measurement but a result of some simulation based on past observations.

8872-16, Session 5

The compact, high peak power pulse all fiber laser for the high-resolution 3D imaging LIDAR system

Cunxiao Gao, Shaolan Zhu, Linquan Niu, Li Feng, Haodong He, Zongying Cao, Xi'an Institute of Optics and Precision Mechanics (China)

??An all fiber laser with master-oscillator-power-amplifier (MOPA) configuration at 1064nm/1550nm for the high-resolution three-dimensional (3D) imaging light detection and ranging (LIDAR) system was reported. The laser of seed was the directed modulated diode laser output with the fiber pigtail which pulsewidth could be tuned form 1ns to 20ns and the repetition frequence could be tuned form 10kHz~1MHz, which peak power is about 20mW. The three or four stages all fiber amplifier was used to amplify the signal of the seeder, and the exceeded 100kW of the peak power (10W average power) at 30kHz and 2.5ns was obtained finally. The laser was fit for to be the light source of the high-resolution 3D imaging LIDAR system extraordinarily because of its narrow puslewdith, high repetition frequence, good beam mode and high stability. Using this all fiber laser in the high-resolution 3D imaging LIDAR system, the image resolution of 1024?1024 and the distance precision of ±1.5 cm was obtained at the imaging distance of 1km.

8872-17, Session 6

Development of an underwater fibers optic lidar for the characterization of sea water and ice properties *(Invited Paper)*

Gilles A. Roy, Pierre Mathieu, Defence Research and Development Canada, Valcartier (Canada); Xiaoying Cao, Consultant (Canada); Alain Cinq-Mars, Defence Research and Development Canada, Valcartier (Canada)

RDDC Valcartier has developed a unique underwater lidar for the measurement of different properties of sea water and ice. The lidar head is designed to go under water and consists of four telescopes that are connected to the detection and emission unit via five 42 m fused silica optical fibers. Three telescopes are used for data collections, while the forth is used for laser emission. The laser source and the detection unit are located on a surface vessel. The laser beam is injected into a 100 µm in diameter optical fiber. The collimation of the laser beam is done into the lidar head via a 25 mm in diameter 45 mm focal length lens; the laser beam is linearly polarized using a polarization beam splitter. A 50 mm receiving telescope co-aligned with the laser beam is used for linear depolarization measurements. A second 50 mm telescope is used to collect off-axis scattered light while a third 50 mm telescope is used to collect inelastic scattered radiation (raman and induced fluorescence signal).

The laser source and detection units are mounted on a small optical table for easy access/modification. Various laser sources and lidar detection techniques (Q switch pulses or frequency modulated) could be easily implemented. The lidar head can be deployed under water or mounted on a flying platform.

In this work, the lidar system will be described in details and preliminary results obtained with a Q-Switch, 532 nm, 1 ns pulse laser source will be presented and compared with the anticipated performance for different water bodies.

8872-18, Session 6

Rapid scan absorption spectroscopy for remote sensing at 1.6 um *(Invited Paper)*

David F. Plusquellic, Kevin O. Douglass, Stephen Maxwell, Joseph Hodges, David Long, Gar-wing Truong, James R. Whetstone, National Institute of Standards and Technology (United States)

A method to perform rapid step-scan absorption spectroscopy for remote sensing of greenhouse gases in the near-infrared wavelength range is presented. The method is based on a compact, fiber based diode laser system to perform scans over a bandwidth of 37.5 GHz, with a step size of 300 MHz and a scan rate of 40 kHz using a single 2nd order sideband from an electro-optic phase modulator driven by an arbitrary waveform generator. Single sideband selection is accomplished using a low finesse Fabry-Perot filter cavity with a finesse that is sufficiently high to give <2 % transmission of the diode frequency carrier and all other non-resonant sidebands while sufficiently low to ensure fast on-resonance switching times as short as 100 nsec. The diode laser is actively stabilized to the filter cavity to eliminate frequency drift of the cavity's transmission comb used for sideband selection and scanning. The method is first demonstrated in a 45 m long White cell for detection of carbon dioxide near 1602.4 nm and for methane near 1645.5 nm. Ambient level detection is demonstrated with a signal-to-noise ratio of ~5:1 over a path length of 45 m in a 5 ms integration time. The noise equivalent absorption is estimated at 5x10-9 cm-1 Hz-1/2 and the Allan variance is linear for measurement times ranging from 25 us to 1 sec. The scan speed, resolution and bandwidth are well suited for remote sensing using integrated path and differential absorption LIDAR techniques.

8872-20, Session 6

Enhancements to INO's broadband SWIR/MWIR spectroscopic lidar

Simon Lambert-Girard, Martin Allard, INO (Canada); Michel Piché, Ctr. d'optique, photonique et laser (Canada); François Babin, INO (Canada)

Recent advances in INO's broadband SWIR/MWIR spectroscopic lidar are presented. The system is designed for the detection of gaseous pollutants in air via active infrared DOAS. Two distinctive features are a broadband and tunable sub-nanosecond PPMgO:LN OPG and an in-house gated MCT-APD focal plane array. Recent measurements demonstrating a minimum sensitivity of 60ppm-m for methane will be described. Results of enhancements to the laser source using small or large bandwidth seeds indicate that the OPG output spectral energy density can have controllable spectral widths and stable spectral shape from pulse to pulse which will allow more sensitive measurements.

8872-21, Session 6

Development of a field-widened Michelson spectroscopic filter for a near-infrared high spectral resolution lidar

Dong Liu, Yongying Yang, Zhongtao Cheng, Hanlu Huang, Bo Zhang, Yibing Shen, Zhejiang Univ. (China)

High spectral resolution lidars (HSRLs) designed for aerosol and cloud remote sensing are increasingly being deployed on aircraft and called for on future space-based missions. Spectral discrimination between scattering from molecules and aerosols or cloud particles is the basis of the HSRL technique, and several lidar approaches have been developed to obtain this discrimination. Atomic and molecular absorption filters are robust, stable, and can achieve complete separation of Mie scattering (from aerosol or cloud particles) from Cabannes scattering(from molecules); however, absorption filters are lossy and gaseous absorption lines do not exist at many convenient laser wavelengths. Fabry-Perot interferometers are simple and can be tuned to any wavelength, but are limited by acceptance angle. Field-widened Michelson interferometer (FWMI) is considered to have the ability to overcome the deficiencies of the aforementioned filters as it can perform well at relatively large off-axis angles, is nearly lossless, and can be built to any wavelength. In this paper, the development process of an FWMI that is introduced to be the spectroscopic filter for a near-infrared HSRL instrument will be present. The selection of the free spectral range (FSR) of the FWMI, as well as the methods that are employed to obtain the object spectral transmission of the FWMI will be described in detail. Experiments on studying the characteristics of the FWMI will be given.

8872-30, Session 6

On independent lidar ratio retrieval from ceilometer signals

Iwona S. Stachlewska, Univ. of Warsaw (Poland); Christoph Ritter, Alfred-Wegener-Institut für Polar- und Meeresforschung (Germany); Matthias Wiegner, Ludwig-Maximilians-Univ. München (Germany)

We propose a method for retrieving profiles of lidar ratio from ceilometer observations conducted at two elevation angles of the laser beam, pointing into the atmosphere in the vertical and at the 5-20 deg from it. The two-angle evaluation approach is applied to obtain directly the aerosol optical thickness profile, and then the extinction coefficient profile. The vertical measurement signals are elaborated using a modified version of the forward lidar approach to obtain the backscatter coefficient profile. The lidar ratio profiles are calculated by division of the independently retrieved extinction profile with backscatter profile. Although the proposed technique is obviously limited to the atmospheric boundary layer, it is still a cost efficient approach to enhance the quality of deliverable of any simple elastic lidar and/or ceilometer.

8872-22, Session PMon

Analysis of the characters of chromophoric dissolved organic matter in water using laser induced fluorescence and spectral fluorescence signature

Peng Chen, Zhihua Mao, Haiqing Huang, The Second Institute of Oceanography, SOA (China)

A sort of analytical method of fast diagnosis of chromophoric dissolved matter (CDOM) in water is discussed. The total luminescence spectra (TLS) of CDOM in several types of water samples with laser-induced fluorescence (LIF) measurements using a 405 nm wavelength excitation source were measured in the laboratory, and the spectral characteristics of CDOM were analysed. The excitation light direction was perpendicular to the detector, in order that emission light was separated from excitation light. Two dichroic mirrors perpendicular to directions of excitation light and detectors were deployed to reflect the laser beams back to the measurement cell to increase the signal intensity. Background fluorescence was corrected by the way of subtractions between the signal with laser excitation and without laser excitation. The spectra of CDOM were pointed out and obtained with spectral fluorescence signature (SFS) technique, with the capability of detecting and identifying trace substances in a variety of targets in the presence of other, background matter responding to optical excitation with overlapping signals, where the CDOM fluorescence peak is typically located at 508nm and Raman scattering band, peaking at 471 nm, were detected with 405nm wavelength excitation. The spectrum of water Raman scattering and fluorescence of CDOM were separated from TLS with fitting Gaussian of the least squares method, and the curve of fluorescence peak intensity of CDOM against corresponding concentration of CDOM is showed. Correlation (R2=0.87) was observed between CDOM concentration and fluorescence, and a high correlation (R2=0.93) was obtained after fluorescence normalized to water Raman scattering. The results have demonstrated the utility of the LIF technique as an integrated tool for research and observations.

Numerical model of the Doppler lidar network measurements in PBL

Evgeniya A. Shelekhova, Alexander P. Shelekhov, Institute for Monitoring of Climatic and Ecological Systems (Russian Federation)

In this paper the numerical model of the Doppler measurements for high horizontal spatial resolution using the scheme with lidar network are presented. It is assumed that the several Doppler lidars have different location in selected area. The selected area is divided by grid. The Doppler lidars measure the components of mean wind velocity in the points corresponding grid cells and the horizontal spatial resolution of the Doppler measurements is defined the grid sizes. We simulate the variances, which characterize the measurement uncertainty of components of mean wind velocity all lidars. It is shown that the variances are different for all lidars and depend strongly on state of the atmospheric turbulence and the number and sizes of grid cell. Also the variances are the complex functions of the signal-to-noise ratio, VAD sector scan angle, elevation angle, and direction sensing. The measurement uncertainty of mean wind velocity component can be significantly increased if we use the scheme with the Doppler lidar network at one and the same time.

For numerical simulation of atmospheric parameters we use the 1D model of homogeneous PBL model and "e-l" – turbulence model. Numerical simulation of the Doppler lidar measurements was calculated for meteorological conditions, which were observed at the Tomsk Bogashevo Airport (TOF), Russia for August, 2012. The initial meteorological data required for short prediction were taken from archive of website of the University of Wyoming (www.weather.uwyo.edu) and observation data from TOF. Measurement data of geostrophic wind, temperature, humidity, and other atmospheric parameters were obtained from weather station UNNN (www.weather.uwyo.edu), Meteorological Temperature Profiler MTP-5 (TOF) and Weather Transmitter WTX 520 (TOF).

The work was conducted under project of the Russian Federal Thematic Program "Scientific and scientific-educational professionals of innovative Russia" for 2009-2013 (agreement N 14.B37.21.0667).

Design of the field-widened Michelson spectroscopic filter for a high spectral resolution lidar

Hanlu Huang, Dong Liu, Yongying Yang, Zhongtao Cheng, Yibing Shen, Zhejiang Univ. (China)

Atmospheric aerosols play an important role in atmospheric physics, and a more accurate measurement has great research significance and social benefit. Lidars are an effective tool for the detection of the aerosols, among which the high spectral resolution lidars (HSRLs) have been given more and more attention for its robust calibration, simplified inversions without reliance on a priori assumptions. HSRL technique achieves accurate measurement by separating the Mie and Rayleigh scattering signals using the high-spectral-resolution spectroscopic filter. Filters like F-P interferometric filters and atomic/molecular absorption filters have limits while the field-widened Michelson interferometer (FWMI) stands out for large angular acceptance, high photon efficiency and flexibility to any laser wavelength. In this paper, an FWMI, which consists of a cubic beam splitter and two orthogonal arms, is introduced to be the spectroscopic filter of an HSRL. Applied as a filter for HSRL aerosol profiling, the FWMI is different from its compatriots in wind/temperature measurements that the optical path difference (OPD) varies very slowly (no more than approximately 1/20 of the laser wavelength) within the incident angle and environment temperature. The design procedure of the FWMI is described in detail and two different configurations (one is a solid arm combined with a pure air arm, and the other is a solid arm with an air-glass-mixed arm) are studied for comparison. A tolerance evaluation system is also established to assist the design process.

Modeling of a field-widened Michelson interferometer for high spectral resolution lidar

Zhongtao Cheng, Dong Liu, Yongying Yang, Yibing Shen, Zhejiang Univ. (China)

High spectral resolution lidars (HSRL) have shown great advantages for the measurement of backscatter and extinction coefficients of aerosols and clouds due to its spectral discrimination process, which brings about more straightforward and accurate retrieval without a prior assumptions in contrast to standard backscatter lidars. To obtain this spectral discrimination, a field-widen Michelson interferometer (FWMI) is under development at Zhejiang University. The interferometer is composed of a cubic beam splitter, a solid arm and an air arm, and will be employed as the spectroscopic filter of an HSRL to block the aerosol signals but transmit the molecular backscattered photons optimally. The fabrication errors such as the defection of beam splitter coating and polarization, glass length deviation and surface imparallelism, imperfection of anti-reflection coating and so on, can degrade the performance of the spectroscopic filter. Moreover, the limitations from appliance conditions, for instance, photoelectric feedback error for PZT drive, the requirement of tilted placement, the temperature drift during operation, will also make the transmittance of interferometer deviate from designed values. A comprehensive radiometric model of the FWMI is developed, which incorporates all these practical imperfections indicated above. The model can be used to evaluate the machinery tolerance budgets for FWMI design and decide optimal state of usage for FWMI appliance. In this paper, the principle of the tilted FWMI as the spectroscopic fitler of the HSRL will be presented. The general theoretical method to estimate the transmittance characteristics of the FWMI will be expressed and the modeling process will be discussed in detail.

Photon counting detector for satellite laser ranging with sub-picosecond timing stability

Josef Blazej, Ivan Prochazka, Czech Technical Univ. in Prague (Czech Republic); Jan Kodet, Czech Technical Univ. in Prague (Czech Republic) and Technische Univ. München (Germany)

The concept and preliminary experimental results of photon counting detector package based on a single photon avalanche diode with active gating and quenching circuit are presented. The single shot timing resolution of time-correlated photon counting experiment is about 30 ps, however demonstrated long-time stability allows averaging for both indoor and satellite laser ranging experiments. Two picosecond laser versions are employed as signal source – laser diode 43 ps at 778 nm, and fiber based laser 80 ps at 531 nm, used experiment repetition rate are from 500 Hz to 5 kHz. The NPET timing devices are used to register detection events and custom software and algorithm are used to process measured data. The long term delay stability sub-picosecond range and small temperature drifts of all elements of measuring chain are crucial to obtain useful data for final time scale comparison in picosecond range. The experimental results from measurement of long term stability of detector delays, delay independence on position in detector active area, and new achievements in quenching techniques will be presented. The detector is perspective for any remote sensing application based on single photon counting where long-term stability can be capitalized to achieve sub-picosecond timing resolution.

ICESat-2 laser technology development

Ryan Edwards, Nick W. Sawruk, Floyd E. Hovis, Patrick Burns, Theodore Wysocki, Joe Rudd, Brooke Walters, Elias Fakhoury, Vincent Prisciandaro, Fibertek, Inc. (United States)

The NASA Ice, Cloud, and land Elevation (ICESat-2) mission incorporates a high spatial resolution laser altimeter instrument, Advanced Topographical Laser Altimeter System (ATLAS). Fibertek reports on the development of the enabling laser technology and the various architectures explored. The primary design driving requirements were an end-to-end wall-plug efficiency of >5%, temporal pulse widths of < 1.5ns, frequency tunable over 100pm, narrow spectral line width of < 12pm, pulse repetition frequency of 10kHz and diffraction limited beam quality. A 1µm master-oscillator power amplifier followed by a frequency doubler was chosen as the general design architecture. A linear, end-pumped oscillator was chosen for the design as it met all requirements and was based on mature technology. The amplifier architecture was end-pump Nd:YVO4 slabs, chosen for high efficiency and ability to preservation high beam quality. The end result of the 1µm MOPA was a 1.5mJ in a diffraction limited beam (M2<1.5), less than 1.5ns pulse width, and spectral width of <9pm. A single pass critically phased match LBO crystal was used as the frequency doubler due to, radiation hardness and high bulk damage thresholds. Typical frequency conversion efficiencies ranged between 67%-70%. The final system delivered diffraction limited, 1mJ, 1.3ns pulses, and spectral width of < 5pm at 532 nm and an overall optical-to-optical efficiency of 22%. This paper presents the laser design evolution, an overview of the final laser architecture and performance testing results.

Quantitative measurement of ozone and ethylene in remote infrared (9-11 ?m) differential absorption lidar experiments

Taieb Gasmi, Saint Louis Univ.- Madrid Campus (Spain)

Ethylene and ozone behaviours show a high degree of coincidence. The two gases start to increase, reach a peak and then decay to a plateau, which lasts 3 hours. The net difference in ethylene concentration (Delta C2H4) versus that of ozone (Delta O3) is illustrated for successive days. (Delta O3) mimics to a good extent the behaviour of (Delta C2H4) which hence reveals a good relationship between the two gases. However it is well established that in the lower troposphere, especially in urban areas, chemical reactions of biogenic and anthropogenic VOC (Volatile Organic Compounds) and anthropogenic NOX emissions dominate over those of methane and its degradation products. Thus, it is widely accepted that tropospheric ozone results from the interaction of pollutant oxides of nitrogen and non-methane hydrocarbons with solar radiation leading ozone and carbonyl compounds which can further break down to produce additional O3. A key non-methane compound is the ethylene whose atmospheric chemistry is well studied. Basically, the role of this alkene is the efficient conversion of NO to NO2 and subsequently, the increase of tropospheric ozone.

So according to our basic photochemical smog model one should expect a direct correlation between the C2H4 evolution and that of O3 under similar meteorological conditions for the urban atmosphere and UVB radiation that prevailed during the days of the campaign. All these observation constitute additional evidence to the many models that state that ethylene, being a hydrocarbon, has a role to play in the generation of tropospheric ozone.

Effects of wildfire smoke on atmospheric polarization

Joseph A. Shaw, Nathan J. Pust, Elizabeth Forbes, Montana State Univ. (United States)

An all-sky polarization imager was used to measure visible and near-infrared skylight polarization during a three-day period during which the sky was increasingly filled with smoke from a nearby wildfire. In-situ sensors were used to measure the aerosol size distribution, aerosol scattering coefficient, and aerosol extinction coefficient throughout this period. A solar radiometer also measured atmospheric extinction at multiple wavelengths. This presentation uses data from these sensors to show how the evolving aerosols strongly altered the skylight polarization.

Photoelastic modulator non-idealities in magneto-optical polarization measurements

Stefaan Vandendriessche, Thierry Verbiest, Katholieke Univ. Leuven (Belgium)

Modifying and detecting the polarization of light is increasingly important in many contexts such as Faraday isolators and electro-optical modulators. In order to control the polarization of light, it is necessary to know the polarization characteristics of the materials used in the applications. To be able to (magneto-)optically characterize novel materials, we designed a setup using a single photoelastic modulator (PEM) to simultaneously detect natural and magnetic circular dichroism and circular birefringence over a large spectral range.

We then theoretically analyzed and experimentally characterized the effect of non-idealities in the PEM on the setup and the resulting data. Our results demonstrate an influence of PEM non-idealities on the measured signals, resulting in non-negligible mixing of circular birefringence and circular dichroism signals. Our measurements of the wavelength dependence of these non-idealities reveal larger non-idealities towards shorter wavelengths. These results illustrate the necessity to take PEM non-idealities into account when working with PEMs, especially at shorter wavelengths or when dealing with signals spanning different orders of magnitude. PEM non-idealities, while frequently neglected in experimental setup design and theoretical derivations, are expected to be more complicated and possibly exert a larger influence on obtained results for experimental setups with multiple PEMs.

Polarization characteristics of dust aerosol particles

Zengzhou Hao, Delu Pan, Fang Gong, Haiqing Huang, The Second Institute of Oceanography, SOA (China)

Dust aerosol, which is an important natural aerosol, can affect environment by long-distance transport. Dust event is always heavy and covers large region. In this paper, to detect dust aerosol from satellite remote sensing, the phase matrix function of dust aerosol particles are calculated by using the Mie scattering theory and the lognormal distribution function to describe the dust particles size distribution. The polarization characteristics of dust aerosol particles during wavelength 0.2~40?m for solar radiation and earth-atmosphere long-wave radiation are studied at different relative humidity conditions. Some primary results show that, the scattered intensity has less effect by relative humidity and shows a trend of decreasing firstly and then increasing along with the increasing scattering angle, the increasing tendency decreases with the increasing wavelength; And for the linear and circular polarization of scattered radiation, the change with the scattering angle and relative humidity has difference properties at different band; In the forward and backward scattering directions, it only produces the circular polarization by dust aerosol particles, when assuming that incident light is right hand circularly polarized. Polarization properties of scattered light and their differences with humidity mainly change in the backward scattering region, where it is an arched form. The scattering angle for peak point is different at different relative humidity and the peak position drift to the larger scattering angle with the decreasing relative humidity. Those results are nice for detecting dust aerosol by polarization observations.

Optical characterization of amber from Chiapas, Mexico

Guadalupe Lopez , Rafael Espinoza-Luna, Ctr. de Investigaciones en Óptica, A.C. (Mexico); Claudio Frausto-Reyes, Ctr. de Investigaciones en Óptica A.C. (Mexico)

An optical characterization of amber samples from México, the Baltic Sea and fake samples is presented, with the aim of discriminate between genuine and fake samples. We sought to identify the physical variables that could serve as the basis for the development of a device whose operation was able to discriminate between samples of genuine and fake amber.

The optical refractive index was determined by Spectroscopic Ellipsometry, Abbe refractometry, and by the Brewster angle. The Raman spectra and the fluorescence optical responses were also determined. The results obtained indicate that the refractive index is not a robust variable that can differentiate between genuine amber and a fake sample. On the other hand, the Raman spectra and the fluorescence responses provide information that allows discriminating between both types of samples. For this reason, we used the results obtained by fluorescence as a basis for the design and construction of a prototype simple, reliable, portable, and affordable for authentication of the Mexican amber.

A compact and robust method for spectropolarimetry

William B. Sparks, Space Telescope Science Institute (United States)

Motivated by astrobiological remote sensing needs, Sparks et al (2012 Applied Optics 51, 5495 “A compact and robust method for full Stokes spectropolarimetry” present an approach to spectropolarimetry which offers the prospect of high sensitivity over a very wide wavelength range (UV, optical, IR). Using static, robust components the polarization information is encoded onto one dimension of a two-dimensional data array, while the other dimension records the spectrum. A spatially varying retardance along the spectrograph slit, followed by a polarization analyzer, encodes the Stokes parameters as coefficients of orthogonal trigonometric functions perpendicular to the spectrum. No moving parts are required and all polarimetric information is available on a single data frame, hence the technique is immune to time dependencies, free of fragile modulating components, has the potential for high sensitivity and offers a wide wavelength range with full Stokes spectropolarimetry. Within the Solar System, spectropolarimetry offers diagnostics for dust (cometary, zodiacal, rings), surfaces (rocky, regolith, icy), aerosols (clouds, dust storms) and high energy plasma emission processes. Beyond the Solar System, space-based telescopic spectropolarimetry has important contributions to make in the detection of extrasolar planets and their characterization. There are astrobiological applications for full Stokes polarimetry stemming from the interaction of light with chiral living organisms, which offers the potential for a remote sensing detection capability for microbial life.

Orientational tomography of optical axes directions distributions of multilayer biological tissues birefringent polycrystalline networks

Natalia I. Zabolotna, Rostyslav Y. Dovhaliuk, Vinnytsia National Technical Univ. (Ukraine)

We propose a modified structure of polarimetry setup and a novel method to analyze measured distribution of optical axes` orientation in optically thin layer of histological section of muscle tissue.

Our polarimetry setup consists of a semiconductor laser, quarter-wave plate, collimator optics, polarizer and analyzer, micro objective, object of investigation and a CCD camera connected to the computer. The principal difference of our method from other well-known methods lies in direct approach for measuring the direction of optical axis of polycrystalline networks` biological crystals. To obtain such data, the simultaneous rotation of the analyzer and polarizer is performed during the process of measurement.

According to developed methodology to determine whether the particular biological tissue`s slice can be classified as "healthy" or "pathological" one need to evaluate several parameters. They include statistical, correlational and spectral moments of previously measured distribution of optical axes` orientation in polycrystalline network.

To test the validity of proposed method the distribution of optical axes` orientation in optically thin layer of histological section of muscle tissue was measured using previously described polarimetry setup with a 2-3% error.

Our results show that the biggest difference between healthy and pathological muscle tissue slices` values of statistical, correlational and spectral moments exists in case of 2nd, 3rd and 4th statistical moments (difference from 2.5-3 to 3.4-5 times), 2nd and 4th correlational moments (difference 2 times for the 2nd moment and 6 times for the 4th one) and 2nd and 3rd spectral moments (difference up to 2.5 times).

A portable imaging Mueller matrix polarimeter based on a hybrid modulation approach

Israel J. Vaughn, J. Scott Tyo, College of Optical Sciences, The Univ. of Arizona (United States)

Imaging polarimeters have been largely used for remote sensing tasks, and most imaging polarimeters are division of time or division of space Stokes polarimeters. Imaging Mueller matrix polarimeters have just begun to be constructed which can take data quickly enough to be useful. We have designed a full Mueller matrix polarimeter utilizing a hybrid modulation approach (modulated in both time and space) based on a micro-polarizer array camera and rotating retarders. We present this hybrid approach and various reconstruction schemes tailored to specific constraints. We also analyze the trade space, consisting primarily of trade offs between aliasing and noise/signal (SNR), speed of acquisition, and the number of reconstructible Mueller elements. Finally we present example data acquired with the instrument and some specific examples of reconstruction of that data.

8873-43, Session PMon

Analyzing vector diversification

Andrey Alenin, J. Scott Tyo, College of Optical Sciences, The Univ. of Arizona (United States)

Condition Number (CN) and Equally Weighted Variance (EWV) have been shown to be the proper metrics of optimization in order to yield Stokes polarimeters with highest SNR under the assumption of independent and identically distributed noise. However, when that assumption is lifted and more than four measurements are made, it is possible to have designs that indicate an optimal CN and EWV, yet result in performance that is less than maximum attainable. As the number of measurements is increased, so is the dimensionality in which the four vectors of the reconstruction matrix lie. As a result, it is easier to find solutions where those four vectors are orthogonal, thus leading to CN and EWV being overly collapsed in the sense that there exists a huge plateau of optimal results and the distinction of the system's ability to handle other types of noises is not considered. Having a diverse set of measurements will improve the reconstruction in those cases. We present several possible metrics which add the measure of diversity into the design process.

CALIOP receiver transient response study

Xiaomei Lu, Yongxiang Hu, Zhaoyan Liu, Shan Zeng, Charles R Trepte, NASA Langley Research Ctr. (United States)

The Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP), an instrument on the Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO), operated as an atmospheric lidar system to study the climate impact of clouds and aerosols in the atmosphere. This paper discusses the receiver transient response of the CALIOP instrument. A simple numerical model of the receiver transient response is presented, which predicts the relationship among the surface return signals at three range bins. The CALIOP transient response function in 30 m vertical resolution, which is used to remove any impacts on the attenuated backscatter profile of water clouds imparted by a non-ideal transient response of photomultiplier tubes (PMT), was obtained by using twelve adjacent lidar bins of land surface return. An analytical expression of the CALIOP transient response function in high vertical resolution, which is useful for the lidar altimetry study from the CALIOP lidar measurements, was calculated by the least square fitting of lidar measurements from land surfaces.

8873-1, Session 1

Infrared wire grid polarizers: metrology and modeling

Matthew C. George, Jonathon Bergquist, Rumyana Petrova, Bin Wang, Eric W. Gardner, MOXTEK, Inc. (United States)

The wire grid polarizer (WGP) remains one of the most useful optical components in the field. Benefits of the WGP over competing designs include a small form factor, broadband performance, large acceptance angle, and improved durability over organic polarizers. The WGP typically consists of an array of metallic lines with sub-wavelength pitch supported by a transparent substrate. Using our aluminum nanowire, large area patterning capabilities, Moxtek has developed high contrast wire grid polarizers on AR-coated silicon suitable for narrow and broadband applications in the MWIR and LWIR. Accurate metrology was gathered in both transmission and reflection from the SWIR to LWIR using a combination of FTIR and dispersive spectrometers, as well as laser-based light sources. The WGP structures were analyzed using SEM, FIB, and STEM techniques and optical data was derived from IR VASE, transmission, and reflectance measurements. Modeling of device performance was achieved using rigorous coupled wave analysis. Our 144 nm pitch broadband MWIR polarizer transmits better than 95% of the passing state while maintaining a contrast ratio of better than 33dB from 3.3-5.7 microns. Between 7 and 15 microns, our LWIR polarizer transmits better than 70% of the passing polarization state and has a contrast ratio better than 40dB. A narrowband AR-coated WGP for 7.5 micron wavelength transmits better than 94% of the passing state while maintaining a contrast ratio of better than 42dB. Narrow band antireflection-coated wafers for 10.6 micron laser line applications will also be presented. Laser damage thresholds and various damage mechanisms will be presented.

8873-2, Session 1

Assessing consistency of a Mueller matrix measurement by rotation of the sample under test

Thomas A. Germer, National Institute of Standards and Technology (United States)

It is a difficult task to assess the accuracy of measurements obtained by a Mueller matrix polarimeter. In some cases, one can test the behavior under specific conditions, for example, by measuring in the absence of a sample, by measuring the reflection of an isotropic surface, or by measuring the transmittance through a high quality polarizer. However, these ideal materials only test a small subset of the space spanned by all Mueller matrices. Worse yet, they often are part of the procedure used to calibrate the polarimeter, and thus, the polarimeter may be optimized for these polarizations. In this paper, we will present a method which spans a much wider set of Mueller matrices and may give a more realistic indication of systematic uncertainties. The method is based upon the rotational properties of a Mueller matrix. A relatively arbitrary, uniform object, created by stacking a few polarimetric elements together with intentionally misaligned axes, is placed in the polarimeter in a precision rotation stage. The Mueller matrix is then measured as a function of sample rotation. The values of the Mueller matrix elements, with the exception of the corner elements, will thus span a large range. However, they can each be transformed by matrix rotation back into the Mueller matrix at zero angle. The consistency between these resulting matrices is then taken as an indication of the measurement uncertainties. The method is demonstrated with measurements of several different samples.

8873-3, Session 1

Single-angle-of-incidence single-element rotating-polarizer (Single SERP) ellipsometer for film-substrate systems

A. R. M. Zaghloul, Cairo Univ. (Egypt)

The single-element rotating-polarizer ellipsometer is where a rotating polarizer is inserted into the incident beam and the reflected-signal intensity is detected using a photodetector. The polarizer is either rotated mechanically or electromagnetically. The angle of incidence of the beam is adjusted to detect the angles where the detector signal is dc. The ellipsometric function of the film-substrate system under measurement is of a unity magnitude at those detected angle(s). The number of required measurements (such angles of incidence) is related (directly proportional) to the number of system parameters to be determined: film thickness is one parameter, film refractive index is two parameters, and substrate refractive index is two parameters. The more parameters to be determined, the more the number of measurements required. This creates film-thickness bands, which number and width depend on the system physical properties and the wavelength used for measurement, and where a continuum exists above a certain film-thickness value. Accordingly, full characterization of film-substrate systems is limited to systems with large film thicknesses for the required multiple angles of incidence to exist. In this paper, we use only one detected angle of incidence to fully characterize the film-substrate system. This allows for film-substrate systems with much smaller film thicknesses to be fully characterized. A fast genetic algorithm is used to heuristically obtain all the system parameters: film thickness and refractive indices of the film and the substrate, or any subset thereof.

8873-4, Session 1

Real-time combined reflection and transmission ellipsometry for film-substrate systems

M. Elshazly-Zaghloul, Cairo Univ. (Egypt)

Combined reflection and transmission ellipsometry of film-substrate systems provides a wealth of experimental information that proves helpful with extracting the system parameters. In such a technique, both the reflection and transmission ellipsometric functions are simultaneously measured. The technique itself requires a special design of the sample for fixed and for multiple angles of incidence measurements. The data reduction could be done using numerical methods which are tedious and time consuming resulting in an overall slower technique. A closed-form inversion of the system parameters (film thickness, film refractive index, and substrate refractive index) would render a fast technique that is suitable for real-time applications. The sample used is a three-film-thickness sample and measurements are carried out at two angles of incidence. Real simple closed-form equations are derived through successive transformations and algebraic manipulations to obtain the refractive indices of the film and the substrate, in addition to the film thickness. A simple software program, with a limited number of code lines, is developed and tested yielding perfect results.

8873-5, Session 1

Evaluation of calibration methods for visible-spectrum division-of-focal-plane polarimeters

Samuel B. Powell, Washington Univ. in St. Louis (United States)

Recent advances in nanofabrication have facilitated the introduction of visible-spectrum division-of-focal-plane polarimeters. These sensors are made by integrating nanowire polarization filters directly with an imaging array. Size variations of the nanowires due to fabrication can cause the optical properties of the filters to vary up to 20% across the imaging array. If left unchecked, these variations introduce significant errors when reconstructing the polarization image. Calibration methods offer a means to correct these errors. This work compares two calibration methods: applying a single gain and offset per pixel versus multiplying the division-of-focal-plane “super-pixel” by a single matrix. The two methods are compared both quantitatively while varying illumination intensity, wavelength, angle, and degree of linear polarization; and qualitatively using data collected in the field.

8873-6, Session 2

Mathematical tools for the analysis and exploitation of polarimetric measurements *(Invited Paper)*

Jose J. Gil Perez, Univ. de Zaragoza (Spain)

The measured Mueller matrices contain until sixteen independent parameters for each measurement configuration (spectral profile of the wave probe of the polarimeter, angle of incidence, observation direction...) and for each spatially resolved element of the sample (imaging polarimetry). Thus, the polarimetric techniques are widely used for the study of a great variety of material samples in optics and remote sensing. Nevertheless, the relevant physical information does not appear explicitly in the measured parameters and thus the best knowledge of the structure of the physical information contained in a Mueller matrix is required in order to develop appropriate procedures for the polarimetric analysis. In this paper, the physically invariant polarimetric quantities are identified and decoupled, and the main approaches for serial and parallel decompositions of measured Mueller matrices into simple components are reviewed.

8873-7, Session 2

Partial Mueller matrix polarimeter design

Andrey Alenin, J. Scott Tyo, College of Optical Sciences, The Univ. of Arizona (United States)

Partial Mueller Matrix Polarimeters (pMMPs) are active sensing instruments that evaluate the scattering process by controlling both the generator and the analyzer states. Through a careful selection of those states it is possible to probe a subset of the Mueller matrix, thereby creating a partial measurement. In this paper we consider the structure of the Mueller and the measurement matrices by performing an SVD decomposition and investigating the possible arrangements of constituent orthogonal vectors/channels that the instrument supports. Limitations placed by the Mueller space are critical to understand when linear combinations of Mueller elements are part of the same column space-vector. The analysis is necessary in order to construct an instrument that takes a limited number of measurements to determine features of the Mueller object that prior analysis determined to be the most crucial for the task at hand.

8873-8, Session 2

3D radiative transfer effects in multi-angle/ multispectral radio-polarimetric signals from a mixture of clouds and aerosols viewed by a non-imaging sensor

Anthony B. Davis, Michael J. Garay, Jet Propulsion Lab. (United States); Feng Xu, Jet Propulsion Lab. (United States) and Joint Institute for Regional Earth System Science and Engineering (United States); Zheng Qu, Jet Propulsion Lab. (United States) and Raytheon Co. (United States); Claudia Emde, Ludwig-Maximilians-Univ. München (Germany)

It is widely believed that adding polarimetry to multi-angle spectrometric observations of aerosols will lead to vastly improved assays of their columnar burden and characterizations of their microphysics. Even when clouds are present, they have such different polarization signatures than aerosols that they may be essentially removed from the signal, thus exposing only those aerosols that are interacting with the clouds (and these are very high-value targets for climate scientists).

We put this last hypothesis to test using high-fidelity Monte Carlo 3D vector radiative transfer (vRT) simulations of a field of cumulus clouds embedded in more or less aerosol. These synthetic signals are compared with predictions based on an advanced linear mixing model. This idealized forward model uses an areal average of as many sub-pixel elements (each treated with 1D vRT) as are necessary to describe the aerosol- and Rayleigh-scattering atmosphere, assumed horizontally uniform, and the known cloud liquid water content field. We find that the 1D vRT cannot capture the polarization signal properly in the key angular region that contains the cloud bow, at least when there is a significant amount of aerosol. More surprising is that this is true even in limit of single scattering. However, since single scattering can be computed efficiently, even in 3D geometry, this last finding leads to some ideas about how to mitigate the inherently 3D vRT effects, and thus restore to some extent the desired aerosol remote sensing capability of the non-imaging sensor using only information from simple context cameras.

8873-44, Session 2

Measurement and modeling of mirror reflectance spectrum of polarized light in the UV band

Lu Bai, Xiren Zou, Zhensen Wu, Yanhui Li, Yunhua Cao, Haiying Li, Xidian Univ. (China)

Ellipsometry is a well-known and relevant technique that has been used extensively to study specular reflection and transmission properties from surfaces and coatings. With the development of multi-band target detection, the requirement of the measurement in the multi-band is necessary to analysis the scattering properties of a target. The reflect light of a surface contains many features of a surface, which is usually used as a powerful tool for process in situ or ex suit monitoring.

But lots of paper discussed the measurement or model method by using ellipsometry in the visible to infrared band. Few references discuss about the measurement results of the surface in the ultraviolet band. As there has been increasing interest in the study of scattering and reflective properties in ultraviolet band. Researches on the scattering properties in the UV band are necessary.

In this paper, scatter measurements of some typical smooth samples in the UV band are performed by using the ellipsometry WVASE 32 made by J. A. Woolam Co. Inc. The polarized mirror-direction reflectance spectrum measurement results obtained are analyzed and compared. A reflectance spectrum model of the smooth material for polarized light in UV band was proposed. To explore the correctness of the model, we compared it with five-parameter BRDF model.

And these kinds of researches about measuring and analyzing of typical roughness samples in ultraviolet band have significant meanings in a lot of related fields.

8873-9, Session 3

Airborne multiangle spectropolarimetric imager (AirMSPI) observations over California during NASA's Polarimeter Definition Experiment (PODEX) *(Invited Paper)*

David J. Diner, Michael J. Garay, Olga V. Kalashnikova, Brian E. Rheingans, Sven Geier, Michael A. Bull, Veljko M. Jovanovic, Jet Propulsion Lab. (United States); Feng Xu, Jet Propulsion Lab. (United States) and Univ. of California, Los Angeles (United States); Carol J. Bruegge, Jet Propulsion Lab. (United States); Ab Davis, Univ. of Texas (United States); Karlton Crabtree, Russell A. Chipman, College of Optical Sciences, The Univ. of Arizona (United States)

The Airborne Multiangle SpectroPolarimetric Imager (AirMSPI) is an ultraviolet/visible/near-infrared pushbroom camera mounted on a single-axis gimbal to acquire multiangle imagery over a ±67° along-track range. The instrument flies aboard NASA's high-altitude ER-2 aircraft, and acquires Earth imagery with ~10 m spatial resolution across an 11-km wide swath. Radiance data are obtained in eight spectral bands (355, 380, 445, 470, 555, 660, 865, 935 nm). Dual photoelastic modulators (PEMs), achromatic quarter-wave plates, and wire-grid polarizers also enable imagery of the linear polarization Stokes components Q and U at 470, 660, and 865 nm. Example data acquired over California during January-February 2013 as part of NASA's Polarimeter Definition Experiment (PODEX), a field campaign designed to refine requirements for the future Aerosol-Cloud-Ecosystem (ACE) satellite mission, will be shown. Observations of aerosols, low- and mid-level cloud fields, cirrus, aircraft contrails, and clear skies were obtained over the San Joaquin Valley and the Pacific Ocean during PODEX. Analyses of radiance and polarization imagery are presented to illustrate instrument sensitivity to aerosol optical depths and microphysical properties, 3-D cloud morphologies and droplet size distributions, and bidirectional intensity and polarized reflectance factors for a variety of land and ocean surface targets.

8873-10, Session 3

Influence of polarization phenomenology on material discriminability using multi-view polarimetric imagery

Chabitha Devaraj, South Dakota State Univ. (United States); Michael Gartley, John R. Schott, Rochester Institute of Technology (United States)

In addition to spectral information acquired by traditional multi/hyperspectral systems, passive electro optical and infrared polarimetric systems also measure the polarization response of different materials in the scene. Such an imaging modality offers a complete optical description of a surface that can be utilized in identifying objects with complex morphological and camouflaged structures. The polarization property of the radiation from a remotely sensed surface, however, depends on the observation geometry of the system. Therefore, acquiring a polarimetric image in a single viewing direction is not sufficient to improve the material discriminability in the absence of a priori knowledge about the object geometry. Hence, this paper presents a novel multi-view polarimetric system for improving the target-background discriminability. The proposed system takes the approach of imaging the scene in three different viewing directions to infer the physical characteristics of the observed surface by utilizing the angular variation in the polarization response. The sensitivity analysis of the proposed polarimetric system that relates target-background discriminability to various scene related parameters indicates the imaging conditions under which the material discriminability is maximized. Furthermore, scenarios where polarization information can be very useful in improving the target contrast are identified by comparing the detection performance of the proposed system to that of a multispectral system.

8873-11, Session 3

How clear-sky polarization varies with wavelength in the visible and near infrared

Nathan J. Pust, Joseph A. Shaw, Montana State Univ. (United States)

Questions frequently arise as to how the clear-sky polarization pattern varies with wavelength. In the visible and near-infrared portion of the spectrum, it is sometimes erroneously believed that the degree of polarization (DoP) varies as inverse wavelength to the fourth power, as does the Rayleigh-scattered skylight. However, the real answer is much more complex. For example, in conditions with very low aerosol content, approaching the Rayleigh scattering limit, the DoP actually tends to increase slowly with wavelength throughout the visible spectrum. Even more importantly, the DoP spectrum can take on strong spectral features that are driven by similar spectral features in the underlying surface reflectance. This presentation will use a combination of measurements and simulations to illustrate and explain widely varying examples of clear-sky polarization spectra in the visible and near-infrared spectral region. One important conclusion of this study is that simple models which do not incorporate accurate aerosol and surface information have limited utility for simulating or predicting clear-sky polarization.

8873-12, Session 4

Mueller matrix microscopy *(Invited Paper)*

Mircea Mujat, R. Daniel Ferguson, Nicusor Iftimia, Physical Sciences Inc. (United States)

Polarization is a fundamental property of light and its measurement is one of the effective means of investigating the light-matter interaction. Polarization imaging provides additional contrast mechanisms as compared to traditional intensity imaging, without having to stain or label the sample. The most complete spatial polarimetric characterization of biological tissue is provided by Mueller matrix imaging. In addition to the classical intensity image, the Mueller matrix contains information on birefringent, dichroic or depolarization properties of tissue. Subsequently, these properties could be used to differentiate between normal and diseased tissue with the purpose of non-invasive optical diagnosis or for imaging microscopic structures relevant for both material science and biomedical research and to illustrate anisotropies not visible in the regular microscopy images. We describe here a new imaging technique, Mueller matrix microscopy, for investigating the anisotropic properties of the refractive index in biological samples. The system's capabilities are demonstrated first on mica, quartz and biological samples. Current polarization microscopes are working in transmission through transparent samples and in general measuring only in orthogonal polarization channel or doing partial polarization measurements. We have developed a polarization microscope capable of performing complete Mueller matrix imaging in both transmission and reflection configuration and at different wavelengths. Polarimetric microscopy can provide unprecedented details in biophysical measurement of cell functions, in analyzing the effects of electric or magnetic fields, photoactivation, testing of drugs or biocompatible polymers on live tissue, or in longitudinal studies on interacting cellular structures during cell division, motility and apoptosis.

8873-13, Session 4

Extraction of the inclination angle of nerve fibers in the human brain with 3D-polarized light imaging

Julia Reckfort, Hendrik Wiese, Melanie Dohmen, David Graessel, Forschungszentrum Jülich GmbH (Germany); Uwe Pietrzyk, Forschungszentrum Jülich GmbH (Germany) and Bergische Univ. Wuppertal (Germany); Karl Zilles, Forschungszentrum Jülich GmbH (Germany); Katrin Amunts, Forschungszentrum Jülich GmbH (Germany) and Heinrich-Heine-Univ. Duesseldorf (Germany); Markus Axer, Forschungszentrum Jülich GmbH (Germany)

Recently, the neuroimaging technique 3D-polarized light imaging (3D-PLI) has opened up new avenues to study the complex nerve fiber architecture of the human brain at unprecedented spatial resolution. This polarimetry technique is applicable to histological sections of postmortem brains utilizing the birefringence of nerve fibers caused by the regular arrangement of lipids and proteins in the myelin sheaths surrounding axons. 3D-PLI provides a three-dimensional description of the anatomical wiring scheme defined by the in-section direction angle and the out-of-section inclination angle. To date, 3D-PLI is the only available method that allows bridging the microscopic and the macroscopic description of the fiber architecture of the human brain.

Here we introduce a new approach to retrieve the inclination angle of the fibers independently of the properties of the used polarimeters. This is relevant since the image resolution and the signal transmission influence the measured birefringent signal (retardation) significantly. The image resolutions were determined using the USAF-1951 testchart applying the Rayleigh criterion. The signal transmissions were measured by elliptical polarizers applying the Michelson contrast.

Based on these results, a modified retardation-inclination-conversion function was proposed to extract the fiber inclination. The improvement of the extraction of inclination angle was verified using sections of the optic tract cut under different angles. The optic tract, composed of homogeneously oriented fiber, was chosen as a biological reference sample. The comparison of the actual and the inclination angles calculated with the theoretically proposed and the new modified function reveals significant improvement in the extraction of the fiber inclination.

8873-14, Session 4

Polarization-components techniques for NDE of composite heat damage

Brian G. Hoover, David E. Taliaferro, Virgil Kohlhepp III, Advanced Optical Technologies (United States)

Active/laser polarization-components techniques (PCT) is applied to non-destructive evaluation (NDE) of heat damage in aircraft-grade carbon-fiber bismaleimide (CF-BMI) composites. Polarization signatures of CF-BMI coupons subjected to various temperatures in a cone calorimeter are measured by a laboratory DRR laser polarimeter at visible wavelength. Machine-learning algorithms are trained on the polarimeter data to define PCT channels invariant over composite orientation and probe incident angle, and a classifier is applied to demonstrate the sensitivity and resolution of PCT NDE compared to conventional destructive damage-evaluation methods including Shore D surface hardness and residual mechanical strength in 3-point-bend tests. Background on heat damage in fiber composites and phenomenological mechanisms for the observed polarization signatures are also discussed.

8873-15, Session 4

LWIR polarization sensing: investigation of liquids and solids with MoDDIFS

Gilles Fortin, AEREX avionique inc. (Canada); Jean-Marc Thériault, Defence Research and Development Canada, Valcartier (Canada); Paul Lacasse, AEREX avionique inc. (Canada)

MoDDIFS (Multi-option Differential Detection and Imaging Fourier Spectrometer) is a DRDC Valcartier technology built around a differential Fourier Transform Infrared (FTIR) spectrometer optimized for optical subtraction in the long wave infrared (LWIR). MoDDIFS is a dual use hyperspectral prototype offering two fore-optics configurations: a long range fore-optics, specialized for the detection of small quantities of gaseous substances, and a polarization fore-optics, built to investigate liquids and powders spills. We report and present a preliminary analysis of a series of measurement tests made with the latter (polarization) configuration of MoDDIFS. The tests were performed under indoor and outdoor environments. Different liquid and solid substances were deposited on up to twelve different types of surfaces. Many liquid targets and some solid materials produce a noticeable linearly-polarized signal, with a more or less characteristic spectral modulation. For the liquids, the behavior of the observed radiance spectrum seems more predictable when the liquid is thick, or when it is deposited at any thickness on non-absorbing and weakly-reflective substrates. The behavior of the radiance spectrum observed becomes more complex when a thin layer of the liquid is deposited on a smooth and strongly-reflective substrate, or on an absorbing substrate. Polarized hyperspectral radiance measurements bring additional information on both targets and the backrounds as compared to standard unpolarized hyperspectral measurements, as long as the signal acquired is noticeably polarized. The tests performed can then help determine the materials for which the detection and the identification will be improved with polarized measurements.

8873-16, Session 4

Using linear polarization for LWIR hyperspectral sensing of liquid contaminants

Jean-Marc Thériault, Defence Research and Development Canada, Valcartier (Canada); Gilles Fortin, Paul Lacasse, AEREX avionique inc. (Canada); François Bouffard, Hugo Lavoie, Defence Research and Development Canada, Valcartier (Canada)

Passive Fourier-transform spectrometry can be used to remotely detect and identify liquid surface contaminants in the long wave infrared (LWIR). To be fully efficient, current passive FTIR techniques would greatly benefit from a significant improvement in signal-to-clutter ratio. Hyperspectral polarization sensing is seen as an approach with great potential to significantly improve the remote detection and identification of liquid contaminants. DRDC Valcartier recently initiated the development and field-validation of the novel imaging FTIR sensor MoDDIFS (Multi-option Differential Detection and Imaging Fourier Spectrometer) to address this issue. The primary focus of our study is to address the passive standoff detection of liquid contaminants by exploiting their polarization attributes. The MoDDIFS hyperspectral instrument has a unique capability to probe the horizontal and vertical polarization components of a scene in direct and differential modes. This paper reviews recent results obtained with MoDDIFS. Field measurements of polarized spectral radiance done on liquid contaminant simulants (Ethylene Glycol and SF96) probed at distances of 12 meters and 450 meters have been used to develop and test a GLRT-type algorithm adapted for liquid contaminants. The hyperspectral measurements and GLRT detection results are analyzed in view to establish the advantage of probing the two orthogonal linear hyperspectral polarization components for improving the passive remote detection and identification of liquid contaminants.

8873-17, Session 5

Thermally stable imaging channeled spectropolarimetry

Julia M. Craven-Jones, Brandyn M. Way, Jeffery P. Hunt, Sandia National Labs. (United States); Michael W. Kudenov, North Carolina State Univ. (United States); Jeffrey A. Mercier, Sandia National Labs. (United States)

Channeled spectropolarimetry can measure the complete state of polarization of light as a function of wavelength. Typically, a channeled spectropolarimeter uses high order retarders made of uniaxial crystal to amplitude modulate the measured spectrum with the spectrally-dependent Stokes polarization information. A primary limitation of conventional channeled spectropolarimeters is related to the thermal variability of the retarders. Thermal variation often forces frequent system recalibration, particularly for field deployed systems. However, implementing thermally stable retarders results in an athermal channeled spectropolarimeter that relieves the need for frequent recalibration. Recent work has identified two methods for producing thermally stable retarders for channeled spectropolarimetry. One technique combines multiple uniaxial crystals, while the other uses a biaxial crystal cut at a thermally insensitive angle. In this paper, we compare these two techniques in the context of producing an imaging thermally stable channeled spectropolarimeter. A preliminary design for a snapshot imaging channeled spectropolarimeter is also presented.

8873-18, Session 5

A novel design for a spectropolarimeter

Ad L. Verlaan, TNO (Netherlands); Hedser van Brug, TNO Science and Industry (Netherlands); Huib Visser, Technisch Physische Dienst-TNO (Netherlands)

We present a novel design for an Earth orbiting of high altitude spectropolarimeter for the measurement of aerosol concentrations. Purpose of the instrument is to measure both the radiance and the polarization state (degree and angle of linear polarization). As the degree of linear polarization is extremely sensitive to the microphysical properties of atmospheric or surface particles, this instrument can yield valuable information of these particles in the Earth's atmosphere. In previous studies (SPEX) an instrument was realized, targeted for operation on a Mars orbiter. Various experiments confirmed the instruments functionality and assessed its accuracy. This new design aims at measurements of the Earth's atmosphere. Core aspects in the instrument design are the absence of moving parts, the use of proven technology and a flexible and modular design. As a result an instrument is designed, based on a push broom spectrometer with a 30degree field of view and a 2.5km

by 2km instantaneous ground pixel. Spectropolarimetric measurements are performed over a wavelength range from 375nm to 850nm with a predicted measurement accuracy of better than 10-3 on the Degree Of Linear polarization.

8873-19, Session 5

Fabrication and performance evaluation of pixelated nano-wire grid polarizer

Shengkui Gao, Raphael Njuguna, Viktor Gruev, Washington Univ. in St. Louis (United States)

Metal-based nano-wire grid polarizer (NWGP) is a grid of periodic and parallel metallic wires that transmits parallel polarized light and reflects cross polarized light. It is widely used in division of focal plane (DoFP) imaging sensors to capture polarization information of the imaged environment. NWGP has benefits of thin form factor, wide field of view, high durability under UV exposure and temperature, etc. Extensive research work has been conducted to explore performance of NWGP with large areas regarding to feature size, thickness, duty cycle, and material. However, less work has systematically explored the NWGP at the pixel level. Advancement in nano-technology has enabled the fabrication of high performance NWGP structures in small area. A typical fabrication technique creates desired NWGP onto a substrate using a combination of lithography and etching techniques. In this work, we use electron beam lithography (EBL) and reactive ion etching (RIE) to fabricate aluminum pixelated NWGP structures. We present the procedure of the nano-fabrication, and evaluate the on-chip performance of the NWGP structures in terms of different orientations (0o, 45o, 90o, 135o), feature sizes (50nm to 500 nm), thicknesses (100nm to 200nm), and spectral response (450nm to 800nm). Based on the fabrication results and theoretical analysis, a pixelated NWGP model is developed and will act as a reference for future DoFP polarization imaging sensor design.

8873-20, Session 5

Wide field snapshot imaging polarimeter using modified Savart plates

Naooki Saito, Satoru Odate, Katsura Otaki, Nikon Corp. (Japan); Masahiro Kubota, Rintaro Kitahara, Kazuhiko Oka, Hokkaido Univ. (Japan)

We propose a snapshot imaging polarimeter using modified Savart plates for a wide field-of-view, and report a measurement error compensation. The snapshot imaging polarimeter using Savart plates consists of all passive optical components with the Savart plates, imaging lenses, wave plates, and a polarization analyzer. Spatial distributions of all four Stokes parameters can be determined simultaneously from a single image by using polarization interference patterns modulated at spatial carrier frequencies in the snapshot imaging polarimeter. Compared with conventional polarimeters which repeat several measurements of the light intensity distributions, our polarimeter has the capability of stable and fast Stokes measurements because of features of its configuration with no moving mechanical parts and no electrical components. Such feature is adequate to a real time measurement of spatial distribution of polarized light in a remote sensing application. For the purpose of a wide field-of-view with the feature effectively, we modified and improved the snapshot imaging polarimeter. The results from functional experiments show that there exist some measurement errors to be corrected and some optical components to be replaced for a wide field of view. To reduce those errors, we employed modified Savart plates and some calibration procedures of our polarimeter configuration. The verification experiments were carried out for the snapshot imaging polarimeter of the wide field-of-view.

8873-21, Session 5

An adaptive multi-channel spectropolarimeter(MSP) for identifying the spots of pollutants on the water surface

Ferdenant A. Mkrtchyan, Institute of Radio Engineering and Electronics (Russian Federation)

The problem of detection and identification of the pollution spots on the water surface, especially of oil spills, is being solved by many scientists. The recently developed technology of an adaptive identification of the environmental elements from measurements in the visible spectral region permits to synthesize an expert system for an adaptive identification of the environmental parameters (ESAIEP). The system's structure includes a compact multi-channel spectropolarimeter (MSP), information interface with computer (IIC), computer software (STW), and extending database (EDB). The STW realizes a number of algorithms to process the data fluxes from MSP and provides service functions of visualization and control of the regime of measurements. The EDB consists of the sets of standard spectral images of the spots of pollutants represented by points in the multi-dimensional vector space of indicators, pre-calculated on the basis of learning samples.

The principle of the ESAIEP functioning is based on fixation of changes of the light flux at the MSP output and their transformation into a digital code. Further processing of these data with respect to their efficiency is determined by the STW composition containing various algorithms of recognition of 2D objects. The adaptability of the recognition procedure is determined by the level of accumulated knowledge about special features of intensity fluctuations and polarizing properties of the light reflected from the water surface. The STW includes the means that make it possible, in case of uncertain identification of the pollution spot, to make an expert decision based on the visual analysis of its spectral image. This procedure is realized in the mode of dialogue with ESAIEP, and if decision is made, the operator can fix it in the database in the form of a standard for subsequent situations of an appearance of similar spots.

8873-22, Session 5

SWIR active polarization imaging

Daniel A. LeMaster, Air Force Research Lab. (United States); Adoum H. Mahamat, College of Optical Sciences, The Univ. of Arizona (United States); Bradley M. Ratliff, Space Computer Corp. (United States); Andrey Alenin, J. Scott Tyo, College of Optical Sciences, The Univ. of Arizona (United States); Bradley M. Koch, Air Force Research Lab. (United States)

Nighttime active SWIR imaging has resolution and SWaP advantages over passive MWIR and LWIR imagers for applications involving target identification. We propose that the target discrimination capability of active SWIR systems can be extended further by exerting polarization control over the illumination source and imager, i.e. active polarization imaging. In this paper, we show how partial Mueller matrix signatures can be used to uniquely identify targets. This paper includes a description of the camera and laser systems used to collect these data; data reduction and analysis techniques; and an overview of a new method for Mueller matrix imager calibration.

8873-23, Session 6

Evaluation of Mueller matrix of achromatic axially symmetric waveplate

Kazuki Komaki, Tositaka Wakayama, Saitama Medical Univ. (Japan); Israel J. Vaughn, J. Scott Tyo, College of Optical Sciences, The Univ. of Arizona (United States); Yukitoshi Otani, Utsunomiya Univ. (Japan); Toru Yoshizawa, NPO 3D Associates (Japan)

In recent years, an axially symmetric polarized beam has been attracted attention in optical fields, because it has unique properties of states of polarization. There is a singularity of zero intensity at the center of the intensity distribution. For example a radial polarized beam is well-known as one of the axially symmetric polarized beam. This beam focused by an objective lens can generate z-polarization. Using these optical properties, the beam is used to optical tweezers, acceleration of electrons, super-resolution microscopes and so on. To generate the axially symmetric polarized beam, photonic crystals, liquid crystals, and sub-wavelength structure elements have been used. However, these elements strongly depend on both temperature and wavelength. From this background, we have proposed achromatic axially symmetric wave plates (AAS-WPs) with no spatial dispersion. The AAS-WPs has a concave conical surface similar to an element rotated about optical axis by the Fresnel rhomb. After a linearly polarized beam is incident on the AAS-WPs, Fresnel reflections are generated the phase difference. According to this, the total of phase differences is given by 90 degrees, achromatically. We designed a slope angle of the element based on Fresnel reflections. As a result, the slope angle was 44.3 degrees. The AAS-WPs has been made by SiO_2 to work coaxially. We evaluated the element by two-dimensional distribution of Mueller matrix. Moreover, we discussed the polarization properties of the AAS-WPs.

8873-24, Session 6

Compact spatial heterodyne interferometer using polarization gratings

Michael W. Kudenov, Matthew N. Miskiewicz, Michael Escuti, North Carolina State Univ. (United States); Eustace L. Dereniak, College of Optical Sciences, The Univ. of Arizona (United States)

The implementation of an all polarization spatial heterodyne interferometer (SHI) is detailed. While a conventional SHI incorporates a Michelson interferometer and Littrow-configured diffraction gratings, the described polarization SHI exploits mechanically robust Wollaston prisms and polarization gratings. To this end, a theoretical model for the polarization SHI is developed and validated with data from proof of concept experiments. Additional modeling of the device is also incorporated to describe the PG's Mueller matrix in order to characterize non-ideal effects in the system. This included imaging the PG's Mueller matrix using a dual-rotating retarder Mueller matrix polarimeter. Comparisons to theory are made and error sources for the spatial heterodyning capability are described. Applications for this sensor includes high resolution spectroscopy in biomedical imaging, remote sensing, and machine vision.

8873-25, Session 6

Spectroscopic full polarimeters using spatial carriers

Kazuhiko Oka, Yujin Haga, Yoshihiko Komaki, Hokkaido Univ. (Japan)

The spectropolarimetry using spatial carriers are an alternative method for the snapshot spectroscopic measurement of the state of polarization (SOP) of light. In this presentation, we report on two implementations of the spectroscopic full-polarimetry using the spatial carriers. In the first implementation, a beam of light to be measured its spectroscopic SOP successively passes though a focusing lens, two Savart plates, an analyzer, and a Fourier transform lens. The entrance slit of a spectrometer with a two-dimensional CCD is placed on the back focal plane of the Fourier transform lens so that the spatial distribution of the spectrum along the slit can be resolved. The spatial intensity distribution at each wavelength includes three sinusoidal components carrying the information of the SOP. The frequency filtering along the spatial coordinate axis allows us to demodulate the four Stokes parameters at each wavelength. Accordingly, the wavelength-resolved Stokes parameters of the light under interest can be determined from a single two-dimensional spectrum. Unlike the channeled spectropolarimetry, the spectral resolution of the SOP measurement can be enhanced up to that of the spectrometer. In the second implementation, two achromatic birefringent prism pairs are used to generate a two-dimensional spectrum with spatial carriers. This implementation has an additional feature that the spatial carrier frequencies are less dependent on the wavelength variation. The feature allows us to decrease the limitation in the design of the spectropolarimeter. The feasibility of both implementations has been demonstrated by experiments in the spectral range between 450 and 800 nm.

8873-26, Session 6

Design of a polarimeter with two ferroelectric liquid crystal panels

Alba Peinado, Angel Lizana, Juan Campos, Univ. Autònoma de Barcelona (Spain)

Polarimeters are the basic instruments to measure the polarization of an electrical field and to determine the polarimetric interaction of that field with the matter. Nowadays, polarization metrology is used in many fields, such as in medicine, material characterization, remote sensing or astronomy.

Typical architectures of polarimeters are a rotating quarter wave plate and a polarizer, a set of polarization detectors arms initially divided by a beam splitter or a camera divided by macropixels based on a set of polarization analyzers.

Our work presents a polarimeter based on liquid crystal panels. This type of polarimeters presents an important advantage with respect to polarimeters based on mechanical elements because it is possible to avoid positioning misalignment errors by carrying out an accurate calibration before starting measuring, and so the initial elements offsets will be considered.

The polarimeter design is based on two ferroelectric liquid crystal monopixel panels, presenting a very fast polarization switching capability. It can be approximated as uniaxial birefringent waveplate layer with two stable optical axis orientations when a square electrical signal is addressed. Therefore, it can be modeled as a waveplate with a constant retardance, and with two possible orientations for its fast axis.

We have calibrated some important optical features of our ferroelectric panels: retardance, initial orientation and rotation of the optical axis. In addition, we have conducted an optimization of the orientation of these panels in the setup in order to obtain a minimum condition number of our polarimetric measurement matrix. Then, an experimental calibration is carried out and several measurements are taken in order to analyze its performance.

8873-28, Session 7

Identifying scattering functions from polarization correlations in backscattering

John Broky, Aristide C. Dogariu, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

Random electromagnetic fields (REF) have a number of distinctive statistical properties that may depend on their origin. There are situations when one can observe only the superposition of multiple underlying REFs caused by the interaction with different media. We show here that when two mutually coherent fields overlap, the individual characteristics are not completely lost. If prior knowledge about one of the fields is available, some information about the other one can still be retrieved. In particular, we will demonstrate that if assumptions can be made regarding the field correlation length of one of the overlapping REFs, the relative field correlation length of the second REF can be retrieved using the polarization properties of the combined field. High order field correlations such as the complex degree of mutual polarization (CDMP) provide the means.

We demonstrate experimentally that different effective scatter sizes can be identified even for depolarizing media which have, in average, the same diffusive properties. We examine the practically relevant geometry of backscattering and find that that the single scattering contribution largely retains the information about the state of polarization of the incident field. Examining the spatial extent of the CDMP correlation provides a straight measure of the spatial coherence properties of the REF primarily caused by single scattering, which is directly related to particle size and its scattering properties. It should be emphasized again that all the information recovered is the result of a single realization of the random interaction between light and matter.

8873-29, Session 7

The retrieval of scattering coefficient of marine particles from polarimetric observations

Amir Ibrahim, Alexander Gilerson, Jan Stepinski, Ahmed El-Habashi, Samir Ahmed, The City College of New York (United States)

Polarized light in the oceans carries intrinsic information that can be utilized to estimate the optical and microphysical properties of the oceanic hydrosols. It is especially sensitive to the scattering coefficient, which cannot be retrieved from the unpolarized light used in current ocean color remote sensing algorithms. Through the unpolarized remote sensing reflectance (Rrs), these classical algorithms can only estimate backscattering coefficients bb, but the total scattering coefficient b could be solely retrieved based on the characteristics of polarized light. The correlation is quantified in this paper. Based on extensive simulations using the vector radiative transfer program RayXP, the attenuation-to-absorption ratio (c/a), from which b is readily computed, is shown to be closely related to the degree of linear polarization (DoLP). The relationship is investigated for the upwelling polarized light for several wavelengths in the visible part of the spectrum, for a complete set of viewing geometries, and for varying concentrations of phytoplankton, non-algal particles, and color dissolved organic matter (CDOM) in the aquatic environment. It is shown that there is an excellent correlation between the DoLP and c/a for a wide range of viewing geometries. That correlation is investigated theoretically using fitting techniques, which show that it depends not only on the general composition of water but also on the particle size distribution (PSD) of the (mainly non-algal) particles. A large dataset of Stokes components for various water compositions, measured in the field with a hyper-spectral and multi-angular polarimeter, then provides the opportunity to validate the parameterized relationship between DoLP and c/a. This study opens the possibility for the retrieval of additional inherent optical properties (IOPs) from air- or space-borne DoLP measurements of the ocean.

8873-30, Session 8

Fully polarimetric passive W-band millimeter wave imager for wide area search

Jonathan R. Tedeschi, Bruce E. Bernacki, James F. Kelly, David M. Sheen, Douglas L. McMakin, Thomas E. Hall, Brian K. Hatchell, Patrick L. J. Valdez, Pacific Northwest National Lab. (United States)

We describe the design and phenomenology imaging results of a fully polarimetric W-band millimeter wave (MMW) radiometer developed by Pacific Northwest National Laboratory for wide area search. Operating from 92-94GHz, the W-band radiometer employs a Dicke switching heterodyne design isolating the horizontal and vertical MMW components with 40dB of polarization isolation. Design results are presented for both infinite conjugate off-axis parabolic and finite conjugate off-axis elliptical fore-optics using optical ray tracing and diffraction calculations. The received linear polarizations are down converted to a microwave frequency band and recombined in a phase shifting network to produce all 6 orthogonal polarization states of light simultaneously, which are used to calculate the Stokes parameters for display and analysis. The resulting system performance produces a heterodyne receiver noise equivalent delta temperature (NEDT) of less than 150mKelvin. The radiometer provides novel imaging capability by producing all four of the Stokes parameters of light, which are used to create imagery based upon the polarization states associated with unique scattering geometries and their interaction with the downwelling MMW energy. The polarization states can be exploited in such a way that man-made objects can be located and highlighted in a cluttered scene using methods such as image comparison, color encoding of Stokes parameters, multivariate image analysis, and image fusion with visible and infrared imagery. We also present initial results using a differential imaging approach use to highlight polarization features and reduce common mode noise. Persistent monitoring of a scene using the polarimetric passive mm-wave technique shows great promise for anomaly detection caused by human activity.

8873-31, Session 8

Simulations of polarization dependent contrast during the diurnal heating cycle for passive millimeter-wave imagery *(Invited Paper)*

John P. Wilson, Maciej Murakowski, Univ. of Delaware (United States); Christopher A. Schuetz, Phase Sensitive Innovations, Inc. (United States); Dennis W. Prather, Univ. of Delaware (United States)

Passive millimeter-wave (mmW) sensors operate in a unique part of the electromagnetic spectrum that is able to penetrate through a variety of common obscurants while still producing resolutions that are adequate for human operators to identify targets of interest. Their passive nature can be important for military applications and they are especially suited to persistent surveillance applications due to their ability to operate independently of day/night conditions and through transient atmospheric obscurants such as clouds, rain and fog.

The radiometric temperature of objects will change throughout the day since the radiometric temperature is dependent on the kinetic temperature. As the kinetic temperatures of different objects change at different rates, the contrast between objects will vary throughout the day (the same is true for infrared imagery). Since mmW imagery is heavily dependent on the reflections of objects and not just the kinetic temperature, imagery is often strongly polarized. This is especially relevant for passive mmW sensors since many of these sensors are only able to detect a single linear polarization state (often due to waveguide and component limitations).

Simulations are presented from a modified open source ray-tracing program called Blender. The new program incorporates a sky temperature generator as well as the ability to modify the dielectric constants and kinetic temperatures of different objects. The ability to measure different linear polarization states has also been added, allowing for polarimetric modeling capability. Simulations show large differences of contrast between different polarization states of radiation throughout the day. In extreme cases, the contrast of a target can drop to zero during a crossover event for a linear polarization state while the orthogonal polarization state exhibits contrasts on the order of 10 K. Preliminary experimental results are also presented from a passive mmW polarimetric sensor during a 24 hour test.

8873-32, Session 9

Polarization display based on the human visual system just noticeable difference

Adoum H. Mahamat, J. Scott Tyo, College of Optical Sciences, The Univ. of Arizona (United States)

Polarization imaging infers the orientation of the electric field of light that is coming from the illuminated objects in the scene being imaged. Our group and several other groups have been working on the measurement of the optical polarization information on natural scenes. Even though mathematical analyses allow us to know the orientation of the electric field, the human vision system is not able to perceive polarization, and human observers generally have no experience interpreting polarization data. A number of methods have been developed to represent polarization data in pseudocolor, texture, and motion. However, no studies have been performed to our knowledge that test the usefulness of any of these methods to assist observers in performing tasks. In this study we are designing several visual tasks for observer to accomplish while looking at polarization information displayed using various representation methods. We design the study using several tasks that include finding an object in scenes, and tracking a target in the presence of clutter. In this task two methods of polarization display are presented. First method uses colorfuse based on a hue equation that we determined using the human visual system (HVS) response to the just noticeable difference (JND) in color as well as a method using coherent motion of dots. In the coherent motion of the dots, polarization is displayed with dots moving in the direction of orientation of the E-field, and dot sizes or randomness determine degree of polarization. Collected data will be compared as a result.

Material characterization using passive multispectral polarimetric imagery

Melissa Sawyer, Air Force Institute of Technology (United States)

A new method for characterization of unknown targets using passive multispectral polarimetric imagery is presented. Previous work makes use of a pBRDF derived equation for the degree of linear polarization and with the aid of multiple incidence angles estimates refractive index and reflection angle. This work uses known incidence and reflection angles along with dispersion equations and polarimetric data at multiple wavelengths to recover the index of refraction. Although imagery is collected with a division of amplitude polarimeter in iterative, manual steps, this algorithm could be applied to the data produced by a recently introduced compact division of focal plane multispectral polarimeter with many remote sensing applications. Experimental results are presented showing the new method's ability to characterize a range of materials.

8874-1, Session 1

Deep turbulence propagation of a Gaussian-beam wave in anisotropic non-Kolmogorov turbulence *(Invited Paper)*

Larry C. Andrews, Ronald L. Phillips, Robert Crabbs, Univ. of Central Florida (United States); Troy T. Leclerc, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

In the conventional Kolmogorov model of turbulence the turbulent fluctuations of the index of refraction are assumed to be statistically homogeneous and isotropic, and there is a specific mathematical form for the power spectral density of the index of refraction fluctuations. Development of the turbulent theory of passive scalar transfer has shown that although the conventional Kolmogorov spectrum model with a 11/3 power-law index is generally correct near the ground (within the inertial subrange), it constitutes only one part of the more general behavior of passive scalar transfer in a turbulent flow. Hence, deviations from the conventional Kolmogorov model are possible. In this study we develop theoretical models for beam spot size, beam wander, spatial coherence, and scintillation index that are valid in weak irradiance fluctuation regimes as well as in deep turbulence or strong irradiance fluctuation regimes. These theoretical models are based on power-law index variations from 11/3 in the spatial power spectrum model of atmospheric turbulence in addition to anisotropic conditions.

8874-2, Session 1

Comparison of the split-step method for various power spectral models

Heba Yuksel, Demet Yuksel, Bogaziçi Üniv. (Turkey)

Turbulence remains an important unsolved problem of classical physics. When the collimated beams traverse the striated region, the beam first suffers random phase perturbations due to variations in the phase velocity within the medium. These phase variations in the propagating wavefront introduce small random changes in the direction of propagation of the beam. Thus portions of the once plane wavefront now propagate in different directions relative to other portions. As the beam propagates further, diffraction or angular scattering causes constructive and destructive interference which introduces fluctuations in amplitude as well as phase. These time-varying amplitude and phase fluctuations represent an undesired complex modulation of the carrier. We propose a phase-screen method based on a split-step approach to numerically solve the parabolic wave equation. The accuracy of the split-step solution for wave propagation in random media is proven by variety of studies but it will be the first in its field that the aperture averaging factor will be explored using the split-step method. In our previous work, the Modified Kolmogorov spectrum has been used in the modeling. In this work, different spectral models will be used and the effect of the model on the results will be investigated. All of our simulation results will be compared with other simulation models as well as empirical results. Our simulation will be unique and useful in developing a better turbulence model within all of the turbulence regimes.

8874-3, Session 1

Optical signal fade-time statistics for multiple-aperture communications in atmospheric turbulence

Troy T. Leclerc, Univ. of Central Florida (United States)

Mean and variance of optical signal fade-time for multiple aperture communication system in atmospheric turbulence are analyzed. Closed form expressions are presented and compared to experimental results obtained by an array of receiving apertures located at the Townes Institute Science and Technology Experimentation Facility (TISTEF) 1km laser range located within the Kennedy Space Center at Cape Canaveral, FL. Measurements are made under various turbulence conditions, ranging from weak to strong, over multiple days of operation. Simultaneous measurement of weather conditions and scintillometer instrumentation are utilized to verify atmospheric conditions. Signal quality of multiple apertures is compared to the signal quality of a single aperture receiver. The fade-time statistics of apertures of identical size diameter, and non-identical size diameter, are compared. Spacing distance between apertures and improvement related to the total number of apertures is considered. Gamma-gamma irradiance model is utilized to obtain theoretical results; the gamma-gamma model has previously been shown to be an effective prediction for both the weak and the strong fluctuation regime.

8874-4, Session 1

Wave optics simulation for beams with spatially varying coherence properties

Xifeng Xiao, David G. Voelz, New Mexico State Univ. (United States)

Propagation studies of partially coherent beams typically assume a Gaussian Schell model where the spectral degree of coherence between two spatial points is assumed to be spatially stationary. Partially coherent beams with spatially varying coherence functions have been recently introduced and it is believed that the design flexibility of this type of beam can lead to improved performance for applications such as free space laser comm. Some theoretically analysis exists for certain spatially varying coherence classes, however, verifying the results and extending the analysis to more cases is difficult due to the complexity of the problem. In this work we propose a numerical wave optics approach for simulating the propagation of a beam with spatially varying coherence properties. The concept involves the development of a random screen with the spatially varying correlation properties that is implemented in the source plane. A large sequence of screen realizations is applied and the intensity results after propagation are averaged to yield the partially coherent result. This approach allows the propagation characteristics of a wide range of beam types to be evaluated. In this paper we describe the method and present several propagation examples of "designer" beams with spatially varying coherence.

8874-5, Session 1

Measurement system for analysing the spectral radiation pattern of light sources for FSO systems

Pimrin Pezzei, Erich Leitgeb, Nacira Stiebler, Markus Loeschnigg, Technische Univ. Graz (Austria)

For the verification of Free Space Optics systems it is common to determine optical power measured depending on illuminated area at a certain wavelength. In the context of this work a new measurement system was developed, which is able to measure not only the optical power but also the complete spectral distribution of the light beam. Free Space Optics (FSO) is becoming more and more important, because of the high usable bandwidth (leading to high data-rates) in optics compared to RF.

The paper is structured into 5 main parts. After a short introduction the authors show the theoretical background of the relevant optical beam

distributions, the mechanical and electrical set-up of the measurement, before the graphs and figures illustrate the measurement results.

The measurement system consists of a mechanical structure, where a collimator is mounted on. This collimator can be moved in two dimensions to enable the measurement of predefined points. It is connected with a spectrum analyzer using an optical fibre. A PC controls the position of the collimator and initiates the spectrum analyzer to record the spectral curves, the maximum peak of power, the -3dB bandwidth and the total power of spectrum. The obtained data covers a measurement area of 0.91 m by 0.77 m which can be surveyed at a high local resolution of 0.7 mm. Collimated beams in the range between 600 and 1750 nm are analysed.

Retrieval of structure functions of air temperature and refractive index from large eddy simulations of the atmospheric boundary layer

Jeremy A. Gibbs, Chris Wilson, Evgeni Fedorovich, The Univ. of Oklahoma (United States); Alexander M. J. van Eijk, TNO Defence, Security and Safety (Netherlands)

Structure functions and associated structure-function parameters of meteorological variables are extensively employed in practical applications for quantification of the spatial variability of atmospheric turbulent flow fields. Particularly, turbulent fluctuations of temperature and humidity can strongly affect the propagation of acoustic and electromagnetic waves in the atmosphere by causing the variability of the refractive properties of the air. Such fluctuations can also significantly modify the transmission of signals from remote sensing devices, such as radars and sodars, which are increasingly popular tools for investigation of the atmospheric structure.

In this study, the second-order structure functions of air temperature and refractive index are directly evaluated from numerical large eddy simulation (LES) output for representative atmospheric boundary-layer flow cases. Since LES provides values of the considered flow variables at the very high spatial (of the order of few meters) and temporal (of the order of seconds) resolution in a domain that extends throughout the entire boundary layer and even above it, it appears promising to use LES output data for practically-oriented structure-function parameter calculations. In previous attempts to evaluate structure-function parameters from LES data, they were typically estimated through supplementary relations between these parameters and turbulence dissipation rates.

Calculated structure functions of temperature and refractive index in many cases exhibited 2/3 power slopes over extended ranges of separation distances. The structure-function parameters were evaluated within these scale ranges. Lower limits of the 2/3 slope range depended on the spatial resolution and subfilter-scale closure employed in LES. The behavior of structure-function parameters evaluated from LES in the lower portion of the CBL generally agreed with predictions by Monin-Obukhov similarity relationships that are commonly employed for evaluation of the structure-function parameter in the atmospheric surface layer. Under convective conditions, the non-dimensionalized structure-function parameter for humidity was strongly influenced by entrainment at the boundary-layer top. Spatial anisotropy of turbulence structure in the boundary layer was investigated through comparison of structure functions calculated along individual horizontal coordinate directions.

8874-7, Session 2

GPS synchronized UV communication system performance based on USRP

Gang Chen, Linchao Liao, Univ. of California, Riverside (United States); Brian M. Sadler, U.S. Army Research Lab. (United States)

Recently, Ultraviolet communication is paid more and more attention, with its solar blind and Non-Line-of-Sight characteristic. However, it is hard to capture and recover the transmitted signal outdoor without synchronized signal. In this work, we integrate GPS clock into Universal Software Radio Peripheral (USRP) based UV communication system and employ it as synchronized signal. At receive side, photon counting and adaptive threshold method are used to recover original signal. Through experiments, we test the BER of the UV system under different configuration geometry. Some results compared to the normal UV system without synchronized signal are also presented.

8874-8, Session 2

Scattering and propagation of UV pulses in soot aerosols

Haiying Li, Zhensen Wu, Lu Bai, Yunhua Cao, Yanhui Li, Xidian Univ. (China)

As the rapid development of UV band research, the applications of UV wave in communication, imaging, detective and other fields attract more and more attention. Multiscattering of complicated environments may cause amplitude fluctuation, pulse broading[1].

Generally, soot aerosols can be seen as the random aggregate systems, which are composed of the unburned fuel and dust. Compared with the wavelength of UV band, aggregate systems can be considered as the cluster of spherical elements. Generally, these soot aggregate systems have complex structure and fractal properties. The propagation of UV pulses in random aggregate systems plays an important role in the UV communication field.

Several electromagnetic scattering theories have been published regarding multi-sphere scattering [2–4], Such as, the discrete-dipole approximation(DDA) [2], Generalized Lorenz-Mie theory[3], and the generalized multi-particle Mie-Solution(GMM) [4]. These methods are widely applied to an arbitrary aggregate of spherical particles.

A number of important studies have been reported on the propagation of plane wave and beam wave pulses in random media by many investigators[5-9]. Ishimaru[5] developed the theory of pulse propagation in discrete random media, derived the correlation function of a wave in a random distribution of stationary and moving scatters, and reported the multiple scattering effects on coherent bandwidth and pulse distortion of a wave propagating in a random distribution of particles.

In this paper, Scattering and propagation of UV pulses in random soot aggregate system are studied using generalized Multi-sphere Mie theory(GMM) and pulse wave propagation theory. Soot aggregates are obtained by the DLA model. For soot aggregate, scattering characteristics of a single aggregate in soot aggregate systems are analyzed by GMM. Scattering intensities versus scattering angles are given. The effects of different-positions average of the aggregate on the scattering intensities, scattering efficiency factors, extinction efficiency factors and absorption efficiency factors are computed and compared. The results obtained from GMM will provide some parameters for the analysis of propagation of pulses in random soot aerosols.

Based on pulse wave propagation in random media presented by Ishimaru[5], the transmission of UV pulses in random soot aggregate system is determined by the two-frequency mutual coherence function.

Numerical simulations of two-frequency mutual coherence function, coherent bandwidth are given and analyzed for UV pulses. The effects of soot aerosols parameters are discussed.

Innovative beacon approach for turbulent atmosphere characterization *(Invited Paper)*

Anatoliy Khizhnyak, Vladimir B. Markov, Advanced Systems & Technologies, Inc. (United States); Phillip A. Sprangle, U.S. Naval Research Lab. (United States); Joseph R. Chavez, Air Force Research Lab. (United States); Lew DeSandre, Office of Naval Research Global (United States)

Characterization of atmospheric perturbations is critical for effective compensation of turbulence-induced effects in coherent and incoherent imaging, laser communication and laser beam propagation, in general. The related parameters of the turbulence are derived by detecting the characteristics of a reference wave passing through an inhomogeneous medium. On practice, this requires a reference wave generated by a localized beacon placed at the opposite end of the light path where the parameters of the turbulence will be measured. Therefore, the beacon is critical for various systems that perform characterization of perturbations and its correction systems, including the adaptive optics. Formation of the beacon in a turbulent environment remains one of the most pressing and difficult-to-solve problems, especially in the case of an extended or image-resolved target with a diffuse-scattering surface.

To date, several approaches targeting the formation of a localized beacon have been attempted with little success. Most of the proposed methods and techniques have been simulated and studied experimentally in laboratories, but didn't prove a reliable performance in a realistic environment, mostly due to the complexity of the problem. The most effective solution to the problem would be to develop a system for atmosphere characterization that can use the light scattered by a non-localized extended target. This presentation discusses the results of the analysis, simulations and experimental studies of the technique that allows characterization of turbulence in an image-resolved scenario.

8874-10, Session 3

Pointing, acquisition, and tracking considerations for mobile directional wireless communications systems

John Rzasa, Christopher C. Davis, Univ. of Maryland, College Park (United States)

High capacity directional wireless communications networks are an active research area because of their Gb/s or greater data-rates over link lengths of many kilometers, providing fiber-like networks through the air. Their high data-rates arise partly from their very high carrier frequencies and partly because of their narrow beamwidths. This second characteristic requires that transceivers be pointed precisely to their counterparts. In almost all cases this means that the transceiver aperture is mechanically pointed by a rotation stage, commonly known as a gimbal. How these platforms initially point at a target, acquire the signal, and then stay locked on the signal is known as pointing, acquisition, and tracking (PAT). Approaches for PAT in both RF and FSO have some similarities, but require overall divergent solutions, especially if the platforms are moving. This paper elaborates on the various considerations required for designing and implementing a successful PAT system for both directional RF and FSO systems. In particular, approaches for GPS or beacon based pointing, types of acquisition scans, totally blind acquisition possibilities, and different tracking algorithms are analyzed. Finally, some results from a custom built six platform FSO system are described, along with their use as a testbed for future PAT experiments.

8874-11, Session 3

An innovative modulating retro-reflector for free-space optical communication

Etai Rosenkrantz, Shlomi Arnon, Ben-Gurion Univ. of the Negev (Israel)

Modulating retro-reflectors (MRR) are beneficial for asymmetric free-space optics communication links. An MRR includes an optical retro-reflector and an electro-optic shutter. The main advantage of an MRR configuration is that it shifts most of the power, weight, and pointing requirements onto one end of the link. In this study an innovative device comprising of nanoparticle-embedded ferroelectric thin film is used as an MRR. The new modulator is mounted in front of a passive retro-reflector. In our study we calculated the link budget for lunar exploration scenario. The scenario includes a base station that communicates with several robots or astronauts. In our simulations, the base station illuminates a robot with a continuous-wave beam, i.e. an interrogating beam. The un-modulated beam strikes the MRR, which is located on the robot, and is passively reflected back to the base station carrying the data that has been modulated onto it by the MMR. In this scenario a robot and a base-station are 4km apart, with a clear line of sight. In addition, the innovative MRR is capable of achieving 12dB contrast ratio. Under these assumptions and using the nanoparticle-embedded ferroelectric MRR we calculated the required transmission power for a given bit-rate and BER.

8874-12, Session 3

Comparison and evaluation of the laser beam-shaping techniques

Peter Barcík, Lucie Hudcová, Otakar Wilfert, Brno Univ. of Technology (Czech Republic)

Over the past several decades, free-space optical (FSO) systems have gained a specific place in the wireless technology area. The application of these systems is advantageous for high bandwidth, a license free band and quick installation. The main drawback of FSO systems is their dependence on the state of the atmosphere causing deterioration of the

FSO systems availability. One of the atmospheric effects which has an essential impact on the performance of the FSO systems is atmospheric turbulence. Atmospheric turbulence leads to fluctuation of the optical intensity in the plane of the receiving aperture. It has been shown that to reduce the effect of atmospheric turbulence, uniform distribution of the optical intensity within a cross section of the beam in the plane of transmitting aperture (phenomenon of diffraction is neglected) and a sufficiently large diameter of the circularly symmetric receiving aperture (to achieve aperture averaging effect) are needed. The main idea of our paper is the problem of beam shaping at the transmitter. In our contribution the technique of transformation of a Gaussian beam into a beam with uniform distribution of optical intensity is discussed. For the mentioned transformation we experimentally tested several shaping methods such as multi aperture beam integrators, diffractive diffusers, etc. Usage of laser sources with different degrees of coherence was considered.

The purpose of these techniques is to create an optical beam with uniform distribution of optical intensity on the transmitter output. In order to compare and evaluate the particular shaping techniques, a new "Transformation Complex Quality (TCQ) parameter" was defined. The TCQ parameter indicates the optimal shaping technique and also evaluates the quality of the resulting transformed beam with respect to its resistance towards atmospheric turbulence.

8874-13, Session 3

Extracting atmospheric turbulence and aerosol characteristics from passive imagery

Colin N. Reinhardt, David Wayne, Kevin McBryde, Galen Cauble, SPAWAR Systems Ctr. (United States)

Obtaining accurate and timely information about local atmospheric meteorological conditions such as turbulence and aerosol/particulate content remains a difficult problem with incomplete solutions. It has important applications in optical and IR free-space communications, imaging systems performance, and the propagation of directed energy. The capability to utilize passive imaging data to extract parameters characterizing atmospheric turbulence and aerosol/particulate conditions would represent a valuable addition to the current toolset for atmospheric sensing.

Our research investigates the novel application of fundamental results from optical turbulence theory and aerosol extinction theory combined with current blind/no-reference image-quality-metrics (IQM) and image-quality-assessment (IQA) methods. We have developed an algorithm which extracts important parameters used for characterizing atmospheric turbulence and aerosols/particulates along the propagation channel, such as the refractive-index structure function C_n^2 , the Fried atmospheric coherence width r_0, and the atmospheric extinction coefficient ?, from passive image data of remote Siemens star resolution targets. We will analyze the algorithm performance using simulations based on modeling with turbulent and aerosol modulation transfer functions (MTF), and high-resolution wave-optics phase-screen propagation computational models. An experiment campaign was organized and data were collected from passive imaging of Siemens star resolution targets over a 700m littoral path in San Diego. We examine the algorithm's effectiveness using this data and compare against measurements taken concurrently with other standard atmospheric characterization equipment.

8874-14, Session 4

Propagation of light through ship exhaust plumes *(Invited Paper)*

Miranda van Iersel, TNO Defence, Security and Safety (Netherlands)

Looking through the atmosphere it is sometimes difficult to see the details of an object. Looking through exhaust plumes of e.g. a ship can make it even harder to see the details. Exhaust plumes come in different shapes, sizes, and opaqueness and they depend on atmospheric parameters like wind speed and direction, as well as engine settings (power, gas or diesel, etc.).

A model to characterize the plume as function of the aforementioned parameters has been developed and an analysis was made of amount of detail still visible through a plume under different conditions.

This plume module will be incorporated in the TNO EOSTAR-model, which provides estimates of detection range and image quality of EO-sensors under varying meteorological conditions. The plume module improves EOSTAR in two aspects, i.e., a more accurate calculation of a ship's signature and the shading of the scene behind the ship due to plume absorption.

8874-15, Session 4

A novel method for measuring atmospheric transmission using a modulated laser source

David Wayne, Colin Reinhardt, Kevin McBryde, Galen Cauble, SPAWAR Systems Ctr. (United States)

Current transmissometer designs can be physically bulky, electronically complex, and susceptible to background light; ultimately limiting performance. We describe a novel transmissometer design based upon a modulated laser/LED source and an AC-coupled receiver to improve upon the aforementioned shortcomings. This design aims to reduce both complexity and SWAP through the use of a high frequency modulation technique. We describe the theory associated with our technique, particularly how the effects of atmospheric turbulence are handled. The transmissometer is built and tested in the laboratory then demonstrated over a 700m littoral path in San Diego; an Optec PLV-3 commercial transmissometer is setup in parallel to provide a baseline atmospheric transmission measurement. Two signal processing techniques are described, one to calculate the atmospheric transmission and the other to calculate the optical depth. The processed data are compared with concurrent measurements from an Optec LPV-3 commercial transmissometer. The data from the new transmissometer tracks the commercial instrument very well.

8874-16, Session 4

Modified plenoptic camera for phase and amplitude wavefront sensing

Chensheng Wu, Christopher C. Davis, Univ. of Maryland, College Park (United States)

A plenoptic camera is a camera that preserves the light field entering its object lens and facilitates future processes such as refocusing at different depths and 3D microscopy. It is also changing the paradigm in photography, allowing people to take casual shots first but produce high quality pictures later. This new generation of camera incorporates a micro-lens array where the image sensor of a traditional camera would be and places a focal plane array in the focal plane of the micro-lens array. This forms a tiny camera array recording each spot in the aperture of main objective lens. By acquiring extra information about a scene and weighted averaging of this data, the plenoptic camera provides additional information to traditional cameras. We have determined that with slight geometric changes of its components, a modified plenoptic camera will be able to solve phase and amplitude wave front sensing problems such as analyzing interference patterns and recording phase difference between light patches of a distorted laser beam. Our modified plenoptic camera uses the micro-lens array as a viewing tool aimed at the focal plane of the main objective lens. In combination with Fourier optic analysis, a complex wave-superposition is sorted and divided into much simpler wave forms on different regions of the final image plane, which can be recorded and analyzed. Simulations have been conducted to verify these concepts, and show that this modified plenoptic camera can reveal phase information in addition to spatial and angular information provided by a traditional Shack-Hartmann Wave front sensor. This may lead to promising approaches for correcting atmospheric turbulence induced distortions on laser beams that have passed through deep turbulence.

8874-17, Session 4

Multifractality and the effect of turbulence on the chaotic dynamics of a HeNe laser

Damián Gulich, Luciano Zunino, Ctr. de Investigaciones en Óptica, A.C. (Argentina) and Univ. Nacional de La Plata (Argentina); Darío Pérez, Pontificia Univ. Católica de Valparaíso (Chile); Mario Garavaglia, Ctr. de Investigaciones en Óptica, A.C. (Argentina) and Univ. Nacional de La Plata (Argentina)

We propose the use of multifractal detrended fluctuation analysis (MF-DFA) to measure the influence of atmospheric turbulence on the chaotic dynamics of a HeNe laser. Fit ranges for MFDFA are obtained with goodness of linear fit (GoLF) criterion.

The chaotic behavior is generated by means of a simple interferometric setup with a feedback to the cavity of the gas laser. Such dynamics have been studied in the past and modeled as a function of the feedback level. Different intensities of isotropic turbulence have been generated with a turbulator device, allowing a structure constant for the index of refraction of air adjustable by means of a temperature difference parameter in the unit.

Considering the recent interest in message encryption with this kind of setups, the study of atmospheric turbulence effects plays a key role in the field of secure laser communication through the atmosphere. In principle, different intensities of turbulence may be interpreted as different levels of white noise on the original chaotic series. These results can be of utility for performance optimization in chaotic free-space laser communication systems.

8874-22, Session PMon

Propagation and split of the filamentation of femtosecond pulses in air by multiphase screen method

Jifeng Zu, Qijie Huang, Xusheng Zhou, Peng Zou, Yameng Zheng, Ting Yu, Shanghai Institute of Optics and Fine Mechanics (China); Yimeng Wang, Yachen Gao, Heilongjiang Univ. (China)

The propagation and split of the filamentation of femtosecond pulses in air have been paid much attention since last a few years. However, most research works are performed with few considerations of the turbulence effects of atmosphere due to the difficulties of utilizing analytical solutions and experiment conditions. In this work, we will attempt to introduce a kind of numerical simulation method to analyze the transmission features of femtosecond laser pulses in air or in the turbulent air, namely, it is called multi-phase screen method (MPSM) which use phase screen to simulate atmospheric turbulence. In this presentation, the main laser parameters are as follows: 85 fs pulse-width, 0.8cm radius of the beam, the two kinds of 160GW and 1.0 TW peak-power operating at 800 nm. Then utilizing the structure of Vortex soliton to control the filamentation is proposed. In our cases, four Gaussian pulses with a difference of $\pi/2$ in the phase of each adjacent beam as a ring to control the filamentation by utilizing its characteristics of the vortex soliton. Some results show that the coupling and interaction among four Gaussian pulses cause the rotational transfer of the energy of the four beams. Finally, we obtain the transmission features of the beams propagating in the turbulent air with different intensities by the MPSM.

8874-35, Session PMon

Space qualified photon counting detector package

Josef Blazej, Ivan Prochazka, Czech Technical Univ. in Prague (Czech Republic); Jan Kodet, Czech Technical Univ. in Prague (Czech Republic) and Technische Univ. München (Germany)

The laser time transfer link is under construction for the European Space Agency for its application in the experiment Atomic Clock Ensemble in Space. We have developed and tested the photon counting detector optimized for operation in space for this project. The detector package is rugged and compact. The optical, photon counting, electrical and timing properties of the detector package have been tested. In this paper are reported the main characteristics which changed after the irradiation by ionizing radiation. The effective dark count rate was measured using actively quenching and gating circuit. It will be used also during space operation. The radiation sources was protons at 53 MeV and gamma ray radiation source 60Co. The long term detection delay stability in the sense of time deviation of detected single photon signal is excellent – typically 200 fs for averaging times of several hours. The device is capable to operate in a temperature range of ?55°C up to +60°C. The change of the detection delay with temperature is typically below 500 fs/K. The detector has been approved for application in the European Laser Timing experiment, the flight module is under manufacturing now. The detector might be employed in other future space missions including long-term, where sub-picosecond timing and radiation stability is required and interesting for other photon counting application under ionizing radiation.

Prototyping FM data demodulation in free-space optical communication systems using discrete wavelet transformation

Lan Tran, Esam El-Araby, Nader M. Namazi, The Catholic Univ. of America (United States)

One of the inherent limitations on the quality of a free-space optical (FSO) communications link is the degradation of the received beam due to atmospheric turbulence. Some of the effects of atmospheric turbulence on FSO received beams are beam wander, beam break-up, and scintillation. All of these atmospheric effects can cause a reduction of signal to noise ratio (SNR), reduction in effective link range and/or bandwidth, and often complete loss of the received data. Atmospheric turbulence effects are especially difficult to overcome in the case of analog modulation of the optical beam since fluctuating received power levels translate directly to fluctuations in the amplitude of the modulating signal.

In this paper, we consider the effects of atmospheric turbulence on an FSO link that uses analog frequency modulation. The atmospheric effects are treated as noise signals which decrease the signal-to-noise ratio of the link. Based on the results presented in [1], we investigate the use of the discrete wavelet transformation (DWT) to considerably reduce the effect of the noise signals. The method in [1] will be used and implemented real-time on FPGA using Xilinx System Generator for DSP.

Phase-space distribution of optical field intensity of laser beam propagation through atmospheric turbulence

Wei Lu, Jianfeng Sun, Deyan Xu, Xiaoping Ma, Bing Li, Liren Liu, Shanghai Institute of Optics and Fine Mechanics (China)

Phase-space optics has its advantage over the research of laser beam propagating through atmospheric turbulence channel due to its special joint space-spatial frequency representation, which can be used to describe the property of optical signals between variables that form a Fourier transform pair. In this paper, we try to introduce the effect of atmospheric turbulence in terms of matrix into the phase-space analysis of laser beam propagation through turbulence. The far field optical intensity in the channel will be given in terms of phase-space representation and the phase-space distribution of received optical intensity can be plotted. Furthermore, we also try to deduce phase-space representation of several turbulent layers and get the combined result. We try to give the phase-space representation of optical scintillation if possible, which may be a new method analyzing optical scintillation under the turbulent condition.

The effects of the relay beam size and data rate on self-homodyne detection efficiency in the satellite-to-ground laser communication

Xiaoping Ma, Jianfeng Sun, Ya'nan Zhi, Wei Lu, Liren Liu, Qian Xu, Shanghai Institute of Optics and Fine Mechanics (China)

Atmospheric turbulence influences the wave-front, and reduces homodyne detection efficiency and bit error rate in the Satellite-to-Ground Laser Communication. Free-space differential interference structure based on differential phase shift keying (DPSK) is applied in the optical signal receiver. The free-space Mach-Zehnder delay interferometer without lens is suited for differential delay which is equal to the one bit period. Differential information is obtained by the subtraction of the two successive wave-front phases when made to interfere. Differential distance at the interference receiver is varied with transmission rate from satellite to ground. And through the receiving telescope, the spot size of incident signal light within the interference became small than before, which influences the interference efficiency of the two unequal branches. So that, it is significant for increasing homodyne efficiency to determine the optical signal rate and choose the magnification of receiving telescope. In this paper, the effect of the spot size of incident light and transmission data rate on homodyne detection efficiency is analysed. By the simulation result of efficiency in different spot size and transmission date of incident light, the homodyne efficiency will be predicted in the given data rate and light spot size on the basis of experiment setup. And application condition of free-space differential structure at DPSK differential receiver is proposed.

8874-39, Session PMon

Measurement and modeling of the effects of atmospheric turbulence on coherent laser communication system

Jian Zhou, Wei Lu, Jianfeng Sun, Liren Liu, Shanghai Institute of Optics and Fine Mechanics (China)

It is well known that optical field propagates through the atmospheric channel is subject to random fluctuations in phase and amplitude which are caused by atmospheric turbulence. For the heterodyne reception free space coherent laser optical communication (FSO) system, phase fluctuation results in the mismatch between the signal field and the local oscillator. As a result, loss of heterodyne efficiency will occur. In recent years, much attention has been paid to adaptive optics and many techniques have been presented to correct the wave-front distortion. However, it is necessary to study how the effects of atmospheric turbulence on FSO system performance can be predicted and modeled. In this paper, we describe work that will enable the analysis of collected data to efficiency loss model. A polarization-based shearing interferometer is used to detect the distorted laser wave-front and reconstruct the wave-front after propagates through a 1Km near-ground atmospheric channel. Further, the heterodyne efficiency of the optical heterodyne reception system would be given under special consideration of the mismatch between the signal field and the local oscillator. By analyzing the optical heterodyne efficiency data and the real-time atmospheric coherence length data, a mathematical model of the heterodyne efficiency loss is given, which would meet the need for the description of turbulence in terms of its impact on FSO.

8874-18, Session 5

Underwater wireless optical communication using LED *(Invited Paper)*

Shlomi Arnon, Vladimir Pilipenko, Etai Rosenkrantz, Ben-Gurion Univ. of the Negev (Israel)

In recent years the need for high data rate underwater wireless communication (WC) has increased. Nowadays, the conventional technology for underwater communication is acoustic technology. However, the maximum data rate that acoustic technology can provide is below 1Mbps. Therefore, underwater optical WC has been proposed as an alternative, which could provide high data rate for short distances. The distance limitation of optical technology is due to the high attenuation of underwater environment. Nonetheless, the wavelengths that provide minimum attenuation are the blue-green light in the visible spectrum. In order to reduce cost and increase demand of underwater optical WC systems, the use of a blue LED has been proposed. The proposal is a result of the fact that LED offers low cost, high efficiency, reliability and compactness. However, there are some challenges to incorporate LED as part of the optical transmitter, such as low modulation rate and high non linearity. In this paper, we present measurement of non linearity and transfer function of blue LED. In addition, we discuss these challenges in a realistic scenario of underwater WC.

8874-19, Session 5

New technologies in underwater optical acquisition and tracking providing new possibilities for laser communication

Marco Tausendfreund, Cassidian Optronics GmbH (Germany)

Underwater communication has mainly been driven by the Navy under specific circumstances and challenges. Currently used here are conventional technologies using acoustic transmission, which can only realize data rates up to several kilobits. From the perspective of the operators of a submarine there is a logical prioritization towards covert operation against an evolution in data rates.

A completely different situation comes up by the use of UUVs, that create new potentials in the field of reconnaissance but one is also confronted with new problems coming up. With the development of optical sensors through to HD technology, that do not stop on the water surface, these underwater drones are indeed used for various purposes, but is an issue that data transfer in the Mbit range to a reference buoy or a submarine is just possible over a fiber optic connection. The risk of breaking of such a cable is extremely high when maneuvering the UUV.

On distances that are common for the operation by glass fiber, optical communication provides the better alternative. From the experience taken in space applications and the subsequent development of various terrestrial systems through the recent years, together with the German Naval Research Center experiments were repeated to verify the added

value of this technology. Therefore ranges of optical communication underwater were evaluated for all occurring underwater visibilities worldwide.

Largest caused problems so far is the first acquisition under water as well as the mutual optical tracking, since under water at adequate pressure no gyro-stabilized platforms can be used. Cassidian Optronics has developed and patented special optical methods, wherein based on the combined use of a modulated retro-reflector and a 4-quadrant detector underwater these difficulties can be overcome. The report describes the underlying process and thereby gives an outlook on the possibilities opened up.

8874-20, Session 5

The recovery of LED diode optical spectrum

Jan Vitasek, Jan Latal, Petr Siska, Jan Skapa, Martin Papes, Vladimir Va?inek, Technical Univ. of Ostrava (Czech Republic)

White power LED diodes could be used for illumination of rooms. These power LED diodes could be modulated too, so they could transmit data. The power LED diodes could be used for illumination and communication at the present time. The great problem of white power LED diodes is that they are limited in modulation rate because the light is generated by chemical reaction between blue light and yellow luminophore. The way, how to increase the modulation rate, is as follows. The narrow part of white power LED diode spectral characteristics is suppressed by optical filter. The suppressed part is then recovered by other LED diode, call as communication LED diode. The final optical spectrum should be as an original spectrum of white power LED diode. Now, only the communication LED diode is modulated. It could be construct a transmitter which provides an illumination and communication at the same time. This article deals with recovery of original spectrum of white power LED diode.

8874-21, Session 5

Measurements and modeling of resolved laser radiometry in the maritime environment

John S. deGrassie, Ike Bendall, Jason W. Cole, Galen Cauble, Space and Naval Warfare Systems Ctr. Pacific (United States)

A model for predicting the radiometry for a resolved laser scattering in the maritime atmosphere has been developed in the Electro-Optics group in Atmospheric Propagation Branch of SPAWAR Systems Center, Pacific. The model predicts the power received at a sensor from the local meteorological conditions of the atmosphere. Field experiments conducted in San Diego, CA allowed an opportunity to validate the predictions of the model. Radiometric calibrations of a CCD camera provided power measurements of a resolved laser to be taken from various senor-laser beam orientations. The performance of the laser scattering model is assessed from the field measurements.

8874-23, Session 6

Using speckle imaging techniques as a starting point for MFBD scene reconstruction from long horizontal-path, turbulence-degraded imagery *(Invited Paper)*

Jeremy P. Bos, Glen Archer, Michael C. Roggemann, Michigan Technological Univ. (United States)

In recent works presented at this conference we have detailed our work on quantitatively evaluating the performance of image reconstruction methods applied long horizontal path imaging scenarios through turbulence. Our work has focused on two image-processing methods, speckle imaging and methods based on Multi-Frame Blind Deconvolution (MFBD). In recent presentations, the performance of the bispectrum and Knox-Thompson phase recovery methods were compared quantitatively using simulated images sets of an object observed over a long (1000m) horizontal path through the atmosphere. In a separate presentation, the performance of a MFBD method was evaluated using similar methods. Our initial MFBD algorithm used the ensemble average of the centered image frame set as a starting for the MFBD algorithm. In this work, iteration using the MFBD begins with the scene estimate provided via speckle imaging methods (both Knox-Thompson and bispectrum phase recovery methods are explored). As with our previous work, performance is evaluated in terms of the MSE in normalized intensity value per pixel compared to a diffraction-limited reference image. We have found that an additional 4% reduction in MSE is available compared to images recovered using speckle imaging techniques alone. This technique also results in images with a lower MSE (as much as 7%) compared to using the average image as a starting point when the same exit conditions are used. In addition to residual MSE other performance metrics such as processing time and noise immunity will also be discussed.

8874-24, Session 6

Simulating video through turbulence

Kevin McBryde, Kristofor Gibson, SPAWAR Systems Ctr. (United States)

Atmospheric turbulence can cause significant degradation to video over long horizontal paths. The refractive index fluctuations along the path from scene to camera lead to blur, varying across the frame and from frame to frame. Computationally inexpensive methods model this effect with an MTF blur function; however this technique neglects anisoplanatic effects. Wave optics techniques have been developed taking into account anisoplanatism, but ignoring scintillation, and spatial and temporal effects.

Since long horizontal paths over varied surfaces (e.g. water to land or vice versa) will encounter varying turbulence strength along the path, the turbulence strength should be defined independently at each phase screen. Also important, turbulence strength can vary over short time scales (<1s), so a physically accurate simulation must allow time-dependent phase screens. We will present results of a wave optics simulation technique that includes these spatial and temporal variations. The results will provide validation for turbulence removal algorithms.

8874-25, Session 6

The feasibility of vision systems to form free-space optical links

Mohammed A. Eslami, Ching-Hui Chen, John Rzasa, Stuart D. Milner, Christopher C. Davis, Univ. of Maryland, College Park (United States)

Active systems and raster scans are the most popular methods for achieving the pointing accuracy required to form an optical link. With advances in vision system technology, a potential extension to current methods of alignment is to use cameras to control coarse and/or fine pointing acquisition and tracking to establish optical communication links. Using a stereo-setup to localize a target's 3D location is of great benefit to find the appropriate pointing settings to establish such links. The narrow beam widths of an optical link require very accurate calibrations of the camera's intrinsic (focal length, skew, distortions) and extrinsic (pose and orientation) parameters to provide a proper mapping between the 3D world coordinate and a 2D pixel coordinate for proper pointing. Currently, the most widely used calibration schemes use the pinhole model of a camera – which optically translates to a smaller aperture that captures only chief rays from the target – to extract the intrinsic and extrinsic parameters. In this paper, a model is presented to analyze the effects of focal length and principal point deviation on the achievable pointing accuracies. The effects of radial distortion from a lens on the achievable pointing accuracies are also presented.

8874-26, Session 6

Propagation of J0-Bessel correlated beams in weak atmospheric turbulence

O. Korotkova, Univ. of Miami (United States); Charles Nelson, Svetlana Avramov-Zamurovic, Daniel J. Whitsett, J. Watkins, Reza Malek-Madani, U.S. Naval Academy (United States)

When a partially coherent beam propagates through a turbulent medium, at relatively short distances from the source, it generally exhibits lower scintillation index in comparison to that of a comparable coherent beam.

Optimal intensity shaping and reduction in the scintillation index are of great importance to the wave propagation in maritime environment due to the significant impact of random medium on the effective delivery of energy on the target. At the United States Naval Academy, we have been successfully generating various random beams of Schell type using a nematic, phase-only spatial light modulator (SLM) and propagating them along paths set in different turbulent conditions. The latest experiments involving J0-Bessel correlated Schell-model beams have shown interesting propagation properties compared to those for the other beam classes. The conference presentation will cover the results of generation and propagation over the several hundred-meter link for both classic Gaussian Schell-model beams and J0-Bessel correlated Schell-model beams with wide range of source coherence states. For such beams, the reduction in the scintillation index has been demonstrated reliably.

8874-27, Session 6

Detection of non-standard atmospheric effects in FSO systems

Juraj Poliak, Otakar Wilfert, Brno Univ. of Technology (Czech Republic)

Modern free-space optical (FSO) communication systems in many aspects overcome wire or radio communications. They offer a license-free operation and a large bandwidth. Operation of outdoor FSO links struggles with many atmospheric phenomena that deteriorate phase and amplitude of the transmitted optical beam. Thanks to the recent advancing development, these effects are more or less well understood and described. Goal-driven research increased the link availability.

Besides increasing the availability of data links it is necessary to focus on the accuracy and reliability of testing optical links. Research of the data optical links is focused on the transmission of a large amount of data whereas the testing FSO link is designed to achieve maximal resolution and sensitivity thus improving accuracy and repeatability of the atmospheric effects measurement. Given the fact that testing links are located in the measured media, they are themselves influenced by it. Phenomena such as the condensation on transceiver windows (rain, frost) and the deviation of the optical beam path caused by the wind are referred to as non-standard effects. Non-standard effects never occur independently; therefore we must always verify the cross-sensitivity of the testing link.

In the paper we respond to an increasing number of articles dealing with influence of the atmosphere on the link but ignoring the cross-sensitivity of the testing link on other variables than tested. In conclusion, we carry out qualitative and quantitative analysis of self-identified non-standard effects.

8874-28, Session 7

Improved sparse spectrum model for the turbulent phase *(Invited Paper)*

Mikhail I. Charnotskii, National Oceanic and Atmospheric Administration (United States)

Recently published Sparse-Spectrum (SS) model of the phase front perturbations by atmospheric turbulence [M. Charnotskii, JOSA A, 30 479-488 (2013)] is based on the trigonometric series with discrete random support. SS model offers substantial savings of the computational efforts, while preserving the wide range of scales typically associated with turbulence perturbations. We present an improved version of the SS model that accurately reproduces the power-law spectral density of the phase fluctuations in the required spectral band that can be as wide as six orders of magnitude in each direction. SS model offers a substantial flexibility in the choice of the probability distributions of the wave vectors of the individual spectral components while preserving the prescribed second statistical moment including the spectrum. We use the Monte-Carlo model to examine the higher-order statistics of the SS phase samples. The number of spectral components and the degree of overlapping used in the model are the primary parameters affecting the SS phase statistics. We also present the calculations of the practically important long-exposure and short-exposure Strehl numbers for the different versions of the SS model, and discuss the long-term and short-term scintillations in the image of the point source.

8874-29, Session 7

Calculating phase shifts using a bubble model for free-space optical communication links

Heba Yuksel, Demet Yuksel, Bogaziçi Üniv. (Turkey)

Atmospheric turbulence has a significant impact on the quality of a laser beam propagating through the atmosphere over long distances. Turbulence causes intensity scintillation and beam wander from propagation through turbulent eddies of varying sizes and refractive index. This can severely impair the operation of target designation and Free-Space Optical (FSO) communications systems. In addition, experimenting on an FSO communication system is rather tedious and difficult. The interferences of plentiful elements affect the result and cause the experimental outcomes to have bigger error variance margins than they are supposed to have. Especially when we go into the stronger turbulence regimes the simulation and analysis of the turbulence induced beams require delicate attention. We propose a new geometrical model to assess the phase shift of a laser beam propagating through turbulence. The atmosphere along the laser beam propagation path will be modeled as a spatial distribution of spherical bubbles with refractive index discontinuity calculated from a Gaussian distribution with the mean value being the index of air. For each statistical representation of the atmosphere, the path of rays will be analyzed using geometrical optics. These Monte Carlo techniques will assess the phase shift as a summation of the phases that arrive at the same point at the receiver. Accordingly, there would be dark and bright spots at the receiver that give an idea regarding the intensity pattern without having to solve the wave equation. The Monte Carlo analysis will be compared with the predictions of wave theory.

8874-30, Session 7

Geometrical optics analysis of atmospheric turbulence

Chensheng Wu, Christopher C. Davis, Univ. of Maryland, College Park (United States)

Atmospheric turbulence has a significant effect in reducing system performance in long range free space optical (FSO) communications. Atmospheric turbulence causes cumulative distortion of propagating beam waves, causing their constituent light rays to deviate from straight line paths, which results in intensity redistribution at the plane of the receiver. The analysis of the received field is traditionally carried out with wave analysis using phase screens and Kirchoff-Fresnel diffraction analysis. However, since the smallest diffracting structures (eddies) in the atmosphere are much larger than the wavelength, a geometrical optical analysis should be able to provide substantial information. We have previously shown that such an analysis correctly predicts beam wander and aperture averaging effects. We have modeled the atmospheric turbulence as a collection of curved interfaces with refractive index discontinuities or as a collection of spherical bubbles with distributed sizes, positions, and refractive indices. This method, though reasonable in mimicking the reality, consumes enormous computational resources to acquire considerable accuracy in simulating and estimating the impact of atmospheric turbulence. We have developed a much more manageable approach to evaluating the turbulence effects on FSO systems by using linearized segments of light ray trajectories to represent real curved light rays. Thus the gradually shifted wave fronts are simulated by a number of integrated reflections distributed randomly inside the channel. In our approach, air bubbles are equivalently replaced by a large number of tiny mirrors with random orientations that mimic different magnitudes of turbulence. As a result, these tiny mirrors set up statistically in a Monte Carlo simulation lead to the same conclusions predicted by established theories, such as the (Range)3 dependence of beam wave mean-squared wander, aperture averaging, the breakup of beams, and reduced coherence of the beam wave. This random-walk approach to the passage of light rays through a turbulent medium allows the analysis of a model where the turbulence is continuously distributed rather than collapsed into phase screens.

8874-31, Session 7

Understanding spatial diversity using a geometrical model for optical wireless applications

Heba Yuksel, Demet Yuksel, Bogaziçi Üniv. (Turkey)

Ways of calculating phase shifts between laser beams propagating through atmospheric turbulence can give us insight towards the understanding of spatial diversity in Free-Space Optical (FSO) links. We propose a new geometrical model to estimate phase shifts between rays as the laser beam propagates through a simulated turbulent media. Turbulence is simulated by filling the propagation path with spherical bubbles of varying sizes and refractive index discontinuities statistically distributed according to various models. The level of turbulence is increased by elongating the range and/or increasing the number of bubbles that the rays interact with along their path. For each statistical representation of the atmosphere, the trajectories of two parallel rays separated by a particular distance are analyzed and computed simultaneously using geometrical optics. The three-dimensional geometry of the spheres is taken into account in the propagation of the rays. The bubble model is used to calculate the correlation between the two rays as their separation distance changes. The total distance traveled by each ray as both rays travel to the target is computed. The difference in the path length traveled will yield the phase difference between the rays. The mean square phase difference is taken to be the phase structure function which in the literature, for a pair of collimated parallel pencil thin rays, obeys a five-third law assuming weak turbulence. All simulation results will be compared with the predictions of wave theory.

8874-32, Session 8

On modeling and simulating controls and predicting network instabilities in mobile directional wireless networks

David M. Coleman, Stuart D. Milner, Christopher C. Davis, Univ. of Maryland, College Park (United States)

Research in mobile directional wireless backbone (DWB) networks has yielded technological advances in free-space optical and directional RF link performance. However, there has been a lack of research on the performance of these links in a DWB. We have addressed this need by developing network control models and by customizing modelling and simulation software for testing their effectiveness in an internet using OPNET and MATLAB. We introduce correct physical models for FSO and RF links, augment the medium-access control layer for true narrow-beam point-to-point links, and introduce a new layer in the Internet Protocol stack for the control in mobile DWB networks. We provide a customized modelling and software platform, which will extend simulations beyond single-link and relay performance and in the direction of full mobile DWB networks. In addition, we extend our novel analogy between a mobile DWB network with molecular dynamics to achieve a reduced penalty during link disruption events (including full partitions) and ultimately predict unstable configurations. In this approach, we model the effects of end-user mobility, platform geometries/dynamics, terrain, and obscuration as catalysts in the environment of the mobile DWB network, which invoke a link disruption event or more severely a network reconfiguration. This effort yields an analysis of the network on the order of minutes prior to a network reconfiguration and is obtained through inherent properties of the aggregate network (not from individual link performance) through normal mode analysis.

8874-33, Session 8

Capacity maximizing precoder design for a MIMO optical wireless channel using RGB LEDS

Qian Gao, Gang Chen, Univ. of California, Riverside (United States)

In this paper, we consider the problem of precoder design for an optical wireless communication system employed with multiple transmitters and receivers. In our intensity modulated (M) system, each transmitter contains a red-green-blue light emitting diode (RGB LED) array. For detection purpose, imaging devices are used so that the LED arrays are imaged onto the detector arrays, which are combined with color filters to provide independent RGB tunnels. We show that the resulting channel matrix between LED and detector arrays is of full rank. thus multiple finite-alphabet data streams can be modulated onto the LED arrays simultaneously. We then formulate an optimization problem targeted at maximizing the system capacity by searching for the linear precoding matrix which optimally rotates the data symbols, allocates powers, and loads the beams along the channel eigenvectors. The design constraints includes: the average optical power constraint, the non-negative real intensity constraint, and several lighting constraints such as the color rendering, luminous efficacy, and flickering-free. The supremacy of multi-color over monochrome, precoded over uncoded, and multiplexing over spatial modulated systems are elaborated with the simulation and experimental results as evidences.

8874-34, Session 8

Spatial modulated color shift keying and constellation design

Qian Gao, Tian Lang, Gang Chen, Zening Li, Univ. of California, Riverside (United States)

In this paper, we propose a scheme called spatial modulated color shift keying (SM-CSK), a promising candidate supporting high speed transmission of VLC which uses multiple red/green/blue (RGB) light-emitting diodes (LEDs) as transmitters and thus takes advantage of the diversities in wavelength and space domain. During each modulation interval, only one among N LED lights is allowed to be turned on, and binary sequences are mapped onto a constellation of size M with color basis. Therefore, log2(MN) bits get conveyed at once. We show this by simulation and experimental results which SM-CSK have higher spectrum efficiency than the widely applied optical modulation schemes: on-off-keying (OOK) and pulse position modulation (PPM). Moreover, multiple input multiple output (MIMO) has also been studied for its channel interference trade off. Taking into account the intensity modulation and direct detection (IM/DD), the luminous efficacy rate (LER) and the color rendering index (CRI) constraints, we propose a constellation design algorithm based on non-convex optimization. For a target bit error rate (BER) at 10 -9, our algorithm finds power efficient constellations offline without increasing complexity at both the transmitter and receiver side. Our result is compared to the billiard algorithm which is a pioneer work for constellation design for CSK.

8875-13, Session PMon

SILICON CARBIDE: AN ADVANCED PLATFORM FOR NEXT GENERATION QUANTUM DEVICES *(Invited Paper)*

Stefania Castelletto, RMIT Univ. (Australia); Brett C. Johnson, The Univ. of Melbourne (Australia); Albert Parker, RMIT Univ. (Australia)

Deep defects are ubiquitous in many advanced materials. Whilst for conventional applications they can be detrimental and, for many years, their effects diminished devices functionalities and performances, more recently some of these defects are found to be useful in applications such as solid state quantum computation and quantum optical communication.

Silicon carbide, due to its harbouring of optical and paramagnetic deep defects, is presently indicating the opportunity to advance and merge several areas of research, providing the means to advance quantum-physics-based devices. Its recently studied functionalities, described in this paper, could allow the implementation of several degrees of freedom quantum systems in fully integrated operational devices. The harshening of SiC advance in engineered quantum systems could also open new avenues for fundamental quantum physics research.

In particular we will show recent breakthroughs on the engineering for the first time of single photon emission in SiC monolithic crystals and nanocrystals.

8875-32, Session PMon

Non-deterministic quantum CNOT gate with double encoding

Amor Gueddana, Moez Attia, Rihab Chatta, SUP'COM (Tunisia)

We define an Asymmetric Partially Polarizing Beam Splitter (APPBS) to be linear optical component having different reflectivity (transmittance) coefficients, on the upper and the lower arms, for horizontally and vertically Polarized incident photons.

Our CNOT model is composed by two APPBSs, one Half Wave Plate (HWP), two Polarizing Beam Splitters (PBSs), a Beam Splitter (BS) and a pi-phase rotator for specific wavelength.

Control qubit operates with dual rail encoding while target qubit is based on polarization encoding.

To perform CNOT operation in 4/27 of the cases, input and target incoming photons are injected with different wavelengths.

Towards the demonstration of interference between single photons from independent Ni:diamond Lattice and SPDC sources

Oliver T. Slattery, National Institute of Standards and Technology (United States) and Univ. of Limerick (Ireland); Paulina Kuo, Yong-Su Kim, Xiao Tang, National Institute of Standards and Technology (United States); Igor Aharonovich, Univ. of Technology Sydney (Australia); Stefania Castelletto, RMIT Univ. (Australia) and ARC Ctr. for Engineered Quantum Systems (Australia)

The production of verifiably indistinguishable photons from independent sources is a critical element in the application of long distance quantum communications. Observation of Hong-Ou-Mandel (HOM) interference of single photons is a common technique to verify such indistinguishability. Nickel-related color centers in diamond (Ni:diamond) have been identified as a good sources of single photons at room temperature. Meanwhile, spontaneous parametric down-conversion (SPDC) is a well-established method for single photon pair production and can be designed for degenerate or non-degenerate pairs at wavelengths suitable for long distance communications. Here we outline an experiment that will measure the Hong-Ou-Mandel (HOM) interference between a single photon produced by SPDC and a single photon from a Ni-related defect in diamond. The independent photons exhibit different frequencies and spectral linewidths and therefore require spectral engineering to achieve successful Hong-Ou-Mandel interference. We propose to use a non-linear frequency upconversion scheme to match the SPDC photon to the frequency of the photon from the Ni:diamond while preserving the single photon statistics of the source. The upconversion process also serves as a narrow bandpass filter of the broadband SPDC photons. Therefore, tunable narrow bandpass filtering of the photons from the Ni:diamond will be required to ensure indistinguishability of the photons from each source. We propose to use a volume Bragg grating to suitably filter the photons from the Ni:diamond. Independent single photon sources can facilitate hybrid quantum communications schemes and advance the state of quantum communications.

Quantum limits of optical super-resolution and a priori information *(Invited Paper)*

Mikhail Kolobov, Univ. des Sciences et Technologies de Lille (France)

The conventional concept of resolving power of an optical instrument was developed at the end of the nineteen century in classical works of Abbe and Rayleigh. In the framework if the modern Fourier optics the resolving power of an optical system is characterised by its spatial-frequency transmission band. Classical super-resolution is an attempt to restore the spatial Fourier components of the object outside the transmission band of the system. Such super-resolution is possible when one has some a priori information about the object, for example, that the object has a finite size.

We shall give an overview of the quantum theory of optical resolution and show that super-resolution crucially depends on the amount of a priori information about the object. We shall demonstrate that the standard quantum limit of super-resolution for discrete objects is much higher than that for continuous objects due to higher amount of a priori information. We shall prove that one can go beyond the standard quantum of super-resolution using spatially multimode squeezed light. We shall present the latest results for the quantum limits of super-resolution for sparse optical images using the compressed sensing approach.

8875-3, Session 1

Atom lithography with subwavelength resolution *(Invited Paper)*

M. Suhail Zubairy, Zeyang Liao, Texas A&M Univ. (United States); Mohammad Al-Amri, KACST (Saudi Arabia)

The resolution of optical lithography and the spacing of atom lithography are limited by about half of the wavelength due to the Rayleigh diffraction limit. Here we propose a coherent atom lithography experiment which can print nanometer structures. In this proposal, we show that sub-wavelength spatial distribution of the atom in the excited state can be achieved by inducing a spatially modulated Rabi oscillations in a two-level atom. We use the internal energy of the atom to excite the photoresist and we can then print the sub-wavelength structure into the photoresist. For the peak Rabi frequency of about 2GHz and the recoil limited collimation, we show that sub-10nm spacing is possible.

8875-4, Session 1

On using intensity interferometry for feature identification and imaging of remote objects *(Invited Paper)*

Baris I. Erkmen, Dmitry V. Strekalov, Nan Yu, Jet Propulsion Lab. (United States)

Intensity interferometry is a well-known and widely utilized technique in both classical and quantum optics, as well as in astronomy. Conventional intensity interferometry correlates the photocurrents from two pinhole detectors facing an extended thermal source, for different transverse displacements of the two detectors, obtaining an estimate of the magnitude-square of its mutual coherence function at the measurement plane. This allows one to estimate features of the source such as its diameter, or to form an image of its photon-flux density (with some regularity conditions). In this work, we focus on using this technique to identify or image an object that is in the line-of-sight between a well-characterized source and the detectors. We derive the observed perturbation to the intensity correlation map due to the object, showing that under some reasonable approximations it is proportional to the real part of the Fourier transform of the source's photon-flux density times the Fourier transform of the object's intensity absorption. We identify from this signature the key parameters that impact its visibility. We discuss the requirements for estimating object-related parameters, e.g., its size, velocity or shape, as well as the feasibility of reconstructing an image, provided that some knowledge of the source and the propagation geometry is available a priori. We consider an application of this result to determining the orbit inclination of an exo-planet orbiting a distant star. Finally, motivated by the intrinsically weak nature of the signature, we study its signal-to-noise ratio and determine the impact of system parameters.

8875-5, Session 2

Protecting quantum entanglement from amplitude damping *(Invited Paper)*

Zeyang Liao, Texas A&M Univ. (United States); Mohammad Al-Amri, KACST (Saudi Arabia); M. Suhail Zubairy, Texas A&M Univ. (United States)

Quantum entanglement is a critical resource for quantum information and quantum computation. However, entanglement of a quantum system is subjected to change due to the interaction with the environment. One typical result of the interaction is the amplitude damping that usually results in the reduction of the entanglement. Here we propose a protocol to protect quantum entanglement from the amplitude damping by applying Hadamard and CNOT gates. As opposed to some recently studied methods, the scheme presented here does not require weak measurement in the reversal process, leading to a faster recovery of entanglement. We propose a possible experimental implementation based on linear optical system.

8875-6, Session 2

Quantum optical state engineering and continuous variable entanglement enhancement *(Invited Paper)*

Adarsh S. Prasad, Roohollah Ghobadi, Christoph Simon, Aveek Chandra, Univ. of Calgary (Canada); Yury Kurochkin, Alexander I. Lvovsky, Univ. of Calgary (Canada) and Russian Quantum Ctr. (Russian Federation)

The technology of preparation of quantum states is of key importance for applications in quantum information technology, such as quantum communication, metrology and computation. Here we demonstrate two separate experiments relating to quantum state creation and continuous variable quantum state enhancement.

Our first experiments relates to Schrödinger's famous thought experiment involving a (macroscopic) cat whose quantum state becomes entangled with that of a (microscopic) decaying nucleus. Here we demonstrate conclusively for the first time the creation of such micro-macro entanglement in light. The macro system involves over a hundred million photons, while the micro system is at the single-photon level. We show that microscopic differences (in field quadrature measurements) on one side are correlated with macroscopic differences (in the photon number variance) on the other side. We demonstrate entanglement of our state by bringing the macroscopic state back to the single-photon level and performing full quantum state tomography of the final state.

In our second experiment we demonstrate an efficient experimental technique to enhance continuous variable entanglement of a two mode squeezed state. We apply a photon annihilation operator to both modes of a two mode squeezed state generated by a Type –II spontaneous parametric down-conversion. The annihilation operator is implemented using a polarization independent asymmetric beam splitter. Conditioned on simultaneous 'clicks' heralding successful photon annihilation, we employ homodyne tomography to reconstruct the resulting two mode state and verify entanglement distillation.

8875-7, Session 2

Entangled photon generation in a phase-modulated, quasi-phasematched crystal *(Invited Paper)*

Paulina Kuo, Joint Quantum Institute (United States) and National Institute of Standards and Technology (United States); Jason S. Pelc, Hewlett-Packard Labs. (United States); Oliver T. Slattery, Yong-Su Kim, Xiao Tang, National Institute of Standards and Technology (United States)

Polarization-entangled photon pairs can be generated using spontaneous parametric downconversion (SPDC) in type-II, quasi-phasematched crystals. A pair of crystals is often used to generate the |HV? and |VH? states. For this scheme, the temporal distinguishability (or "which crystal" information) must be erased in order to produce the entangled state. This temporal distinguishability can be erased by using a birefringent crystal or Michelson interferometer after the SPDC crystal. The distinguishability can also be removed during the SPDC process if the quasi-phasematching is designed to simultaneously generate the |HV> and |VH> states. We design a phase-modulated periodically poled LiNbO3 crystal for the near-degenerate SPDC process 776 nm --> 1535 nm + 1570 nm. Two type-II processes are simultaneously phasematched: |H776nm> --> |H1535nm V1570nm> and |H776nm> --> |V1535nm H1570nm>. The phase-modulation allows both states to be generated simultaneously in a distributed fashion throughout the nonlinear crystal.

Working near degeneracy makes the downconversion bandwidths nearly matched, which is needed for good entanglement visibility. The photon pair emerge collinearly but can be efficiently separated using a dichroic filter. This polarization-entangled source can be used to demonstrate violation of Bell's inequality or quantum teleportation.

8875-8, Session 3

Breaking the diffraction limit using entanglement based microscopy *(Invited Paper)*

Daniel Schlenk, Ludwig-Maximilians-Univ. München (Germany); Harald Weinfurter, Ludwig-Maximilians-Univ. München (Germany) and Max-Planck-Institut für Quantenoptik (Germany)

The resolution of optical scanning microscopes is limited by the spot size of the scanning beam. It has been proposed by Boto et al. (Rhys. Rev. Lett. 85, 2733) and Nasr et al. (Phys. Rev. A 65, 023816) that momentum entangled photons can be focused more tightly than classical light. We obtain momentum entangled photons pairs from a spontaneous parametric down conversion source in our confocal microscope setup to demonstrate a two-photon spot size below the classical diffraction limit.

Momentum entangled photon pairs at a center wavelength of 812 nm are created in a BBO-crystal cut for type I collinear down conversion which is pumped by a laser diode with a wavelength of 406 nm. An objective with a numerical aperture of NA=1.4 is used to focus the photon pairs. In the confocal setup light reflected from an object is collected with the same objective used for illumination and separated from the incoming light with a 50/50 beam splitter. Two avalanche photodiodes behind a second 50/50 beam splitter detect photons reflected from the object and allow to measure the single and two-photon detection probabilities for reflected photons.

As a test object a single gold stripe deposited on a glass surface is moved through the focused beam to determine the resolution of this microscope. We obtained a two-photon spot size of 194 nm FWHM which is well below the classical diffraction limit of 295 nm for 812 nm photons and even breaks the two-photon spot size limit of 209 nm FWHM.

8875-9, Session 3

Superresolving power quantum microscope using ghost imaging technology *(Invited Paper)*

Sanjit Karmakar, Univ. of Maryland, Baltimore County (United States); Ronald E. Meyers, U.S. Army Research Lab. (United States); Yanhua Shih, Univ. of Maryland, Baltimore County (United States)

Research and development are progressing very rapidly in different areas of biomedical and biosciences. Biomedical imaging is one of these exciting important areas. Super resolving power, non-invasive camera with a feature of not damaging any cell or tissue enables physicians and scientists to see and better understand tissue and organ function. Using two-color ghost imaging technology, we wish to propose a camera capable of achieving very high resolving power, i.e. super resolving power, without any destruction of cells and tissues.

In an experimental configuration of two-color ghost imaging entangled photon pairs with ?s > ?i generated from spontaneous parametric down-conversion (SPDC) reproduce a ghost image with enhanced resolving power by a factor of ?s / ?i by means of higher imaging amplification which is enhanced by a factor of ?s / ?i than that of the one-color ghost imaging as well as the classical imaging set up, where ?s is the wavelength of the radiation that illuminates the object, ?i is the wavelength of idler beam. If one can use ?s (? 500 nm) in the visible region and ?i in the x-ray region (? 1 nm), then resolving power can be improved by a factor of 500.

In case of the one-color ghost imaging as well as the classical case, we can resolve few µm with visible light. The size of human cell and tissue are of the order of µm. This proposed technique can improve the resolving power by a factor of 500 than the usual one-color ghost imaging and the classical case. Also, in this configuration the cell and tissue are illuminated by the visible light instead of x-ray and hence there is no chance of destruction of the cells and tissues.

8875-10, Session 3

Toward sub-wavelength lithography with atomic coherence *(Invited Paper)*

Philip R. Hemmer, Texas A&M Univ. (United States)

There has been much interest in the possibility of using optical or quantum nonlinearities to perform sub-wavelength lithography. Techniques that have been proposed so far include quantum N00N states, Dopplerons, Raman dark states, light shifts (in gradient fields), and Rabi flops. However none of these coherent or quantum techniques have yet demonstrated the ability to expose photoresist with a resolution and aspect ratio better than incoherent techniques like optical donut-beam lithography. But this is a serial step-and-repeat exposure protocol much like e-beam lithography, and hence is not very convenient for exposing large areas. In this talk I will review our current progress in super-resolution optical lithography using the analog to magnetic resonance imaging in two level transitions in solid state hosts. The first system is nitrogen-vacancy (NV) diamond. It has both optical and microwave transitions that are suitable for coherent lithography. In the case of the microwave transitions, room temperature operation is possible. The second system is rare earth doped crystals like Pr doped YAG or YSO. Here there is potential for using a two-photon transition to transfer the optical super-resolution pattern to a UV transition that can more easily expose photo-resist. The relative merits and unsolved problems of these two systems will be discussed.

8875-11, Session 3

Quantum measurements and sensings *(Invited Paper)*

Shigeki Takeuchi, Hokkaido Univ. (Japan)

In this invited talk, we will report our recent progresses on quantum measurements and sending.

Optical phase measurement is a key technology in many kinds of metrology. The accuracy of the measurement for a given light intensity, or the number of photons, is limited by the standard quantum limit. However, recently it has been demonstrated that the standard quantum limit can be beaten by using entangled photons.

In this presentation, we report the first demonstration of an entanglement microscope, which is the differential confocal microscope where an entangled photon pair source is used for illumination. We show that the S/N ratio of the image obtained by the entanglement microscope is 1.35 times better than that limited by the standard quantum limit. This experimental demonstration will open the door for the broad application of entanglement-enhanced metrology from biology to material science.

We will also report other topics on quantum measurements and sensing, including the experimental demonstration of the dispersion-tolerance of the quantum optical coherence tomography in the high resolution regime, and adaptive quantum state estimation of single photon quantum bit, and discuss the advantages of AQSE to currently used quantum state tomography.

8875-12, Session 4

Aqueye Plus: a very fast single photon counter for simultaneous multicolor astronomical photometry equipped with an optical vortex coronagraph *(Invited Paper)*

Cesare Barbieri, Giampiero Naletto, Mirco Zaccariotto, Elettra Mari, Enrico Verroi, Anna Sponselli, Filippo Romanato, Univ. degli Studi di Padova (Italy); Luca Zampieri, INAF - Osservatorio Astronomico di Padova (Italy); Tommaso Occhipinti, Adaptica S.r.l. (Italy)

In recent years we developed two very high speed single photon photometers, Aqueye and Iqueye (Naletto el al. 2009, Barbieri et al. 2012) as prototypes for 'quantum' photometers for the Extremely Large Telescopes of the next decade. The instruments, based on single photon avalanche photodiodes (SPAD) and a 4-fold split-pupil concept, have been successfully used to obtain data of the highest quality on optical pulsars (Gradari et al., 2011, Germana' et al., 2012). Subsequently, we performed an attempt to utilize the Orbital Angular Momentum and associate Optical Vorticity to achieve high performance coronagraphy (Mari et al., 2012). Presently, we are building Aqueye Plus for the 1.8m telescope of the Asiago - Cima Ekar Observatory, a new instrument which combines both functions, namely high speed simultaneous multicolor photometry and coronagraphy. The innovative capability of Aqueye Plus is to take advantage of the two parallel outputs (NIM and TTL) of the four SPADs. The NIM output preserves the best timing capability, the TTL output drives a deformable 32-element mirror in a sort of quadrant detector to correct for defocus, tip/tilt and low order aberrations of the stellar image on the phase mask discontinuity. The concept has been already used for free space quantum communication experiments (Capraro et al., 2012). The phase mask (Massari et et al.,2011) has 512 steps and is tailored to 530 nm wavelength.

The paper will describe the instrument and its first results in the laboratory.

8875-14, Session 4

Phase retrieval near 2 bits/photon using a heralded single-photon source *(Invited Paper)*

Reihaneh Shahrokhshahi, Niranjan Sridhar, Univ. of Virginia (United States); Saikat Guha, Raytheon BBN Technologies (United States); Aaron Miller, Albion College (United States); Adriana Lita, National Institute of Standards and Technology (United States); Brice Calkins, Albion College (United States); Thomas Gerrits, Antia Lamas-Linares, National Institute of Standards and Technology (United States); Jonathan L. Habif, Raytheon BBN Technologies (United States); Sae Woo Nam, National Institute of Standards and Technology (United States); Olivier Pfister, Univ. of Virginia (United States)

We report progress towards information-efficient quantum imaging. We implemented a 4-mode interferometer which uses both polarization and spatial encoding to image Hadamard-encoded phase arrays. This demonstration is a particular case of a generalized M-path interferometer which can yield log_2(M) bits of information with a single measurement of a single photon, the photon being placed in a W state over the different arms of the interferometer.

In the ideal, lossless case, any single-mode, pure-state or mixed quantum input in the interferometer will appear unchanged at either one of the 4 output ports, depending on the Hadamard phase codeword in the interferometer (which is a combination of 0 and pi phase shifts). The Photon Information Efficiency (PIE) is then log_2(4)/< N>, where < N> is the average photon number.

For an arbitrary quantum state with rho=sum_n p_n |n>< n|, PIE=log_2(4)/(sum_n n p_n).

The photon-number-resolving ability of transition edge sensors thus allowed us to directly measure p_1 and p_2 and to evaluate the PIE. A maximum PIE of 2 bits per photon (bpp) for the above mentioned interferometer can be achieved by preparing a perfectly heralded single photon source, with < N>=1 and g^(2)(0)=0, as input of the interferometer.

In our experiment, we achieved the construction of a highly quantum heralded single photon source with g^(2)(0) =0.03 and achieved PIE=1.97 bpp, with a non-zero probability of error. Currently efforts are underway to reduce losses and increase the heralding ratio of the single photon source to decrease the error.

8875-16, Session 4

BEC expansion and interferometry in microgravity *(Invited Paper)*

Vincenzo Tamma, Wolfgang Zeller, Albert Roura, Wolfgang P. Schleich, Univ. Ulm (Germany)

Interferometry with expanding BEC in microgravity can be exploited to probe fundamental physics at the border between quantum mechanics and general relativity. In particular, by using an asymmetric Mach-Zehender configuration interference fringes for expanding BEC in microgravity have been recently observed in pioneering QUANTUS experiments [1].

We describe the physics behind the BEC expansion and interference in microgravity in the time-dependent Thomas-Fermi (TF) regime [2,3] in generic interferometric configurations. We provide physical insight into the validity of the TF approximation depending on the experimental conditions. Moreover, we demonstrate how first order perturbation theory leads to space-dependent corrections to the BEC fringe spacing which may be fundamentally important in future metrology experiments.

The QUANTUS project is supported by the German Space Agency DLR with funds provided by the Federal Ministry of Economics and Technology (BMWi) under grant number 50WM1136.

8875-17, Session 5

Some recent progresses in quantum tomography realised at INRIM *(Invited Paper)*

Marco Genovese, Istituto Nazionale di Ricerca Metrologica (Italy); Ivo P. Degiovanni, Istituto Elettrotecnico Nazionale Galileo Ferraris (Italy); Marco Genovese, Marco Gramegna, Fabrizio Piacentini, Ivano Ruo Berchera, Istituto Nazionale di Ricerca Metrologica (Italy)

The rapid development of quantum systems has enabled a wide range of novel and innovative technologies, from quantum information processing to quantum metrology and imaging, mainly based on optical systems.

Precise characterization techniques of quantum resources, i.e. states, operations and detectors play a critical role in development of such technologies.

In this talk, after a short summary of our past works in the field (as on-off reconstruction), we will present few recent experiments related to quantum tomography related to photon number resolving (PNR) detectors realised at INRIM: three addressed to reconstruct the POVM of PNR detectors, one considering a simple method for reconstructing mode occupation.

In the first case [1] we will discuss the reconstruction of a TES POVM based on the use of a quorum of coherent states.

In the second case [2] we present the first experimental characterization of quantum properties of an unknown PNR detector, a detector tree, that takes advantage of a quantum resource, i.e. an ancillary state. This quantum-assisted reconstruction method requires no prior information about the detector under test, and its convergence is more stable and faster to reach a final result. This is achieved by exploiting strong quantum correlations of twin beams generated in a parametric down conversion process: one beam is characterized by a quantum tomographer, while the other is used to calibrate the unknown detector.

Then, we will discuss the experimental realisation a self consistent quantum tomography of a PNR detector POVM and its application [3].

Finally, we present a work where we experimentally demonstrate the reconstruction of the mode structure of several quantum optical fields by exploiting a PNR detector.

Protecting entanglement from decoherence using weak measurement and quantum measurement reversal *(Invited Paper)*

Yong-Su Kim, Jong-Chan Lee, Osung Kwon, Yoon-Ho Kim, Pohang Univ. of Science and Technology (Korea, Republic of)

Decoherence, which causes degradation of entanglement and in some cases entanglement sudden death, is a critical problem in quantum information. Protecting entanglement from decoherence, therefore, is essential in practical realization of quantum computing and quantum communication protocols. In this talk, I will describe our recent work on protecting entanglement from amplitude damping decoherence via weak measurement and quantum measurement reversal.

8875-20, Session 5

Anomalous g2 values *(Invited Paper)*

Ron Folman, Ben-Gurion Univ. of the Negev (Israel)

g2 is perhaps one of the most calculated and measured observable in quantum optics. It has given rise to numerous insights. Here we calculate the value of g2 (in the time domain) under new experimental conditions and find an anomalous behavior of this observable.

8875-21, Session 6

The role of quantum memory in quantum information processing *(Invited Paper)*

Kae Nemoto, Ashley M Stephens, National Institute of Informatics (Japan); Keith A Harrison, National Institute of Informatics (Japan) and Kismet Institute (United Kingdom); William J Munro, National Institute of Informatics (Japan) and NTT Basic Research Laboratories (Japan)

Until recently, it had been believed that long-lived quantum memory was necessary for long-distance quantum communications. Using error correction codes in an efficient way against photon loss, it is possible to transmit quantum information over a long distance without quantum memories. For quantum computation, the recent architectures of topological quantum computation indicate that the simplest structure could be memory-less.

A quantum memory is no longer an essential resource for quantum networks, however as it is in our current computer, it nonetheless could be a key device in the development of quantum information technology. It is still not clear what functional device could bring what benefits to our quantum informational systems. This is largely due to the lack of detailed models for quantum information systems.

Recently we have developed a detailed model for quantum network from a device design for building blocks to the system architecture. The device is based on optical cavity with an NV diamond center. This model naturally integrates quantum communication to computation most suitable for quantum communication, and using this model, we can discuss the cost of quantum memory effect in the processes. With or without quantum memory, it is necessary for us to be able to preserve quantum information for a long period of time in either communication or computation. The function of quantum memory can be then assessed quantitatively.

8875-22, Session 6

Verification of light shift blockade via collective state Raman-Rabi oscillations for ensemble based quantum computing *(Invited Paper)*

Selim M. Shahriar, May Kim, Yanfei Tu, Resham Sarkar, Northwestern Univ. (United States)

Recently, we have been exploring the feasibility of realizing a quantum computer using ensembles of atoms as deterministic qubits. In contrast with single atom quantum bits, this process has the potential advantage of a very high vacuum Rabi frequency, thus enabling the use of a large cavity that can accommodate many qubits held by dipole force traps. A key requirement for this process is the so-called light-shift imbalanced induced blockade (LIB), which restricts higher order transitions in the collective excitation of an ensemble of atoms so that the ensemble behaves effectively as a single atom. Here, we present a technique for demonstrating LIB using Raman-Rabi oscillations in a lambda system, via coincidence detection in a Hanbury-Brown-Twiss setup. We will describe results of numerical simulations, and present details of our experimental efforts towards this demonstration.

8875-23, Session 6

A hybrid quantum system of atoms trapped on ultrathin optical fibers coupled to superconductors *(Invited Paper)*

Steven Rolston, Jeff Grover, Univ. of Maryland, College Park (United States); Jonathan Hoffman, Joint Quantum Institute (United States); Sylvain Ravets, Kristen Voigt, Jongmin Lee, Jared Hertzberg, J. R. Anderson, Luis Orozco, Fred Wellstood, Chris Lobb, Univ. of Maryland, College Park (United States)

We are developing a system using atoms trapped in the evanescent field of ultrathin optical fibers to magnetically couple to a superconducting (SC) circuit containing a SC qubit. This hybrid system can utilize the speed of the SC device, and long coherence time of the atoms. It provides coupling to photons through the fiber mode. While developing a system compatible with a cryogenic environment, we have produced tapered fibers with >99.9% transmission, and propagated higher order modes with >95% transmission. We will discuss progress and opportunities associated with the strong photon-atom coupling of these ultrathin fibers,

8875-24, Session 6

Photonic quantum computing *(Invited Paper)*

Jeremy L. O'Brien, Univ. of Bristol (United Kingdom)

Quantum information science aims to harness uniquely quantum mechanical properties to enhance measurement, information and communication technologies, as well as to explore fundamental aspects of quantum physics. Of the various approaches to quantum computing [1], photons are particularly appealing for their low-noise properties and ease of manipulation at the single qubit level [2], which also makes them appealing for other quantum technologies [3–5]. We have developed an integrated waveguide approach to photonic quantum circuits for high performance, miniaturization and scalability [6–10]. We have begun to address the challenges of scaling up quantum circuits using new insights into how controlled operations can be efficiently realised [11], and demonstrated Shor's algorithm with consecutive CNOT gates [12] and the iterative phase estimation algorithm [13]. We have shown how quantum circuits can be reconfigured, using thermo-optic phase shifters to realise a highly reconfigurable quantum circuit able to perform almost any function on two photonic qubits [14], and electro-optic phase shifters in lithium niobate to rapidly manipulate the path and polarisation of telecomm wavelength single photons [15]. We have addressed miniaturisation using multimode interference coupler architectures to directly implement NxN Hadamard operations and the 'Boson sampling problem' [16], and by using high refractive index contrast materials such as SiOxNy, in which we have implemented quantum walks of correlated photons [17], and Si [18], in which we have demonstrated generation of orbital angular momentum states of light [19]. We have begun to address the integration of superconducting single photon detectors [20] and diamond [21,22] and non-linear [23–25] single photon sources. Finally, we give an overview of recent work on fundamental aspects of quantum measurement, including a quantum version of Wheeler's delayed choice experiment [26].

8875-25, Session 7

Which-way experiment with internal degrees of freedom *(Invited Paper)*

Konrad Banaszek, Univ. of Warsaw (Poland); Pawel Horodecki, Gdansk Univ. of Technology (Poland); Micha? Karpi?ski, Czes?aw Radzewicz, Univ. of Warsaw (Poland)

We present an inequality relating visibility and which-way information for a particle equipped with an internal degree of freedom travelling through a Mach-Zehnder interferometer. The inequality paints an unexpectedly intricate picture of wave-particle duality in the general case. Strikingly, in some instances which-way information becomes erased by introducing classical uncertainty in the internal degree of freedom. Furthermore, even imperfect interference visibility measured for a suitable set of inputs can be sufficient to infer absence of which-way information.

8875-26, Session 7

Sub-shot noise measurements with an acousto-optic modulator *(Invited Paper)*

Jason P. Simon, Yanhua Shih, Univ. of Maryland, Baltimore County (United States)

The need for high precision measurements continues to increase at an incredible pace. It is a problem in all areas of research, from communication to sensing, etc. The solution is ultimately rooted in understanding and overcoming the shot noise limit. One method of doing so is by tailoring the quantum fluctuations of a light beam so the fluctuations in the observable of interest are "squeezed", the so called squeezed states of light. Both theoretically and experimentally, nonlinear interactions have been extremely successful in generating squeezed states with squeezing well below the shot noise limit. Yet, we continue to seek after a solution to the shot noise problem.

We wish to discuss an experiment that uses an acousto-optic modulator(AOM) to over- come the shot noise limit. As is well known, the AOM can be used as a beam deflector and a frequency shifter. By orienting the AOM in a specific way, we generate two output beams, such that their frequencies and phases sum to the pump frequency and phase respectively. Furthermore, we can properly say that the output beams are correlated due to this inter- action. Then by using a dual heterodyne detection scheme, one for each output field, and measuring only the difference current from each detector, we can reproduce the squeezing effect, that so commonly defines a squeezed state. This source is useful because it relies only on a non-linear-like interaction with a strength that depends on the power of the acoustic field in the modulator.

8875-27, Session 7

Effect of decoherence in quantum reading with phase shift keying signal of entangled coherent states *(Invited Paper)*

Kentaro Kato, Osamu Hirota, Tamagawa Univ. (Japan)

Quantum reading of a classical digital memory, which was originally proposed by Pirandola, is one of attractive topics for both practical and theoretical aspects of quantum detection theory. For this problem?a quantum reading model of purely phase-encoded classical digital memory has been proposed by one of the authors and it has been shown that error-free discrimination is possible in this model under the situation that there is no channel loss. Particularly, the model employs a quasi-bell state of entangled coherent states as a probe state. Here a natural question arises: where is the error-free limit of discrimination between phase shift keying signals that is generated from an entangled coherent state when there is channel loss or other disturbance? Therefore the aim of this paper is to investigate the effect of decoherence in such a quantum reading model with phase shift keying signal of entangled coherent states. To illustrate the effect, analysis and simulations of the model will be done by using the quantum minimax strategy in quantum signal detection theory.

8875-28, Session 8

A quantum network with atoms and photons II *(Invited Paper)*

Ronald E. Meyers, U.S. Army Research Lab. (United States)

No Abstract Available

8875-29, Session 8

Software-defined quantum communication *(Invited Paper)*

Travis S. Humble, Oak Ridge National Lab. (United States)

We formalize software-defined quantum communication (SDQC) framework by considering a quantum transmitter (TX) and quantum receiver (RX). A functional decomposition of each terminal separates development concerns with respect to the hardware physics, the software protocol, and a middleware that mitigates between the other two domains. Similar decompositions can be applied to previously developed QC systems, however, our objective is to show how to identify these domains at an abstract level and develop them into concrete realizations, i.e., a top-down approach to SDQC design.

We consider a representation of the SDQC framework in which the TX hardware layer is expressed as a quantum light source for preparing quantum states and accessing the quantum channel, the middleware is represented as a hardware device driver, and the software layer is represented by a general purpose processor running user-defined

software. The classical channel is assumed to be a local area network while the quantum channel is represented by some quantum optical modes.

We further demonstrate this framework using the implementation of an entanglement distribution system. The purpose of the system is to distribute entangled qubits between the TX and RX and to validate the presence of the transmitted entanglement. In this implementation, the TX and RX monitor the visibility of the measured correlations as a form of channel diagnostic by sharing metadata over a LAN. We identify that layers within this example and give concrete description of their implementations.

8875-30, Session 8

Implementation of an m-ary three-stage quantum cryptography protocol

Mayssaa El Rifai, Nikhil V. Punekar, Pramode K. Verma, The Univ. of Oklahoma - Tulsa (United States)

This paper introduces an m-ary version of the Three-stage Quantum Cryptography protocol. The three-stage protocol was first proposed in 2006 and implemented in 2012. The three-stage protocol is a multi-photon tolerant protocol that does not require a classical channel. It uses unitary transformations known only to the sender and the receiver. Furthermore, these unitary transformations can be independently and simultaneously changed by the communicating parties. The three-stage protocol is not susceptible to the photon number splitting attacks, thus it is not subject to the requirement of no more than one photon per pulse as the BB'84 is. A recent paper discussed its implementation as a multi-photon tolerant protocol along with its security issues and proposed some security measures that should be taken. The m-ary version of the three-stage protocol presented in this paper results in enhanced data transfer rate between Alice and Bob, since each pulse carries more than one bit of information. An experimental realization of the m-ary three-stage protocol is also reported in this paper. The implementation has used free-space optics as the transmission medium and passive optical components controlled through LabView. Furthermore, analytical results that address the impact of the noise factor and its trade-off with data rate are presented. This analysis includes a study of the probability of errors and channel capacity variations in terms of the noise variance factor for the m-ary three-stage protocol using two, four and eight levels. Limits within which the m-ary three-stage protocol can be used with higher performance efficiency compared to its original version counterpart are set.

8875-31, Session 8

Hybridization of superconducting flux qubits and diamond ensembles: a route to local gates for quantum repeaters *(Invited Paper)*

William J. Munro, Xiaobo Zhu, Yuichiro Matsuzaki, NTT Basic Research Labs. (Japan); Ashley M Stephens, Kae Nemoto, National Institute of Informatics (Japan); Shiro Saito, NTT Basic Research Labs. (Japan)

Quantum mechanics was one of the most important discoveries of the twentieth century. It is a set of principles describing physical reality at the atomic level of matter and allows for radially new ways to transmit, store and process information. Quantum communication is now regarded as a primitive necessary for any future quantum internet, regardless of whether such communication is over distances of centimeters or thousands of kilometers. Over the last decade there has been a considerable worldwide effort to develop quantum repeaters – a device that allows one to extend the range in which quantum information can be transmitted. There has been a significant effort to investigate and demonstrate the fundamental building blocks necessary for such repeaters to the extent that entanglement distribution over tens of kilometers is now relatively routine. However to extend the range further we need entanglement swapping – which require local two qubits. Such gates have proved challenging and are now seen a significant performance bottleneck. Hence we need to find mechanisms to efficiently perform such gates. It is well known that superconducting flux qubits have excellent processing ability while electron-spin nitrogen-vacancy centers in diamond are a natural memory and optical interface. Hybridization of these two systems thus presents the promise of an effective and efficient way to perform such local gates. Here we report on the realization of quantum memory operations between these hybrid systems as well as the realization of quantum memory operations. This is a first step towards superconducting based gates for quantum repeaters.

8876-1, Session 1

The James Webb Space Telescope *(Invited Paper)*

Mark Clampin, NASA Goddard Space Flight Ctr. (United States)

The James Webb Space Telescope (JWST) is a large aperture (6.5 meter), cryogenic space telescope with a suite of near and mid-infrared instruments covering the wavelength range of 0.6 ?m to 28 ?m. JWST's primary science goal is to detect and characterize the first galaxies. It will also study the assembly of galaxies, star formation, and the formation of evolution of planetary systems. JWST is a segmented mirror telescope operating at ~40K, a temperature achieved by passive cooling of the observatory, via a large, 5-layer membrane-based sunshield. We present an overview of the observatory systems design, the science instruments and the mission science objectives. We will report on recent highlights such as the completion of all the mirrors in JWST optical chain, and delivery of the first two science instruments. We will also review the predicted performance of the JWST observatory, based on initial measurements of the telescope optics and instrumentation.

8876-2, Session 1

Ultrafast laser inscribed 3D integrated photonics *(Invited Paper)*

Simon Gross, Alexander Arriola, Guido Palmer, Nemanja Jovanovic, Izabela Spaleniak, Thomas D. Meany, Yuwen Duan, Qiang Liu, Peter Dekker, Macquarie Univ. (Australia); David G. Lancaster, Heike Ebendorff-Heidepriem, The Univ. of Adelaide (Australia); Alexander Fuerbach, Michael Ireland, Michael J. Steel, Michael J. Withford, Macquarie Univ. (Australia)

Since the discovery in 1996, that a tightly focused femtosecond laser beam can induce a highly localized and permanent refractive index change in bulk dielectrics, ultrafast laser inscription has found applications in a diverse range of fields. This highly localized index change is a result of nonlinear photoionization, which can be triggered in virtually any dielectric ranging from glasses to crystals and by simply moving the substrate through the focused femtosecond laser beam, 3 dimensional photonic circuits can be sculpted. The fact that these circuits are embedded within the bulk results in an inherent environmental robustness against vibrations and temperature variations. Furthermore, they can offer a high level of integration and as such can be compact and lightweight.

A crucial requirement for ultrafast laser inscription is the deeper understanding of the structural modifications that result in the refractive index change within the sample. This not only enables the appropriate choice of glass and the optimization of the fabrication parameters in order to improve the device performance but it also allows for engineering materials to tailor their properties for ultrafast laser inscription.

In this presentation we will review our current understanding of ultrafast laser – glass lattice interactions, with a particular focus on ZBLAN, phosphate and silicate glasses. We will present the application of these insights to the fabrication of various devices such as compact waveguide lasers with emission covering the near to the mid-infrared, as well as 3 dimensional integrated photonic circuits for astronomical applications.

8876-4, Session 1

Influence of hydrogenation on electrical conduction in HGCDTE thin films on silicon

Stephen Fahey, EPIR Technologies, Inc. (United States) and Air Force Research Lab. (United States); Paul Boieriu, EPIR Technologies, Inc. (United States); Christian P. Morath, Dustin Guidry, Laura Treider, Air Force Research Lab. (United States); Ramana Bommena, Jun Zhao, Sivalingam Sivananthan, EPIR Technologies, Inc. (United States)

HgCdTe is the standard state of the art infrared detector material for space applications. It is known that such HgCdTe detector performance can be lower in the presence of bulk crystal defects and dangling bonds at surfaces or interfaces. Passivation of such bulk defects and surfaces can potentially improve detector performance by saturating dangling bonds in dislocation cores, and at surfaces. Indeed, results showing improvement of HgCdTe current-voltage characteristics after hydrogenation have been published. Here we use multiple-carrier fitting of Hall effect data, acquired at variable magnetic field strengths and sample temperatures, to investigate the physical influence of hydrogenation, as a passivation procedure, on HgCdTe crystalline thin films on Si(211) substrates. We observe the following: (1) evidence of multiple active electrical carriers in all samples, (2) evidence of 2-dimensional electrical conduction before and after hydrogenation, and (3) changes in carrier concentration and mobility induced by hydrogenation.

8876-5, Session 2

Ionizing radiation effects on high operating temperature, broadband visible/infrared HGCDTE photodetectors *(Invited Paper)*

Silviu Velicu, Ramana Bommena, EPIR Technologies, Inc. (United States); Vince M. Cowan, Christian P. Morath, Air Force Research Lab. (United States); Stephen Fahey, EPIR Technologies, Inc. (United States)

Systems that gather data in separate spectral bands can determine both absolute temperatures and unique signatures of objects in the field of view. By providing this new dimension of contrast, broadband multicolor detection enables advanced color-processing algorithms that improve sensitivity beyond that of narrower band single-color devices. We present here our progress on the development of high-performance, two-color focal plane arrays that allow the simultaneous detection of radiation in the visible and infrared bands. The first band cover the 400 nm to 4 ?m wavelength range and is based on standard double-layer planar heterostructures technology. The backside-illuminated array has the substrate removed to allow for visible detection. The second color covers the 4-11 ?m wavelength range and is based on an Auger-suppressed architecture. This architecture allow for dark currents similar to the ones observed in the first color (400 nm - 4 ?m). Our detector architecture is grown using Molecular Beam Epitaxy (MBE) technique. MBE is the method of choice for multiple-layer HgCdTe growth because it produces material of excellent quality and allows composition and doping control at the atomic level. Such quality and control is necessary for the fabrication of multicolor detectors since they require advanced bandgap engineering techniques. State of the art performances over the full wavelength range were demonstrated. We will report on the optical and electrical characteristics of the two-color broadband elements before and after they are subjected to 63 MeV protons producing a total ionizing dose of 100 kRads (Si).

8876-6, Session 2

Proton radiation effects on the photoluminescence of infrared INAS/INASSB superlattices *(Invited Paper)*

Elizabeth H. Steenbergen, Air Force Research Lab. (United States); Zhiyuan Lin, Arizona State Univ. (United States); Vincent M. Cowan, Jeremy A. Massengale, Air Force Research Lab. (United States); Yong-Hang Zhang, Arizona State Univ. (United States); Christian P. Morath, Air Force Research Lab. (United States)

Infrared detector arrays operating in space must be able to withstand defect-inducing proton radiation without performance degradation. Therefore, it is imperative that the proton-radiation hardness of infrared detector materials be investigated. Photoluminescence (PL) is sensitive to electrically-active defects in materials, and thus can be used to quantify the effects of proton-radiation-induced defects. The temperature-dependent and intensity-dependent PL of a set of InAs/InAsSb superlattices (SLs) is examined before and after 63-MeV-proton irradiation. Two different proton doses, 50 kRad(Si) and 100 kRad(Si), were applied to two different pieces of each SL. The low temperature (5 K) peak positions of the irradiated samples varied in energy by only 1% from the non-irradiated sample. The exponent of the power law fit of the integrated intensity versus the input intensity changed by less than 10% for the irradiated samples, indicating negligible change in the recombination mechanism and defect density after irradiation. These results suggest InAs/InAsSb SLs may be suitable for space infrared detector arrays.

8876-7, Session 2

Radiation tolerance of type-II strained layer superlattice based interband cascade MWIR detector *(Invited Paper)*

Vincent M. Cowan, Christian P. Morath, Air Force Research Lab. (United States); Stephen Myers, Nutan Gautam, Ctr. for High Technology Materials (United States); Sanjay Krishna, The Univ. of New Mexico (United States)

Infrared (IR) detectors operated in the space environment are required to have high performance while being subjected to a variety of radiation effects. Sources of radiation in space include the trapped particles in the Van Allen belts and transient events such as solar events and galactic cosmic rays. Mercury cadmium telluride (MCT)–based IR detectors are often used in space applications because they have high performance and are generally relatively tolerant of the space environment when passivated with CdTe; often, the readout-integrated circuit is far more susceptible to radiation effects than the detector materials themselves. However, inherent manufacturing issues with the growth of MCT have led to interest in alternative detector technologies including type-II strained-layer superlattice (T2SLS) infrared detectors employing interband cascade architectures. Much less is known about the radiation tolerance properties of these SLS-based detectors compared to MCT. Here, the effects of 63 MeV protons on variable area, single element, InAs/GaSb SLS detectors utilizing an interband cascade architecture are considered. The device employs a seven-stage cascade region, each stage containing a MWIR absorber, graded T2SLS transport region, and an interband tunneling region. When semiconductors devices are irradiated with protons with energies of 63 MeV the protons are capable of displacing atoms within their crystalline lattice. The radiation effects on these detectors are characterized by dark current and quantum efficiency as a function of total ionizing dose (TID) or, equivalently, the incident proton fluence.

8876-8, Session 2

Noise measurements of an interband cascade MWIR detector in a radiation environment

Laura Treider, Christian P. Morath, Vince M. Cowan, Air Force Research Lab. (United States); Sanjay Krishna, The Univ. of New Mexico (United States)

Infrared (IR) detectors operated in the space environment are required to have high performance, while being subjected to a variety of radiation effects. Sources of radiation in space include the trapped particles in the Van Allen belts and transient events such as solar events and galactic cosmic rays. Mercury cadmium telluride (MCT)–based IR detectors are often used in space applications due to high performance and their being relatively tolerant of the space environment when passivated with CdTe. However, inherent manufacturing issues with MCT growth has led to interest in alternative detector technologies including type-II strained-layer superlattice (T2SLS) infrared detectors employing interband cascade architectures. Much less is known about the radiation tolerance of these III-V based detectors compared to MCT. Here, the effects of 63 MeV protons on InAs/GaSb SLS detectors utilizing an interband cascade architecture are considered. In this report, measurements of the noise current spectral density pre and post irradiation with 63 MeV protons producing a total ionizing dose of 100 kRad (Si) of the mid-wave infrared cascade detectors are presented. Noise is measured using an isolated system incorporating a battery-powered transimpedance amplifier incorporating a dewar-mounted feedback resistor RF and source-follower MOSFET, both held at 77 K. This configuration confines high detector impedance interfacing issues to the dewar, minimizes Johnson noise due to the feedback resistor, and enhances bandwidth by reducing stray capacitance. Features of the detector's noise spectrums at different bias and temperatures are examined.

8876-101,

DE-STAR: A Planetary Defense and Exploration System

Philip Lubin, Univ. of California, Santa Barbara (United States); Gary B. Hughes, California Polytechnic State Univ., San Luis Obispo (United States); Johanna Bible, Jesse Bublitz, Joshua Arriola, Caio Motta, Univ. of California, Santa Barbara (United States)

We propose an orbital planetary defense system capable of heating the surface of potentially hazardous objects to the evaporation point as a futuristic but feasible approach to impact risk mitigation. We call the system DE-STAR for Directed Energy Solar Targeting of Asteroids and exploRation. DE-STAR is a modular phased array of lasers powered by the sun. Modular design allows for incremental development, test, and initial deployment, lowering cost, minimizing risk, and allowing for technological co-development, leading eventually to an orbiting structure that could be erected in stages. The main objective of DE-STAR would be to use the focused directed energy to raise the surface spot temperature to <3000K, allowing direct evaporation of all known substances. The same system will heat the surface of an asteroid and eject evaporated material, which would create a large reaction force to alter the asteroid's orbit. Our baseline system is a DE-STAR 4 (10-km-sized array) system, which allows for asteroid engagement starting beyond 1 AU with a spot temperature sufficient to evaporate all known materials. Such a system can directly evaporate up to 500-m diameter asteroids in one year. Smaller asteroids, such as DA-14, could be completely evaporated in a few hours and the recent Chelyabinsk asteroid in less than one hour. The same system will also produce a reaction thrust comparable to the Shuttle SRB on the asteroid due to mass ejection and thus allow for orbital diversion of even larger asteroids, beyond several km in diameter. Smaller systems are also extremely useful. For example, a DE-STAR 2 (100-m size array) would be capable of diverting volatile-laden objects 100 m in diameter by initiating engagement at ~0.01-0.5 AU. Smaller objects could be diverted on shorter notice. The phased array

configuration is capable of creating multiple beams, so a single DE-STAR of sufficient size could engage several threats simultaneously, such as a Shoemaker-Levy 9 scenario on Earth. An orbiting DE-STAR would also be capable a wide variety of other functions. Narrow bandwidth and precision beam control would aid narrow search and ephemeris refinement of objects identified with wide-field surveys. Propulsion of kinetic or nuclear tipped asteroid interceptors or other interplanetary spacecraft is possible using a “photon rail gun” mode from direct photon pressure on a spacecraft propelling a 100-kg craft to 1 AU in 3 days and a 10,000-kg craft to 1 AU in 30 days. A DE-STAR could also provide power to ion propulsion systems, providing both a means of acceleration on the outbound leg, and deceleration for orbit insertion by rotating the spacecraft and using mirrors to divert the DE-STAR beam into the ion generation cavity. Vaporization and de-orbiting of debris in Earth orbit could be accomplished with a DE-STAR 1 or 2 system. DE-STAR 3 and 4 arrays may allow standoff interrogation of asteroid composition by observing absorption lines in the blackbody spectrum of a vaporizing surface spot. There are a number of other applications as well, including SPS. Multi-function capability aids in justifying such a system.

8876-9, Session 3

Post-flight test results of seed laser module subjected to space exposure *(Invited Paper)*

Narasimha S. Prasad, NASA Langley Research Ctr. (United States)

In this paper, the results of performance testing of a laser diode module sent by NASA Langley Research Center on MISSE 7 mission will be discussed. The objective of the Materials International Space Station Experiment (MISSE) is to study the performance of novel materials when subjected to the synergistic effects of the harsh space environment for several months. MISSE missions provide an opportunity for developing space qualifiable materials. This laser module was a part of lidar component package on the MISSE 7 box that was transported to the international space station (ISS) via STS 129 and returned to the Earth via STS 134. The STS 129 mission was launched on Nov 16, 2009 and the MISSE 7 package was brought back to the earth via the STS 134 that landed on June 1, 2011. This package that was in space environment for more than one and a half year included fiber laser, solid-state laser gain materials, coherent receiver, and semiconductor laser diode. The post-flight testing of several MISSE 7 materials that were recently returned back after more than one year of exposure on the International Space Station (ISS) is underway. This paper will present the comparison of pre-flight and post-flight performance curves and discuss the effect of space exposure on the laser diode module.

8876-10, Session 3

Photonics on the mission to Mars *(Invited Paper)*

Michael D. Watson, NASA Marshall Space Flight Ctr. (United States)

Human missions to Mars present some unique challenges for photonics devices. These devices will have exposure to many different space environments. During assembly they will be exposed to the earth orbiting environment. Upon departure they will need to function through the Earth’s Van Allen Radiation Belt. While the general interplanetary environment is less challenging than the radiation belt, they will operate in this environment for 18 months, subject to sudden saturation from solar flares. These components must continue to function properly through these saturation events presenting quite a challenge to photonic components, both optical and electronic. At Mars, the orbital environment is more benign than the Earth’s. Components used as part of the landing vehicles must also deal with the pervasive dust environment for 3 – 6 months. These assembly and mission execution environments provide every form of space environmental challenges to photonic components. This paper will briefly discuss each environment and the expectations on the components for successful operation over the life of the mission.

8876-11, Session 3

Fiber laser systems for space lasercom and remote sensing *(Invited Paper)*

Shantanu Gupta, Fibertek, Inc. (United States)

Space based laser remote-sensing for Earth observation or planetary atmospheres has traditionally relied on the mature component technologies of diode-pumped solid-state lasers and nonlinear frequency conversion. We highlight a few representative examples, including ongoing space mission programs at Fibertek: ICESat-2 and Cloud Aerosol Transmitter for ISS platform. Key design issues are highlighted, as well as the lessons learned from a multi-disciplinary design process and space-qualification requirements.

Fiber laser/amplifier systems coupled with the use of high-performance single-photon detectors provides a waveform-agile platform for various space based laser applications, such as space lasercom, space-based Earth (or planetary) remote sensing, and space-based imaging. In particular we discuss ongoing efforts at Fibertek on a space-qualifiable, high-performance multi-rate pulse-position modulated 1.5-um Er-doped fiber laser transmitter, for inter-planetary lasercom. Design, performance and qualification issues are discussed, along with recent results on its performance characteristics and ongoing qualification. In addition, high-speed electronics design and related qualification issues are also highlighted. As an example of a waveform-agile laser platform, adaptation of above hardware platform for space based sensing of atmospheric CO2 is also highlighted. As another parallel example, we also compare it to ongoing work on the development of 1-um Yb-fiber laser transmitters for space application.

8876-12, Session 3

A low-power and high-precision miniaturized digital sun sensor

Bart M. de Boer, Murat Durkut, TNO (Netherlands)

At TNO, a prototype of a low-power and high-precision miniaturized digital sun sensor (miniDSS) was developed, which is expected to be launched on QuadSat mid 2013 for in-orbit demonstration. The miniDSS provides a cost-effective, miniaturized an low-power alternative to conventional sun sensors, while maintaining comparably high accuracy.

The 5x5 mm2 application-specific integrated circuit (ASIC), which forms the core of the sun sensor, comprises a 2D active pixel array, read-out circuitry, the sun centroid algorithm and input/output functionality.

The sensor was optimized for low power consumption and consumes only 65 mW. This is roughly a factor 15 lower than found in conventional high-precision digital sun sensors. At dimensions of 69x52x14 mm3 and a weight of only 72 grams, the miniDSS has achieved an extreme reduction in both volume and weight as compared to conventional devices, i.e. roughly a factor 10 and 5, respectively.

Although the miniDSS is a miniaturized low-power device, the performance is state-of-the-art. The resolution is better than 0.007°, the noise equivalent angle was found to be 0.01° (3?) and the uncalibrated accuracy is, in the order of a few hundreds of a degree, across the field of view (FOV) of 102°x102°. Using correction based on ground calibration data, the residual errors can most likely be even further reduced.

In this presentation the innovative architectural design will be discussed, as well as the results of performance tests conducted in our laboratory sun simulator set-up. Finally, an outlook to future developments will be presented.

8876-13, Session 4

Interband cascade lasers: rapidly maturing mid-infrared sources *(Invited Paper)*

Chul Soo Kim, Joshua Abell, William W. Bewley, Charles D. Merritt, Chadwick L. Canedy, Igor Vurgaftman, Jerry R. Meyer, U.S. Naval Research Lab. (United States); Mijin Kim, Sotera Defense Solutions (United States)

Interband cascade lasers (ICLs) with maximum cw operating temperatures as high as 118ºC are extremely promising sources for the 3-6 um spectral range. This talk will review the current status of midwave infrared ICLs, along with future directions for improving their performance. One of the ICL's defining characteristics is its very low threshold drive power required to operate at ambient temperature, with values as low as 29 mW by comparison to nearly 1 W for state-of-the-art quantum cascade lasers (QCLs) emitting in the same spectral region. Approximately 200 mW of cw output power has been generated into a nearly-diffraction-limited output beam at room temperature, and the brightness was further improved by broadening the ridge and incorporating corrugations into the ridge sidewalls to suppress multimode lasing. In this manner, nearly 300 mW of cw output power was produced with M2 = 2.2. Short-cavity (0.5-mm-long) devices fabricated from the same wafer achieved a room-temperature wall-plug efficiency of nearly 15%, which approaches the QCL record. We have also demonstrated distributed-feedback (DFB) ICLs with single-spectral-mode emission at 3.7-3.8 um. One DFB ridge provided single-mode emission from 20ºC to 75ºC, with a maximum tuning range of 21.5 nm at the fixed current of 130 mA. The maximum current-tuning range at fixed temperature was 10 nm at 60ºC. The side-mode suppression ratio was estimated to exceed 30 dB. The maximum single-mode output for a device with HR/anti-reflection (AR) coatings was 27 mW at 40ºC.

8876-14, Session 4

Quantum cascade lasers for aerospace applications *(Invited Paper)*

Igor Trofimov, AKELA Laser Corp. (United States)

After almost two decades since their first demonstration, Quantum Cascade lasers (QCLs) have come of age. High-power continuous wave, as well as narrow linewidth DFB QCLs operating at room temperature are now available over the 4-12?m wavelength region. They have not only demonstrated multi-Watt output power, but also achieved high wall plug efficiency (WPE > 20% at room temperature). QCLs are thus poised to replace currently used laser sources such as CO and CO2 lasers and optical parametric oscillators (OPO) in many applications, and made all but obsolete lead salt diode lasers in mid-IR spectroscopy. The advances in QCLs have opened a wide realm of opportunities for applications of these lasers in defense and security, particularly in the air and space-borne systems.

This paper reviews the advances in QCL technology and its military and civilian applications including environmental monitoring, detection of chemical and biological warfare, infrared countermeasures, etc. It will also discuss issues of QCL reliability that are pertinent to aerospace missions.

8876-15, Session 4

Thermospectral properties of photonic crystal microcavity lasers and applications to systems with local temperature variations *(Invited Paper)*

Nathan J. Dawson, Michael Aviles, James H. Andrews, Michael Crescimanno, Joshua B. Petrus, Anthony Mazzocco, Youngstown State Univ. (United States); Kenneth D. Singer, Eric Baer, Hyunmin Song, Case Western Reserve Univ. (United States)

Microcavity lasers are well suited for future optical devices for space-based applications. They are paper thin and can be made of lightweight materials. Furthermore, melt-process co-extrusion methods can fabricate large sheets of low-cost, all-polymer, microcavity lasers with a variety of materials. Photo-chemically stable doped polymers have been shown to resist damage from solar radiation. The thermal properties of polymers, however, can alter the emission characteristics in these environments that exhibit large temperature fluctuations. Thus, by studying how temperature affects these polymer structures, a temperature stable and radiation resistant, all-polymer, microcavity laser may be designed with the potential to be a low-cost and lightweight optical device for harsh environments.

We report on the thermal properties that affect the emission wavelength during laser operation and some combinations of materials used in co-extruded Bragg reflectors. Two types of microcavity laser configurations are studied; (1) A Distributed Bragg Reflector (DBR) laser with a dye-doped gain medium enclosed by two Bragg reflectors of alternating polymer layers, and (2) a defect Distributed FeedBack (DFB) laser with a doubled center layer that reduces the threshold and increases the slope efficiency of a standard DFB laser. The defect DFB laser and the reflectors on the DBR laser are modeled using transfer matrix theory to observe shifts in the defect location and the reflection band edges that are induced by temperature changes. We use these results to predict stability criteria for future laser materials for space and other harsh environments.

8876-16, Session 5

DE-STAR: Phased-array laser technology for planetary defense, spacecraft propulsion, and other vital tasks *(Keynote Presentation)*

Gary Hughes, California Polytechnic State Univ., San Luis Obispo (United States); Philip Lubin, Johanna Bible, Jesse Bublitz, Joshua Arriola, Caio Motta, Univ. of California, Santa Barbara (United States)

We propose an orbital planet defense system to evaporate or divert potentially hazardous asteroids as a futuristic but possible method of alleviating impact risk. Called DE-STAR (Directed Energy Solar Targeting of Asteroids and exploRation), the system is a solar-powered, planar, modular array of high-power, phase-locked lasers in a synthetic aperture optical arrangement. Surface temperature needed to ablate most solid materials is >3000K, dictating a flux >5MW/m2. Ongoing surface vaporization beginning at 1AU allows sufficient time to evaporate objects approaching 1km diameter, or deflect larger objects. A phased array of side length ~10km produces ~70GW of laser power with ~30m spot size at 1AU, and delivers more than the required flux on target. With 50% sunlight-to-laser conversion efficiency (3x current technology), the required power is produced with a solar array of the same size. Smaller array stages would be capable of vaporizing surface materials at closer distances; reaction to ejected material generates significant force for deflecting an asteroid's orbit. An orbiting DE-STAR could also be used for many other critical tasks. Debris in Earth's orbit could be disintegrated or de-orbited. Interrogation of asteroid composition may be possible by observing blackbody spectra of the heated spot: absorption of characteristic radiation by materials in the evaporation plume could allow chemical analysis. Directing the DE-STAR beam at interplanetary spacecraft delivers significant accelerating force: a 1,000kg spacecraft could travel ~1AU to Mars in <15days. DE-STAR could also be used to decelerate the spacecraft for orbital insertion by envisioning an orbital vehicle that detaches from a larger transport and receiving energy reflected from the transport.

8876-17, Session 6

Superluminal ring laser gyroscopes and accelerometers for hypersensitive and compact inertial measurement units *(Invited Paper)*

Selim M. Shahriar, Joshua Yablon, Zifan Zhou, Ye Wang, Shih Tseng, Northwestern Univ. (United States)

When a ring laser is augmented by a medium that induces anomalous dispersion, the group velocity becomes much larger than the vacuum velocity of light, without violating causality of special relativity, thus producing the so-called superluminal ring laser. We have shown the the sensitivity of frequency shift as a function of cavity length change is enhanced by as much as six orders of magnitude in such a laser. This property can be exploited to realize ultra-sensitive gyroscope and accelerometers, which in turn can be combined to realize a superluminal inertial measurement (SIMU) unit that can outperform the state-of-the art, large scale IMUs while being very compact. An SIMU of this type is of significant interest for many applications under GPS denied conditions. In this talk, we will present details of our efforts towards realizing an SIMU using diode pumped alkali lasers augmented by a cell that induces Raman depletion in the gain profile.

8876-18, Session 6

Compact fiber optic gyroscopes for platform stabilization *(Invited Paper)*

Dave Pechner, William Dickson, James Coward, Andrew McClaren, SA Photonics (United States)

SA Photonics has developed a family of compact Fiber Optic Gyroscopes (FOGs) for platform stabilization applications. The use of short fiber coils enables the high update rates required for stabilization applications but presents challenges to maintain high performance. We are able to match the performance of much larger FOGs by utilizing several innovative technologies.

These technologies include source noise reduction to minimize Angular Random Walk (ARW), advanced digital signal processing that minimizes bias drift at high update rates, and advanced passive thermal packaging that minimizes temperature induced bias drift while not significantly affecting size, weight, or power. In addition, SA Photonics has developed unique distributed FOG packaging technologies allowing the FOG electronics & photonics to be packaged remotely from the sensor head or independent axis heads to minimize size, weight, and power at the sensing location(s). The use of these technologies has resulted in high performance, including ARW less than 0.001 deg/rt-hr and bias drift less than 0.004 deg/hr at an update rate of 10 kHz, and total packaged volume less than 30 cu. in. for a 6 degree of freedom FOG-based IMU.

Specific applications include optical beam stabilization for LIDAR and LADAR, beam stabilization for long-range free-space optical communication, Optical Inertial Reference Units for HEL stabilization, and Ka band antenna pedestal pointing and stabilization. The high performance of our FOGs also enables their use in traditional navigation and positioning applications.

This presentation will review the technologies enabling our high-performance compact FOGs, and will provide performance test results.

8876-19, Session 7

Femtosecond fiber laser based metal and semiconductor blackening and colorizing *(Invited Paper)*

Huan Huang, Lih-Mei Yang, Jian Liu, PolarOnyx, Inc. (United States)

No Abstract Available

8876-20, Session 7

High-power fiber-based laser development for space remote sensors *(Invited Paper)*

Fabio Di Teodoro, The Aerospace Corp. (United States)

Nanosecond(ns)-pulse fiber lasers (PFLs) offer important advantages for field applications over competing bulk solid-state lasers, primarily in terms of pulse format flexibility, efficiency, size and weight, and thermal management.

Recently, very large-core fibers such as photonic crystal fibers (PCFs) have also attained pulse energies, peak powers, and spatial/spectral brightness directly applicable to space-based remote sensors.

In this presentation, we will review the development of innovative ns PFLs having form factor and performance amenable to space deployment. The laser sources discussed will include an actively triggered master-oscillator/power-amplifier (MOPA) driven by a gain-switched, actively pulse-controlled, single-frequency diode laser and incorporating a multi-stage, 975nm-diode-pumped ytterbium(Yb)-doped, single-polarization fiber-based amplifier will be presented. The amplifier terminal stage consists of an Yb-doped segmented, 100um-core, rod-type PCF. The MOPA produced ~1064nm-wavelength, ~1.5ns pulses of energy/peak power in excess of 2.2mJ/1.5MW at pulse repetition frequency = 10 kHz, while exhibiting good beam quality (< 1.2 ? diffraction limit) as well as excellent pulse contrast, spectral brightness (>92% pulse energy within a 0.2nm window), and net electro-optic efficiency ~15%. This optical source was packaged via assembly techniques traceable to optical telecommunications components, within an enclosure of ~0.5ft3 (< 18 liters) volume designed for tolerance of field-level shock, vibration, and thermal profiles.

An outlook to further power scaling and ruggedization of PFLs for space payloads will conclude the presentation.

8876-21, Session 7

Generation of tunable laser sidebands near 2.05um for CO2 sensing application *(Invited Paper)*

Jihong Geng, AdValue Photonics, Inc. (United States); Yingxin Bai, Jirong Yu, NASA Langley Research Ctr. (United States); Shibin Jiang, AdValue Photonics, Inc. (United States)

Greenhouse gas (such as CO2) profiling/monitoring in the Earth's atmosphere is important for better understanding global climate evolution. For this application, high-energy single-frequency pulsed laser transmitters are required at both on-line and off-line wavelengths for use in air-borne/space-born lidar platforms. These high-power pulsed laser transmitters can be generated by injection-seeding technique, which requires multiple single-frequency laser lines. Furthermore, these frequency lines need to be offset-locked each other, and also locked to a specific molecular absorption line as well, which is a challenge if they are provided by multiple seed laser sources. In this talk, we will present our latest development of such a kind of multiple-line single-frequency laser source for the application. A single-frequency 2.05um fiber laser emits a monochromatic electromagnetic wave at a carrier frequency near

150THz. With a sinusoidal intensity modulation at a microwave frequency (several GHz), new laser frequency components (i.e., modulation side bands) can be readily generated, which offer a way to generate multiple well-defined single-frequency laser lines with a frequency spacing precisely controlled by a microwave signal generator. Spectroscopic application with the multiple-line single-frequency laser source will be discussed.

8876-22, Session 7

Improved nanofabrication for plasmonic nanostructures on optical-fiber tip for biosensors *(Invited Paper)*

Yongbin Lin, Robert G. Lindquist, The Univ. of Alabama in Huntsville (United States)

The capability of creating plasmonic nanostructures on the optical fiber tip with conventional nano-fabrication technologies would enable the transition of localized surface plasmon resonance (LSPR) based label-free biosensing technology from laboratory environment to field and space applications. The use of optical fiber platform for LSPR biosensing enables highly integrated and portable solutions for space life exploratory missions related to immunoassays and DNA hybridization assays. Multiple detections can be integrated into a single fiber bundle for multiple parallel analyses. Moreover, this fiber probe is very suitable for remote sensing in space applications where savings in reagents are very valuable. In this report we present an approach to create arrays of metallic nanoantennas on the end facets of optical fiber utilizing planar substrate nanofabrication technologies such as electron beam lithography and lift-off processes. We also show that post annealing of Au nanoantennas can reduce line width of the resonance spectra of Au nanodots array on optical fiber tip. Compared to commercial surface plasmon resonance (SPR) sensing systems (Biacore AB), our proposed device offers several advantages, including (1) it can be inserted into the fluids and specimens for insitu chemical and biological detection, (2) the fiber device can be used as a SERS probe, a function not found in conventional SPR detection systems, and (3) it allows remote sensing naturally. The fabrication methods allow rapid and inexpensive prototypes of nanostructures on optical fiber tip. Highly specific and sensitive detection of human interleukin-6 (IL-6) protein using this fiber-optic label-free biosensor will be presented.

8876-38, Session PMon

Photonic directed energy planetary defense and relativistic propulsion

Johanna Bible, Univ. of California, Santa Barbara (United States)

We propose a directed energy orbital planetary defense system capable of heating the surface of potentially hazardous objects to the evaporation point as a futuristic but feasible approach to impact risk mitigation. The system is based on recent advances in high efficiency photonic systems. We call the system DE-STAR for Directed Energy Solar Targeting of Asteroids and exploRation. DE-STAR is a modular phased array of solid-state lasers, powered by photovoltaic conversion of sunlight. The system is scalable and completely modular so that sub elements can be built and tested as the technology matures. The sub elements can be immediately utilized for testing as well as other applications including space debris mitigation. The ultimate objective of DE-STAR would be to begin direct asteroid vaporization and orbital modification starting at distances beyond 1 AU. Using the phased array to focused the beam the surface spot temperature on the asteroid can be raised to more than 3000K, allowing evaporation of all known substances. Further use of the DE-STAR could be propulsion of kinetic or nuclear tipped asteroid interceptors or other interplanetary spacecraft. A photon drive is possible using direct photon pressure on a spacecraft similar to a solar sail. Given a laser power of 50GW, A 100 kg craft can be propelled to 1AU in approximately 3.5 days achieving a speed of 0.4% the speed of light and a 10,000 kg craft in approximately 35 days.

8876-23, Session 8

Contamination protective coatings: an overview *(Invited Paper)*

Ronald G. Pirich, Independent Consultant and Senior Research Advisor (United States)

Dust, ice, fogging and corrosive contamination is a serious problem for air and space equipment and vehicles. For example, contamination may accumulate on sensors inhibiting accurate and timely data acquisition. Sensors that require transparency to light for maximum efficiency can be seriously affected by contamination buildup. The thermal and radiation environment of space systems also pose unique challenges to protective coatings because of the space environment's large temperature variations, the plasma environment and solar UV and X-rays induced photoemission of electrons. For polymeric materials, not all properties are affected to the same degree by radiation but are often localized at a specific bond. At the nano-scale, van der Waals forces can be significant. In general, these intermolecular forces are not affected by ionizing radiation unless the surface molecular structure is changed since van der Waals interactions are always present between molecules and only dependent on the number of electrons in the molecule and the distance between molecules. Both hydrophilic and hydrophobic coating approaches may be important to address specific design requirements. Hydrophilic materials are composed of polar molecules and have been used to defog glass and enable oil spots to be swept away with water. Hydrophobic molecules tend to be non-polar and thus prefer other neutral molecules and nonpolar solvents. Hydrophobic molecules often cluster and are difficult to wet with liquids. This paper presents an overview of various types of contamination that adheres to critical air and space surfaces and potential coatings phenomenology that may be used to eliminate contamination.

8876-24, Session 8

Simulation framework for space environment ground test fidelity *(Invited Paper)*

Jason A. Cline, Spectral Sciences, Inc. (United States)

The space environment produces a number of performance challenges to satellite and spacecraft manufacturers that require measurements, including effects from hyperthermal atomic oxygen, charged particles, magnetic fields, spacecraft charging, ultraviolet radiation, micrometeoroids, and cryogenic temperatures. Because of the significant resources involved in fielding spacecraft, ground testing against these effects is desirable.

Physics-based models can help test consumers knowledgably interpret the responses of the spacecraft and the uncertainties in the measurements. Ground-based tests are accelerated, the stimuli are sometimes approximate. Breakdown of approximations and synergies between effects can lead to nonlinear results, which without appropriate calibration or model-based guidance can cause inaccurate test readings. For example, Cline et al. (J. Spacecraft, 42(5):810, 2005) showed that accelerated atomic-oxygen tests can produce multicollision effects that decrease the average surface-impact energy of the atomic oxygen fluence. Although individual space effects models exist, we are not aware of a comprehensive model for space effects or for test chambers.

We present initial progress to fill this gap with an extensible multiphysics model network. The model network is designed to adapt to different levels of understanding and/or approximations, including several levels of physics from fundamental rates and parameters to space and test chamber simulations. The starting point for the effort is a rarefied gas dynamics model for atomic oxygen exposures. We present the status of the model, the roadmap for its development, data needs, and likely validation pathways.

8876-25, Session 8

Simulation of a pulsed atomic oxygen beam *(Invited Paper)*

Neal J. Carron, Rock West Solutions, Inc. (United States); Iain Boyd, Univ. of Michigan (United States); Scott M. Frasier, Aravant Corp. (United States); Matt Thomas, ATK Corp. (United States)

The Air Force has recently built a vacuum chamber for simulating the LEO space environment for testing small satellites or satellite subsystems. Seven environmental sources are provided: solar light flux; SC charging; outgassing; and individual beams of electrons, protons, Atomic Oxygen, and Xe ion backflux. In our talk we will present results of our recent computer simulation of the pulsed Atomic Oxygen source. We motivate our choice of the dynamical DSMC code used, and present results such as the AO fluence time history and its spatial distribution over the test article; chamber pressure time history; flow velocity contours; and the importance of particle-particle collisions; and attempts to model the motion of residual source-produced O+ ions in the geomagnetic field. We compare with existing measurements.

8876-26, Session 8

Modeling proton and heavy ion induced effects in thin film coatings for lunar and space environments

Edward W. Taylor, International Photonics Consultants, Inc. (United States); Ronald G. Pirich, Independent Consultant and Senior Research Advisor (United States)

Protective thin film coatings are important for many near-Earth and interplanetary space systems applications such as photonic components, optical elements, solar cells and detector-sensor front surfaces to name but a few environmentally at-risk technologies. The near-Earth and natural space environment consists of known degradation processes induced within these technologies brought about by atomic oxygen, micrometeorites, space debris and dust, solar generated charged particles, Van Allen belt trapped particles and galactic cosmic rays. The paper will focus on presenting the results of an investigation based on simulated ion-induced defect-modeling and nuclear irradiation testing of several innovative hybrid-polymeric self-cleaning coatings that appear to be suitable for many space photonic, lunar surface and avionic applications. Data is reported regarding the radiation resistance of several hybrid polymer coatings for protecting sensors, structures, and space vehicles from dust contamination and space radiation found in space and on the Moon's surface.

8876-27, Session 9

Fluorinated PPV type block co-polymers for nanophotonics *(Invited Paper)*

Sam-Shajing Sun, Thuong Nguyen, Jaleesa Brooks, Norfolk State Univ. (United States)

Polymer based optoelectronic materials and thin film devices exhibit great potential in space applications due to their flexibility, lighter weight, larger light absorption coefficient, and very promising radiation tolerance in space environment as compared to their inorganic semiconductor counterparts. Current existing polymer photovoltaic materials and devices suffer low photoelectric power conversion efficiencies due to a number factors including poor morphologies at nano scale that hinder the charge separation and transport, and poor electronic orbital match between the donor and the acceptor units and the solar spectrum. Due to carbon-fluorine (C-F) chemical bonds are much stronger than the typical carbon-hydrogen (C-H) bonds, fluorinated polymers are very attractive for outer space applications. This paper summarizes our recent work on a fluorinated DBA type block copolymer system where the donor (D) block contains a donor substituted and hydrocarbon based polyphenylenevinylene (PPV), and acceptor (A) block contains a fluorinated and acceptor substituted polyphenylenevinylene (f-PPV). Preliminary results reveal f-DBA exhibiting more efficient photoluminescence quenching (relevant to photo induced electron transfer between the donor and the acceptor blocks) and better nano phase morphologies as compared to D/A blend and the non-fluorinated DBA. The chemical synthesis, characterizations, and preliminary morphological/optoelectronic studies and results will be presented.

8876-28, Session 9

Quantum dots with built-in charge to increase responsivity, detectivity, and operating temperature of quantum dot infrared photodetectors *(Invited Paper)*

Andrei Sergeev, Victor Pogrebnyak, Univ. at Buffalo (United States); Alex Varghese, Michael Yakimov, Vadim E. Tokranov, Serge Oktyabrsky, Univ. at Albany (United States); Guillaume Thomain, Nizami Vagidov, Vladimir Mitin, Univ. at Buffalo (United States)

Quantum well infrared photodetectors are widely used in multi-elements focal plane arrays operating at liquid nitrogen temperatures. Compared to quantum-well structures, quantum dot (QD) nanomaterials are more flexible to control photoelectron processes by engineering of the nanoscale potential profiles formed by charged quantum dots. Quantum dots with built-in charge (Q-BIC) suppress capture of photoelectrons by (QDs) and provide strong coupling to infrared radiation. We review design approaches, fabrication and characterization of photodetectors based on Q-BIC media with strong selective doping to increase the dot charge. Characterization of Q-BIC media includes the structural, spectral (photoluminescence measurements) and electrical characterization (dark current, I-V measurements). After several design-growth-characterization cycles we reached relatively high density of quantum dots, small concentration of defects related to quantum dot growth, and suppressed carrier capture by QDs. Optimized Q-BIC media were used for fabrication of Q-BIC IR photodetectors. We studied spectral and temperature dependences of photoresponse and also its dependences on bias voltage and parameters of Q-BIC medium. Due to enhanced coupling to IR radiation and long photoelectron lifetime we demonstrated room temperature operation of our detectors and reached responsivity of ~10^3 A/W. In our devices the dark current increases with dot's charge approximately in the same way as the responsivity. Because the detector sensitivity is proportional to the responsivity and inversely proportional to the fluctuation current, which in turn is proportional just to the square root of the dark current, the sensitivity improves with charging of quantum dots. Currently the room-temperature detectivity of ~10^8 cm?Hz1/2/W is obtained.

8876-29, Session 9

Radiation effects on solar cells: experiments, models, and simulations: DLTS vs SRIM for trap data *(Invited Paper)*

Alexandre I. Fedoseyev, Marek Turowski, Timothy Bald, Ashok Raman, CFD Research Corp. (United States); Jeffrey Warner, U.S. Naval Research Lab. (United States)

A predictive computational approach that limits use of DLTS experiments is presented, developed using the experimental data and proposed physics based models. Three-dimensional NanoTCAD simulations are used for physics-based prediction of space radiation effects in III-V solar cells, and validated with experimentally measured characteristics of a p+n GaAs solar cell with AlGaAs window. The computed dark and illuminated I-V curves as well as corresponding performance parameters matched very well experimental data for 2 MeV proton irradiation at various fluences. We analyze the role of majority vs. minority and deep vs. shallow carrier traps in the solar cell performance degradation. The traps/defects parameters used in the simulations were derived from Deep Level Transient Spectroscopy (DLTS) data obtained at NRL. It was noticed that the degradation caused by deep traps observed in single-trap numerical tests exhibit a very similar trend to the degradation caused by a full spectrum of defect traps, but to a lesser degree. This led to the development of a method to accurately simulate the degradation of a solar cell by using only a single deep level defect whose density is calculated by the Stopping and Range of Ions in Matter (SRIM) code. Using SRIM, we calculated the number of vacancies produced by 2 MeV proton irradiation for fluences ranging from 6x1010 cm-2 to 5x1012 cm-2. Based on the SRIM results, we applied trap models in NanoTCAD and performed full I-V simulations from which the amount of degradation of performance parameters (I¬sc, Voc, Pmax) was calculated. The physics-based models using SRIM allowed obtaining good match with experimental data.

8876-30, Session 10

Germanium on silicon to enable integrated photonic circuits *(Invited Paper)*

F. Kenneth Hopkins, Air Force Research Lab. (United States); Kevin M. Walsh, Univ. of Louisville (United States)

Although Integrated Photonic Circuits (IPCs) including the optical analog-to-digital converter and the integrated optical spectrum analyzer were first explored during the mid-1970's, the impact of IPCs on DoD and commercial systems has been limited. The need for integrated photonic circuits has been highlighted again in recent DoD program announcements. Requirements for IPC's in general include a common substrate, for which silicon has recognized advantages, and the use of laser wavelengths near1.55µm in order to utilize commercially available ultra-narrow line laser diodes and optical filters. Although many integratable subcomponents have become available during recent decades, an ideal photodiode is conspicuously absent. Silicon photodiodes, although easily integratable, are intrinsically slow (<~1GHz) and not responsive to 1.55µm light. GaInAs photodiodes are fast, well developed, and highly responsive to 1.55µm light but have limited potential for true integration with silicon and optical waveguides. In contrast, germanium photodiodes promise high responsivity with the added benefit of true integration. Within the past year, Duan and others confirmed the high responsivity of Ge photodetectors by demonstrating a photodetector (a Ge detector region and a Si avalanche region) with an enormous responsivity of 12A/W and a high frequency response (8 GHz). [Optics Express 20 (7May2012), 11031] In the presentation, the results of our study of the potential for integrating Ge photodetectors into IPCs will be described. Our efforts entail the deposition of high quality germanium films on silicon to fabricate Ge-based photodiode structures for detecting light in fiber or in optical slab waveguides.

8876-31, Session 10

Recent progress of Spectrolab high-efficiency space solar cells *(Invited Paper)*

Daniel C. Law, Spectrolab, Inc. (United States)

Multijunction space solar cell technology has achieved production cells with average 1-sun efficiency close to 30% with cell sizes ranging from, 26.6 to 74.4-cm2. The latest XTJ SuperCells are built in Spectrolab newly established 150-mm manufacturing line. Inverted metamorphic (IMM) 3- and 4-junction cells with a target average 1-sun efficiency of 33% are being developed. 4-cm2 and 24-cm2 IMM4J cells exceeded 34% and 32% efficiency respectively. The IMM cells were assembled into strings and affixed to rigid aluminum honeycomb panel for thermal cycling characterization. Preliminary temperature cycle data of the IMM cell strings showed no degradation. Semiconductor bonded technology (SBT), an alternative approach that can achieve efficiency ≥35% will also be presented.

8876-32, Session 10

Detection advantages of spatial oversampling in imaging sensors *(Invited Paper)*

Jerry A. Wilson, John T. Caulfield, Cyan Systems (United States); Nibir K. Dhar, Defense Advanced Research Projects Agency (United States)

Cyan Systems has recently developed an approach to focal plane assembly (FPA) architecture which represent a significant advancement in information extraction from the data as it is being collected. This approach utilizes sub-pixels which achieve a high degree of oversampling of the sensors Point Spread Function (PSF), well beyond the Nyquist limit. The data contained in an oversampled image has the obvious advantage of readily discriminating between focal plane and object generated artifacts as the first step in false alarm rejection. However there are further advantages that can be exploited through nearest neighbor subpixel correlation, thresholding and pooling that achieves significant noise reduction and therefore improved sensitivity. In Cyan's architecture these processes are accomplished for the first time at the input to the preamp in the ROIC. This approach not only allows improved fidelity in imaging, but further reduces false alarm rates, improves detection ranges, and demonstrates an improved ability to track closely spaced objects. The architecture has been modeled and simulations run which illustrate the dramatic improvements possible.

8876-33, Session 10

A highly strained INAS/GASB type II superlattice for LWIR detection *(Invited Paper)*

Yiqiao Chen, SVT Associates, Inc. (United States)

IR photo detectors are in high demand for various military and civilian applications, such as airborne surveillance, remote sensing, environmental monitoring, and spectrometry. Recently InAs/GaSb type II superlattice (T2SL) has attracted numerous R&D interest since SLS is the only IR material that has a theoretical prediction of higher performance than HgCdTe. Here we report the improvement of SL photo diodes through a novel design with highly-strained type-II superlattice (HS-T2SL). The HS-T2SL consists of a highly compressively strained thick InSb layer at InAs/GaSb interfaces. The overall net strain in HS-T2SL remains zero as a result of strain compensation, thus avoiding strain-induced defects during growth. At a localized level the strain in HS-T2SL causes tetragonal distortions in k-space which shift the bulk energy levels and split the valence band degeneracy of the light- and heavy-hole energy levels. The presence of coherent strain shifts the band edges such that the SL energy gap is reduced. This reduced band gap is advantageous to photodetectors because longer cut-off wavelengths can be obtained with reduced layer thickness in the strained SL. The highly compressive strain in HS-T2SL also leads to an even higher optical absorption coefficient and lower dark current. Applying this new design resistance-area product (R0A) is measured as high as 2.1 Ohm-cm2 at 85K for 14.5um-cutoff photo diodes without any dark current suppression barriers. The fabricated 14.5um-cutoff photo diode shows Johnson-noise-limited peak detectivity of 8.4?10^10 cmHz1/2/W at zero bias at 85K.

8876-34, Session 11

Quantum interference in electro-optic polymeric modulators *(Invited Paper)*

Javier Perez-Moreno, Skidmore College (United States) and Washington State Univ. (United States)

The performance of polymer-based electro-optic modulator is very dependent on the wavelength of operation of the device. Surprisingly, most of our intuitive understanding of the molecular performance in such devised are based on studies performed in the off-resonance regime, where the nonlinear optical response of the molecule is by assumption not dependent on the wavelength of operation; or/and two-level model extrapolation, where the response is assumed to be dominated by the contribution of only one excited state. In either case, the effects of quantum interference (cancellation and enhancement of the response due to interactions between multiple excited states) are ignored. In this paper we show how in complex molecules with more than one excited state, quantum interference effects plays an important role in determining the on-resonant response, and hence should not be ignored when studying the response of organic-based electro-optic materials.

8876-35, Session 11

Pulse electro-acoustic (PEA) measurements of embedded charge distributions *(Invited Paper)*

J. R. Dennison, Utah State Univ. (United States); Lee H. Pearson, Box Elder Innovations (United States)

Knowledge of the spatial distribution and evolution of embedded charge in thin dielectric materials has important applications in semiconductor, high-power electronic device, and high-voltage DC power cable insulation industries. In space environments, spacecraft are exposed to extreme charged particle fluxes ranging from relatively low (<100eV) to high (>100keV) energies. Charge can accumulate in dielectric materials, until potentials are high enough to initiate electrostatic discharge (ESD). Such events can damage electronic components in the spacecraft and lead to system failures. Knowledge of how, where, and how much charge accumulates and how it redistributes and dissipates for given materials, spacecraft configurations and space environments is the key to prediction, avoidance and mitigation of these destructive “arc and spark” spacecraft charging effects.

High-frequency pulsed-electro-acoustic (PEA) and Pressure Wave Propagation (PWP) measurements are non-destructive methods used to investigate such internal charge distributions. PEA techniques generate acoustic waves within the material by using high-voltage, high-frequency pulsed signals to stimulate motion of the internal charge bound in the solid, then measures the ensuing voltage pulse response. We discuss the instrumentation, methods, theory and signal processing of simple PEA experiments and shows results of PEA measurements. We emphasize system improvements required to achieve high spatial resolution for in vacuo measurements of thin film polymeric, ceramic, or glass dielectric materials using medium to high energy (~103eV to ~107eV) electron beams.

*Work is supported by Phase I and II STTR projects sponsored by the Air Force Research Laboratory (AFRL).

8876-36, Session 11

Deterministic digital WDM LAN for controlled configurations *(Invited Paper)*

John Mazurowski, The Pennsylvania State Univ. Electro-Optics Ctr. (United States)

We present a small digital Local Area Network (LAN) using Wavelength Division Multiplexing (WDM), meant for deterministic applications with fixed or controlled configurations. For these special cases, efficiency can be increased, and acquisition cost decreased. This network uses time, wavelength, and spatial domains to provide determinism and to increase efficiency.

For wavelength efficiency, the network uses a Lambda-Net architecture, where each receiver is dedicated to a specific wavelength. To reach a receiver, a transmitter must transmit at the receiver wavelength.

Transmitters are either dedicated or tuned to a desired wavelength. Typical of communication transmitters in the 1550 nanometer band, controlled cooling is required to maintain wavelength accuracy. To increase cooling efficiency, a bank of transmitter diodes shares a micro-environment with common cooling.

Each transmitter is pre-modulated with a clock; the frequency of the clock depends on the application and the required timing resolution. For low frequency applications, a switch can be used in lieu of a modulator to keep or discard clock pulses, providing a data stream.

To avoid undesired phase modulation, and to provide for timing respective to the network geometry, we have the choice of adding chromatic dispersion or adding incremental delay to each wavelength channel.

All network nodes are transparent. The data plane can be merged with the control plane to accommodate high bandwidth payloads. Within a node, an external signal can replace a section of clock or control signal as a payload. After the payload is transmitted, clock or switched clock signals resume.

8876-37, Session 11

Fiber optic strain, temperature and shape sensing via OFDR for ground, air and space applications *(Invited Paper)*

Joseph J. Bos, Mark E. Froggatt, Eric Sanborn, Justin Klein, Dawn Gifford, Luna Innovations Inc. (United States)

Optical fiber sensors provide numerous advantages for space, air and ground applications. They are small, light-weight, immune to EMI, radiation resistant, and can be embedded in a material or adhered to its surface. In this work, recent advancements in OFDR-based optical fiber temperature, strain and shape sensing are demonstrated.

Utilizing Rayleigh backscatter (RBS) from off-the-shelf single mode fiber as the transducer, OFDR technology enables low-cost, fully-distributed sensing with mm spatial resolution and high dynamic range. Potential applications for this technology include design verification, testing and in-situ structural health monitoring (SHM) of ground, air and space vehicles, satellite structures and subcomponents. Presented here are dynamic, fully-distributed thermal measurements of a thermal-barrier coated metal structure as it is exposed to a high-temperature torch. The thermal field on the surface is mapped in high resolution and coating defects are detected and located.

Advancements in OFDR-based shape sensing systems enable real-time 3D shape, position, bend and twist measurements with unprecedented spatial resolution and positional accuracy. Potential applications for this technology include SHM, coordinate measurements, and real-time feedback for shape-enhanced deformable structures such as flexible antennae, imaging optics and their supporting structures, solar sails and more. Presented in this work are real-time position, shape and twist measurements of a simple structure as it is subjected to various loads.

8877-18, Session PMon

The impact of space-time speckle to the resolution in range and azimuth direction on synthetic aperture imaging ladar

Qian Xu, Yu Zhou, Jianfeng Sun, Ya'nan Zhi, Xiaoping Ma, Zhiwei Sun, Dong Lu, Liren Liu, Shanghai Institute of Optics and Fine Mechanics (China)

Synthetic aperture laser ladar is theoretically the most possible optical method to provide centimeter-class resolution with a real aperture size of a few meters in thousand kilometers. However, as linear chirp laser signal is always employed as the transmitted signal, SAIL is inevitably impacted by the space-time varying speckle effect. In many SAIL two-dimensional reconstructed images, the laser speckle effect severely reduces the image quality. We have indicated that the random phase and random amplitude introduced by space-time speckle is closely related to the ratio of the scale of antenna aperture and the average width of speckle pattern. In this paper, expressions for two-dimensional data collection contained space-time speckle effect are obtained, and the influence of space-time speckle effect to the resolution element imaging is analyzed. According to computer simulation results, the width of the resolution in range direction almost keeps the same, while the peak value of the range resolution decreases when the speckle random phase variance increases. The random phases introduced by Fourier transform in range direction have little influence on the azimuth imaging. After matched filtering, the resolution in azimuth direction is degraded severely by the speckle random phase, even divided into more than one points.

8877-20, Session PMon

Optical imaging process based on two dimensional Fourier transform for synthetic aperture imaging ladar

Zhiwei Sun, Ya'nan Zhi, Liren Liu, Jianfeng Sun, Yu Zhou, Peipei Hou, Shanghai Institute of Optics and Fine Mechanics (China)

The synthetic aperture imaging ladar systems typically generate large amounts of data difficult to compress with digital method. This paper presents an optical SAIL processor based on compensation of quadratic phase of echo in azimuth direction and two dimensional Fourier transform. The optical processor mainly consists of one phase-only liquid crystal spatial modulator(LCSLM) to load the phase data of target echo and one cylindrical lens to compensate the quadratic phase and one spherical lens to fulfill the task of two dimensional Fourier transform. We give detailed description of principle and mathematical analysis of this optical processor and analyze the difference of imaging processing result between complex data and pure phase data. We show the imaging processing result of practical target echo obtained by a synthetic aperture imaging ladar demonstrator. The preferable result indicates the effectiveness of this optical SAIL processor. Due to the inherent parallel and the speed-of-light computing capability of this optical processor, both the time and power demanding to compress SAIL target echo are reduced comparing to the digital processing way. The optical processor is compact and lightweight. It has a promising application future especially in onboard and satellite borne SAIL systems.

8877-21, Session PMon

A transformation approach for aberration-mode coefficients of Walsh functions and Zernike polynomials

Shuai Wang, Ping Yang, Mingwu Ao, Lizhi Dong, Bing Xu, Institute of Optics and Electronics (China)

The power series expansion or function basis expansion is the common way of describing wavefront distortion. At present, the Zernike-polynomial representation has been widely adopted and regarded as the classic and the standard because the polynomials form a complete and orthogonal set and the low-order polynomials have the same distribution with actual aberrations in optical systems. However, the coefficients of the high-order Zernike polynomials cannot be directly measured using common wavefront sensing techniques. Besides, in theory, any complete and orthogonal function series can be used as basis to represent wavefronts. As a result, the binary complete and orthogonal Walsh functions have been modified and utilized as binary-aberration-mode basis by some novel wavefront sensing techniques. These functions have only two values, -1 and 1, so they are especially suitable for representing discrete wavefront. But when wavefront sensing techniques based on binary-aberration-mode detection trying to reconstruct common wavefronts with continuous forms, the Modified Walsh functions are incompetent. The limited space resolution of Modified Walsh functions will leave substantial residual wavefronts. In order to sidestep the space-resolution problem of binary-aberration modes, it's necessary to transform the Modified-Walsh-function expansion coefficients of wavefronts to the Zernike-polynomial coefficients and use Zernike polynomials to represent the wavefronts to be reconstructed. For this reason, a transformation method for wavefront expansion coefficients of the two aberration modes is proposed. The principle of the transformation is the linear of wavefront expansion and the method of least squares. Through expanding each Zernike polynomials with the Modified Walsh functions, the aberration-mode-coefficient transformation matrix is built. The Zernike-polynomials coefficients of a wavefront can be calculated with the matrix and the Modified-Walsh-functions coefficients acquired. The numerical simulation demonstrates that the transformation with the matrix is reliable and accurate.

8877-1, Session 1

Multi-conjugate adaptive optics: capabilities and limitations versus technological demonstration and scientific productivity

Katharine J. Jones, WBAO Consultant Group (United States)

From 1995 to 2000, the first astronomical science results were obtained using Rayleigh scattering by the Starfire Optical Range. The first use of sodium guide stars was obtained at the Calar Alto telescope in 2000. Astronomical LGS was again used in 2004 using the 3 m Lick telescope. The first large telescope was the 10 m Keck II in 2005. The first LGS AO papers from 8 m Gemini - North and VLT appear in 2008. The LGS AO with the Suburu telescope began in 2008.This paper will address ground-based Adaptive Optics Multi-Conjugate observatories requiring compensation for extended aberration. Of particular interest is science productivity. The following observatories will be examinded and compared: Keck I and Keck II, Gemini Nortth and Gemini South, LBT (Large Binocular Telescope) and VLT (Very Large Telescope). Gemini North, Keck I & II and VLT are single conjugate AO. Gemini South is multiple conjugate. LBT is ground layer AO. Science performance is a function of laser return and the number of subapertures.The number of refereed papers is an indictor of science productivity

8877-2, Session 1

Phased beam projection from tiled apertures in the presence of turbulence and thermal blooming

Mark F. Spencer, Milo W. Hyde IV, Air Force Institute of Technology (United States)

The individual phases of a multi-beamlet laser source can be manipulated by exploiting high-bandwidth phase loops to correct for aberrations induced within the optical beamlet trains. With the current state of the art in phasing technology, this phasing of the beamlet trains is successfully accomplished up to a common aperture sharing element or on a point-source target; however, in the presence of an extended target, rough surface scattering through laser-target interaction adds the additional constraints of speckle and depolarizing effects. In particular, speckle phenomena and atmospheric effects create unobservable modes in the beam control system. One such unobservable mode is termed stair mode and is appropriately identified by a stair-step pattern of piston phase across the individual subapertures that comprise a tiled aperture. This paper investigates the effects of turbulence and thermal blooming on phased beam projection from tiled apertures using wave-optics simulations. To represent different array fill factors in the source plane, both seven and 19 element hexagonal close-packed tiled apertures are used in the simulations along with both Gaussian and flat-top outgoing beamlets. Peak Strehl ratio and power in the bucket are calculated in the target plane over multiple random realizations that are then averaged. This is done for all simulation setups with and without the presence of stair mode.

8877-3, Session 1

Image-based wavefront compensation using deformable mirror for remote sensing telescope

Norihide Miyamura, Meisei Univ. (Japan)

We are developing an adaptive optics system for earth observing remote sensing sensor. In this system, high spatial resolution has to be achieved by a lightweight sensor system due to the launcher's requirements. Moreover, simple hardware architecture have to be selected to achieve high reliability. Image based AOS realize these requirements without wavefront sensor. In remote sensing, it is difficult to use a reference point source unless the satellite controls its attitude toward a star or it has a reference point source in itself. We propose the control algorithm of the deformable mirror on the basis of the extended scene instead of the point source. In our AOS, a cost function is defined using acquired images on the basis of the contrast in spatial or Fourier domain. The cost function is optimized varying the input signal of each actuator of the deformable mirror. In our system, the deformable mirror has 140 actuators. We use basis functions to reduce the number of the input parameters to realize real-time control. We constructed the AOS for laboratory test, and proved that the modulated wavefront by DM almost consists with the ideal one by directly measured using a Shack-Hartmann wavefront sensor as a reference.

8877-4, Session 1

Aero-optic analysis of turbulent boundary layer by direct integration method

Chien-Pin Chen, The Univ. of Alabama in Huntsville (United States); John Price, The Univ. of Alabama in Huntsville (United States); George W. Sutton, John E. Pond, Analysis and Applications Associates (United States)

We have investigated the direct integration of the Helmholtz equation for the aero-optical effects of a turbulent boundary layer on a flat plate for a 10-cm aperture. The turbulence of the boundary layer was found by using a hybrid Large Eddy Simulation (LES) -Reynolds averaged Navier-Stokes (RANS) method. The turbulence fields are shown to compare favorably with experimental results. The hybrid methods allowed for the study of the optical models and also validation of their assumptions. The far-field intensity of a uniformly illuminated circular aperture in vacuum was used to validate our direct integration method. It is well established that a turbulent boundary layer has packets of elongated structures with a preferred angular orientation downstream. Thus, aero-optic aberrations should show an anisotropic behavior as a function of propagation angle. We demonstrated this effect, as the downstream-direction propagation through elongated structure results in greater aberration, versus propagation in the upstream direction. The Optical Path Difference, (OPD), was computed and found to compare favorably with experimental data. The OPD was also used for the direct integration of the Helmholtz equation to find the point spread function, (PSF), at various propagation angles. Correlation lengths and variances of the index-of-refraction fluctuations distribution, along the line-of-sight were also calculated. The point spread function was then computed using the assumption that the turbulence in the boundary layer is isotropic and homogeneous. The errors made using these assumptions were found by comparing these results to the direct integration method that uses the OPD from the LES simulation.

8877-5, Session 1

Sodium guide star excitation and preferable laser formats

Katharine J. Jones, WBAO Consultant Group (United States)

Sodium guide stars are in a variety of types. Power, laser type, pulse and spectral format have been tabulated. High output power is not enough. The physics of coupling light to the sodium atom can affect how much of this power is returned as signal to the AO system. Laser beam quantity and launch beam diameter can drastically affect AO system performance. For laser sodium interaction, there are 29 energy levels, 8 ground states and 16 excited states. The transition from the P2a line yielding lambda = 589 nm is the one important for the Laser Guide Star. With proper laser intensity, the atom can be excited once per relaxation line (~16 ns) giving the largest apparent cross section: the most photon return per unit incident light. Some effects can spoil ideal pump conditions. Quenching can be corrected by repumping. Addressing more Doppler bins with lines at least 110 MHz plus the laser line width should be done to mitigate deleterious effects. Some laser spectral formats wii be explored and compared for improved atomic coupling for brighter guide star per unit laser output.

Sequential diversity imaging: experimental correction of dynamic aberrations

Tanwin Chang, Northrop Grumman Corp. (United States); Robert A. Gonsalves, Tufts Univ. (United States); Allan Wirth, Andrew J. Jankevics, Richard G. Egan, Northrop Grumman Xinetics (United States)

Phase diversity has proven to be a viable technique for wavefront sensing but converges too slowly for real-time applications. Sequential diversity imaging (SDI) is a variation on phase diversity that we have implemented on a laboratory testbed, which includes a surface parallel actuated deformable mirror (SPA-DM) and a high frame rate imager in the optical path. The SPA-DM applies small corrections to the wavefront at each frame update. These dithers produce the phase diversities and the sequential images that are the measurement set for the phase diversity algorithm. By taking advantage of the small frame-to-frame wavefront changes in a closed-loop system, convergence within a frame period can be obtained. Our testbed was designed to explore the performance of

the SDI technique under dynamic aberrations. We present experimental results with improved imagery and report on the conditions where the technique is useful. Typically the frame-to-frame OPDs must be reasonably small (< 0.3 waves) and the DM dithering must be much faster than the disturbance (~ 10X). The practicality of performing the SDI calculations at the speeds of interest for atmospheric compensation is discussed.

Multi-shot compressed coded aperture imaging (MCCAI)

Xiaopeng Shao, Tengfei Wu, Changmei Gong, Xidian Univ. (China); Hong Chang, Weihai Vocational College (China)

The classical methods of compressed coded aperture(CCA) still require an optical sensor with high resolution, although the sampling rate has broken the Nyquist sampling rate already. A novel architecture of multi-shot compressed coded aperture imaging(MCCAI) using a low resolution optical sensor is proposed, which is mainly based on the 4-f imaging system, combining with two spatial light modulators(SLM) to achieve the compressive imaging goal. The first SLM employed for random convolution is placed at the frequency spectrum plane of the 4-f imaging system, while the second SLM worked as a selecting filter is positioned in front of the optical sensor. By altering the random coded pattern of the second SLM and sampling, a couple of observations can be obtained by a low resolution optical sensor easily, and these observations will be combined mathematically and used to reconstruct the high resolution image. That is to say, MCCAI aims at realizing the super resolution imaging with multiple random samplings by using a low resolution optical sensor. To improve the computational imaging performance, total variation(TV) regularization is introduced into the super resolution reconstruction model to get rid of the artifacts, and alternating direction method of multipliers(ADM) is utilized to solve the optimal result efficiently. The results show that the MCCAI architecture is suitable for super resolution computational imaging using a much lower resolution optical sensor than traditional CCA imaging methods by capturing multiple frame images.

Investigation results of high-resolution designs for large-scale diffractive coded aperture imaging sensors

Abraham Shrekenhamer, American Systems Corp. (United States); Stephen R. Gottesman, Northrop Grumman Electronic Systems (United States)

An investigation into the feasibility of achieving high-resolution imagery using Coded-Apertures Imaging (CAI) at wavelengths where diffraction effects are significant has yielded a set of design rules for Coded Aperture (CA) mask patterns, cell sizes and mask sizing which are substantially different from the traditional CAI designs presently employed for x-ray and gamma-ray imaging. A key finding in our work is the realization that when operating at longer wavelengths where diffraction becomes a significant factor, the radiance on the focal plane is dominated by speckle patterns which reduce the effectiveness of the traditional image retrieval techniques employing the mask pattern itself for correlation. Image retrieval from diffractive patterns requires a set of reference speckle patterns pre-calculated for point sources. Ultimately the diffractive sensor resolution is defined by the mean speckle size which can be minimized by reducing mask cell size while increasing overall mask dimensions. This implies that large-scale imaging sensors are required to produce high resolution images. We report the results of a comprehensive investigation into the relationship between wavelength, CA cell, mask sizing, and mask pattern type using Large-Scale CAI Simulation tools developed in the previous year. The result is a set of design guidelines researchers can now adapt for the design of high-resolution CAI sensors.

Estimation of illuminator scintillation in laser-illuminated imagery

David C. Dayton, Applied Technology Associates (United States)

It is well known that atmospheric turbulence corrupts the phase front of laser beam propagation. The phase distortions manifest themselves as intensity fluctuations when the beam is propagated over some distance. This intensity fluctuation is often referred to as scintillation. Laser illuminated imaging systems are used for a variety of applications including night time imaging and tracking. The illuminator intensity fluctuation is often considered a noise effect on the imagery, however if an estimate of the scintillation can be separated from the images, it would be useful in estimating atmospheric turbulence parameters. In past work we have used a Bayesian estimation approach to separate the illuminator fluctuations from the target images. In this paper we extend that approach to included calculations of the spatial and temporal statistics of the scintillation estimate to extract atmospheric turbulence parameters.

8877-10, Session 2

Inverse synthetic aperture ladar: a high-fidelity modeling and simulation tool

Casey Pellizzari, Air Force Research Lab. (United States); Mark Spencer, Air Force Institute of Technology (United States); Nicholas Steinhoff, John Belsher, Glenn A. Tyler, the Optical Sciences Company (tOSC) (United States); Skip Williams, Stacie Williams, Air Force Institute of Technology (United States)

A wave-optics model is developed which allows simulation of an Inverse Synthetic Aperture LADAR (ISAL) imaging system. This end-to-end tool models the complex interactions of Linear Frequency Modulated (LFM) chirped pulses, target/beam interactions including target articulation, speckle phenomenology, heterodyne detection with noise, atmospheric turbulence, and laser-guide star adaptive optics. Detected signal outputs are simulated and processed to explore system design trades and to test and compare image processing algorithms. Model verification results will be presented as well as reconstructed images.

8877-11, Session 3

Optimum pattern of the multi-aperture receiver for the synthetic aperture laser imaging ladar in the turbulence environment

Jianfeng Sun, Yu Zhou, Ya'nan Zhi, Liren Liu, Shanghai Institute of Optics and Fine Mechanics (China)

Synthetic aperture laser imaging ladar's optical receiver is a heterodyne detect system, so the atmosphere turbulence will affect the phase history of the ladar seriously. Unlike in conventional passive optical imaging system, both the wavefront distortion and piston term will decrease the imaging resolution. The distortion of the wavefrom decreases the heterodyne mixing efficient; the piston will cause the pulse-to-pulse phase errors. Multi-aperture receiver technology can improve the heterodyne mixing efficient efficiently, but the pattern of multi-aperture should be optimized according to different turbulence intensity. In this paper, we optimize a four-aperture receiver pattern in different turbulence environment. The simulation and experiment results are obtain in our ladar system.

An adaptive total variation image reconstruction method for speckles through disordered media

Changmei Gong, Xiaopeng Shao, Tengfei Wu, Xidian Univ. (China)

Multiple scattering of light in highly disordered medium can break the diffraction limit of conventional optical system. As the propagation properties of light through scattering media can be represented by transmission matrix (TM), once the transmission matrix is measured, the target image can be reconstructed from its speckle image through the disordered media. However, the reconstruction image obtained by common image reconstruction algorithms such as projection method and Tikhonov regularization approach has a rather low signal-to-noise ratio (SNR) due to the experimental noise and reconstruction noise, greatly reducing the quality of the result image. The above two noises can be effectively suppressed by adaptive total variation (TV) image reconstruction method. In this paper, we generate the transmission matrix of a turbid media, and simulate the speckle image formed by the multiple scattering of a test image through the turbid media since the element of transmission matrix of scattering media follows circular Gaussian distribution. Subsequently, a new regularization term corresponding to the statistics characteristic of TM is introduced into adaptive TV image reconstruction model to suppress the noise of restored image further. Numerical simulation experimental results show that the new image reconstruction method can greatly damped the noise of the restored image and consequently boosts the SNR and the sharpness of the restored image.

8877-13, Session 3

L1-based variational methods for low-power surveillance

Matthew S. Keegan, Kang-Yu Ni, Shankar R. Rao, HRL Labs., LLC (United States)

We describe an application of l1- based variational methods to the processing of high-throughput, high-resolution video surveillance data. The goal is to facilitate the design of an efficient surveillance system that detects interesting targets and foregrounds without storing or manipulating massive video data.

For surveillance cameras with small controllable motions, the background scene can be considered stationary, and the foreground data can be considered sparse since they appear fleetingly in the spatiotemporal domain. Our approach first leverages methods for Sparse and Low-Rank Decomposition and Robust Alignment to extract significant and stationary background features while running online. We then apply a novel method that uses optimized projections based on the learned background to reduce the number of measurements necessary for retrieval of foreground objects from the video stream data via l1-based variational reconstruction. Finally, we propose the novel Contiguity-Constrained Compressive Sensing (CCCS) reconstruction framework -- a novel joint l1-TV reconstruction algorithm to isolate the pixel-wise contiguous foreground data. Optimization techniques using functional splitting are proposed to numerically compute the CCCS reconstruction.

The proposed methods allow the reduction of data bandwidth and storage, and can be implemented in optical hardware, such as the Rice single-pixel camera, to reduce the number of measurements captured at each frame. Reducing camera power consumption, these factors facilitate the design of low-power video surveillance systems. Results demonstrate that effective foreground detection can be maintained with as little as 20% of video data.

8877-14, Session 3

Context and task-aware knowledge-enhanced compressive imaging

Yuri Owechko, Shankar Rao, Kang-Yu Ni, HRL Labs., LLC (United States)

We describe a Compressive Optimal Foveated Architecture (COFA) for image analysis applications that utilizes knowledge of the task to be performed to reduce the number of required measurements compared to Nyquist sampling based approaches. COFA adapts the dictionary and compressive measurements to structure and sparsity in the signal, task, and scene by reducing measurement and dictionary mutual coherence and increasing sparsity using principles of Actionable Information and foveated compressive sensing. Actionable Information extracts task-relevant regions of interest (ROIs) from a low-resolution scene analysis by eliminating the effects of nuisances for occlusion and anomalous motion detection. From the extracted ROIs, preferential measurements are taken using foveation as part of the compressive sensing adaptation process.

The task-specific measurement matrix is optimized by using a novel saliency-weighted coherence minimization with respect to the learned signal dictionary. This incorporates the relative usage of the atoms in the dictionary. Therefore, the measurement matrix is not random, but based on the dictionary structure and atom distributions. We utilize a patch-based method to learn the signal priors. A tree-structured dictionary of image patches using KSVD is learned which can sparsely represent any given image patch.

We have implemented COFA in an end-to-end simulation of a vehicle fingerprinting task for aerial surveillance using foveated compressive measurements adapted to hierarchical ROIs consisting of background, roads, and vehicles. Our results show 113x reduction in measurements over conventional sensing and 28x reduction over compressive sensing using random measurements.

8877-15, Session 3

Comparison of forward models and phase retrieval for image formation from intensity interferometer data

Richard B. Holmes, Boeing LTS Inc. (United States); David R. Gerwe, Jean J. Dolne, The Boeing Co. (United States); Peter N. Crabtree, Air Force Research Lab. (United States)

Many imaging techniques provide measurements proportional to Fourier magnitudes of an object, from which one attempts to form an image. One such technique is intensity interferometry which measures the squared Fourier modulus. Intensity interferometry is a synthetic aperture approach that is known to obtain high resolution information, and is effectively insensitive to degradations from atmospheric turbulence. These benefits are offset by the intrinsically low signal-to-noise ratio (SNR) of the technique. Forward models have been theoretically shown to have best performance for many imaging approaches. On the other hand, phase retrieval is designed to reconstruct an image from Fourier-plane magnitudes and object-plane constraints. So it's natural to ask, "How well does phase retrieval perform compared to forward models in cases of interest?" Image reconstructions are presented for both techniques in the presence of significant noise. Preliminary conclusions are presented for attainable resolution versus SNR for unity Fourier magnitude

8877-16, Session 4

Incoherent image simulation approach with wave optics

Thomas A. Underwood, David G. Voelz, New Mexico State Univ. (United States)

An approach is presented for numerically simulating incoherent imaging using coherent wave optics propagation methods. The approach employs averaging of irradiance from uncorrelated coherent waves to produce incoherent results. Novel aspects of the method include 1) the exploitation of a spatial windowing feature in the wave optics numerical propagator to play the role of an absorbing boundary and 2) a simple propagation scaling concept to avoid aliased field components after the focusing element. Classical linear systems theory is commonly used to simulate incoherent imaging when it is possible to incorporate aberrations and/or propagation medium characteristics into an optical transfer function (OTF). However, the technique presented here is useful for investigating situations such as “instantaneous” short-exposure imaging through distributed turbulence and phenomena like anisoplanatism that are not easily modeled with the typical linear systems theory. The relationships between simulation variables such as spatial sampling, source and aperture support, intermediate focal plane, etc., are discussed and the requirement or benefits of choosing these in certain ways are demonstrated.

8877-17, Session 4

Cramer-Rao bounds for variance of Fourier magnitude measurements

Richard B. Holmes, Boeing LTS Inc. (United States); David R. Gerwe, Jean J. Dolne, The Boeing Co. (United States); Brandoch Calef, Boeing LTS Inc. (United States); Peter N. Crabtree, Air Force Research Lab. (United States)

Many imaging modalities measure Fourier components of an object, from which one attempts to form an image. Given such data, reconstruction of an image from noisy and sparse data is especially challenging, as may occur in some forms of Fourier telescopy, intensity interferometry, and speckle imaging. Such Fourier magnitudes, or squared magnitudes in the case of intensity interferometry, must be positive, and moreover must be less than 1 given common normalizations of u-v plane data. Does this additional information provide significant value? Such information can be viewed as either a constraint or a form of prior information. The Cramer-Rao formalism is applied to single Fourier magnitude measurements to ascertain whether a reduction in variance is possible. Results are presented in dimensionless form, based on the Cramer-Rao bound on variance, and compared to maximum-likelihood results for variance and root-mean-square (RMS) error. It is found that application of constraints can significantly reduce variance but that biases are introduced that can increase the RMS error. The Cramer-Rao formalism is also extended to address the value of relatively general prior information, and results are presented for this extended formalism.

8877-19, Session 4

The influence of lenslet number on superresolution reconstruction for TOMBO imagery

Yuan Gao, Ping Yang, Bing Xu, Institute of Optics and Electronics (China)

Thin observation module by bounded optics (TOMBO) is an optical system that achieves compactness and thinness by substituting a micro lens-let array with smaller apertures for a conventional large full aperture. This array allows us to capture multiple low resolution sub-images of the same scene and use them to reconstruct a high resolution image. For one TOMBO system, the number of CCD pixel is usually fixed. The larger lens-let number is, the fewer pixels every sub-image has. For super-resolution algorithms, performance bounds exist. Moreover, resolution improvement quickly becomes marginal when increasing the number of sub-images. Therefore, finding a lens-let number to optimize super-resolution reconstruction for TOMBO imagery becomes an important practical problem.

Our approach simulates image capture process of TOMBO imagery under different lens-let number condition. The degradation processes of input images are decomposed into blurring, global translation, down sampling and adding noise. Then a multi-image super-resolution algorithm based on the maximum a posteriori (MAP) framework is applied for reconstructing high resolution images with sub-images from different lens-let number condition respectively. At last Mean Square Error (MSE), Peak Signal to Noise Ratio (PSNR) and Mutual Information (MI) of super-resolution images are calculated for image quality assessment. With statistical analysis, influence results from hundreds of synthetic and real images as input images are presented. Curves of super-resolution image quality vs. lens-let number show the optimal lens-let number for TOMBO imagery.

8877-22, Session 4

Signal demodulation of Fourier telescopy based on spectrum correction

Yang Li, Bin Xiangli, Wenxi Zhang, Yunfeng Nie, Academy of Opto-Electronics (China)

Fourier telescopy(FT) is a computational imaging technique. Three or more beams from different spatially separated transmitters are pointed at a distant and faint object. The spatial Fourier spectrum of the object is carried on the reflected temporally modulated signals. The conventional demodulation processing is calculating spectrum directly by inverse Fourier transform. However spectrum estimated by inverse Fourier transform has non-negligible errors caused by frequency shift error of the Acousto-optical modulator, the noise and the motion of the target. An improved demodulation method based on spectrum correction of FT is proposed. The method corrects the amplitude and the phase on the demodulated frequency of the signal by which better reconstructed image can be obtained. On the FT applied to fast-moving targets, the exact velocity of the distant target is hard to know. The developed demodulation method is also necessary to be hired to correct the frequency shift error. In this paper, we analyze the effect of the frequency shift error on Fourier telescopy demodulation. The degradation of the reconstructed image is simulated. We summarize the new demodulation method based on spectrum correction and give the simulated comparison between the conventional demodulation and the new method. A FT laboratory experiment result is also given to demonstrate the feasibility of the method.
