8806-1, Session 1

Generalized transformation media: it's all geometry! *(Keynote Presentation)*

Martin W. McCall, Imperial College London (United Kingdom)

The programme of Transformation Optics is known to be exact – invariance of Maxwell's equations under deformation of the underlying manifold prescribes an exact medium recipe for the actual shaping of the electromagnetic field. Why the programme is quite so uniquely successful for electromagnetics is still somewhat unclear (although we have an excellent candidate conjecture that concisely captures the mathematical features of electromagnetism that do not carry over to acoustics and water waves , for example). Therefore, if we wish to develop a generalised approach for transformation media, we must descend from the exact field equations to more approximate theories that have common characteristics with other physical theories. The most promising level of attack appears to be at the level of rays. The prescription for ray behavior develops the rays for a given index distribution. However, the converse problem of finding an index distribution for a given ray deformation can only be given for conformal transformations. Despite this apparently severe restriction, significant generalization is possible when the transformation is into a space that is characterized by an anisotropic metric. We can then achieve an inversion for any desired ray deformation, in principle applicable to a wide class of physical systems, such as acoustics, Schrodinger waves, thermal waves, water waves, and so on. Any context can be addressed, in fact, where an anisotropic "index" can be defined as the directed ratio of a flux to an energy density. Being formulated geometrically also means we are no longer tied to an underlying Euclidean space, and can use our approach to design a cloak on a sphere, for example. Our methodology also accesses quantitatively the relationship between the desired deformation and the induced Riemanian curvature, which, in turn, accesses the criteria for making black holes, white holes, concentrators and a host of other useful devices. The talk will be of general appeal and be set the context of historic cloaking paradigms such as the Pendry/Leonhardt spatial cloak, and, of course, the spacetime cloak.

8806-2, Session 1

Transforming optical forces *(Invited Paper)*

Vincent Ginis, Vrije Univ. Brussel (Belgium); Philippe Tassin, Iowa State Univ. (United States) and Chalmers Univ. of Technology (Sweden); Costas M. Soukoulis, Iowa State Univ. (United States); Irina P. Veretennicoff, Vrije Univ. Brussel (Belgium)

In the interaction between light and matter, linear momentum can be transferred from electromagnetic waves to particles to generate so-called optical forces. Recently, it has been suggested that optical gradient forces can be used to actuate nanophotonic devices. The typical setup consists of two waveguides positioned in each other's vicinity such that they are coupled through the interaction of the evanescent tails. Although the gradient forces between these waveguides can be enhanced considerably with the use of electromagnetic resonators, the resulting displacements remain relatively small. In this contribution, we suggest the use of metamaterials to amplify optical gradient forces. The parameters of the metamaterials are calculated using transformation optics. This technique allows approaching electromagnetic problems from a geometric perspective as it offers an equivalence relation between a transformation of the underlying coordinate system and the material parameters of a metamaterial. Here, we design metamaterials to create the illusion for the electromagnetic fields that the two slab waveguides are positioned at a smaller separation distance from each other. Indeed, optical forces between two waveguides decay exponentially with the separation distance between the waveguides. Therefore, a coordinate transformation that alters the distance between the waveguides also alters the resulting optical forces. To enhance the forces between two waveguides, the distance should be diminished. This can be achieved with a folded coordinate transformation, which translates automatically into an anisotropic metamaterial with negative components in the permittivity and permeability tensors. In this way, metamaterials can support optical forces enhanced by more than 200 times.

8806-3, Session 1

A broadband negative index metamaterial at optical frequencies *(Invited Paper)*

Jennifer A. Dionne, Stanford Univ. (United States)

A broadband metamaterial capable of negatively refracting light across the entire visible and near-infrared spectrum would enable unprecedented manipulation of light, but has to date remained elusive. In this presentation, we introduce a straightforward approach for the design of metamaterials with optical properties that are largely insensitive to the wavelength, orientation and polarization of incident light. Extending a previously described conformal transformation, we transform an infinitely extended periodic metal-insulator-metal waveguide, known to support both capacitive and inductive modes, into a metallodielectric crescent that exhibits both electric and magnetic resonances.

By calculating the phase and amplitude of light transmitted through periodic arrays of crescents, we determine that negative refractive indices can be achieved over a broad spectral range, spanning bandwidths exceeding 200 nm at visible and near-infrared frequencies. The metamaterial shows an isotropic response over a broad range of incident angles, and near-isotropicity with respect to the polarization of incident light. Furthermore, the index of the material can be tuned from layer to layer by changing the relative orientations of the crescents within each layer. We confirm the metamaterial response using simulations of plane wave refraction through a metamaterial prism, and experimentally explore such metamaterials with cathodoluminescence spectroscopy. Our results illustrate the power of transformation optics for new metamaterial design and provide a foundation for future broadband metamaterial devices.

8806-4, Session 1

All-dielectric cloaking structures: design and stereolithographic fabrication

Yaroslav A. Urzhumov, Nathan Landy, Duke Univ. (United States); Tom Driscoll, Duke Univ. (United States) and Univ. of California, San Diego (United States); Dimitri N. Basov, Univ. of California, San Diego (United States); David R. Smith, Duke Univ. (United States) and Ctr. for Metamaterials and Integrated Plasmonics (United States)

We report stereolithographic (STL) polymer-based fabrication and experimental operation of a microwave X-band cloaking device. The device is a relatively thin (about one wavelength thick) shell of an air-dielectric composite, in which the dielectric component has negligible loss and dispersion. In a finite band (9.7-10.1 GHz), the shell eliminates the shadow and strongly suppresses scattering from a conducting cylinder of six-wavelength diameter for TE-polarized free-space plane waves. The device does not require an immersion liquid or conducting ground planes for its operation. The dielectric constant of the polymer is low enough (2.45) to suggest that this cloaking technique would be suitable for higher frequency radiation, including visible light.

In this report, we present a general design and fabrication methodology that yields two-dimensional microwave cloaks composed of only one, virtually lossless, dispersionless, dielectric medium with epsilon=2.45. The cloaks are multidirectional, i.e. invisible with respect to several propagation directions, are capable of hiding objects many wavelengths in diameter, and are thinner relative to the object size than in any previous experimental demonstrations. Using a 2D field mapping apparatus, we measure the scattered electric field in the Fresnel zone of the structure. Visibility of the structure is reduced at optimal frequency by as much as four times relative to an uncloaked cylinder, and 5 times relative to a PEC cylinder coated with a solid ABS shell of the same thickness as the cloak. A far field calculation confirms that the cloak has strongly reduced visibility in the Fraunhofer diffraction zone.

8806-5, Session 1

Experimental demonstration of birefringent transformation optics devices

Vera N. Smolyaninova, Kurt Ermer, Alex Piazza, David Schaefer, Towson Univ. (United States); Igor I. Smolyaninov, BAE Systems (United States)

Transformation optics (TO) has recently become a useful methodology in the design of unusual optical devices, such as novel metamaterial lenses and invisibility cloaks. Very recently Danner et al. have suggested theoretical extension of this approach to birefrigent TO devices, which perform useful and different functions for mutually orthogonal polarization states of light. Theoretical designs which operate as invisibility cloak for one polarization while behaving as a Luneburg lens for another orthogonal polarization have been suggested. Here we report the first experimental realization of similar birefrigent TO designs based on lithographically defined metal/dielectric waveguides. Adiabatic variations of the waveguide shape enable control of the effective refractive indices experienced by the TE and TM modes propagating inside the waveguides. We have studied wavelength and polarization dependent performance of the resulting birefrigent TO devices. These novel optical devices considerably extend our ability to control light on submicrometer scales.

8806-6, Session 2

Natural hyperbolic materials: spatial dispersion and related phenomena *(Invited Paper)*

Evgenii E. Narimanov, Purdue Univ. (United States)

Materials with hyperbolic dispersion, the strongly anisotropic media where the dielectric permittivity tensor components has different signs in two orthogonal directions, support propagating waves with wavenumbers unlimited by the frequency. The resulting broad bandwidth singularity in the photonic density of states, with resulting manifestations in a variety of phenomena, from spontaneous emission to light propagation and scattering.

As the magnitude of the photonic density of states in hyperbolic media is limited by the wavenumber cut-off defined by the inverse unit cell size, the effect is particularly strong in natural hyperbolic materials, as compared to nanostructured composites. Furthermore, in this case the nonlocality of electromagnetic response of the medium, which normally only leads to small corrections on the order of the ratio unit cell size to the propagation wavelength, has a dramatic effect on the system - leading to formation of new hyperbolic bands and enhanced radiative thermal transport.

8806-7, Session 2

Analytical description of optical nonlocalities in nanowire metamaterials *(Invited Paper)*

Viktor A. Podolskiy, Brian Wells, Univ. of Massachusetts Lowell (United States); Anatoly V. Zayats, King's College London (United Kingdom)

Plasmonic nanorod arrays have emerged as candidates for new generation of biosensors, perfect absorbers, sub-wavelength light guides, and super-focusing systems. Plasmonic response, underlying the macroscopic properties of nanowire systems, results in collective resonance of the structures. In the proximity to the plasmonic resonance, effective permittivity of the system becomes vanishingly small. The composite nature of nanowire metamaterial results in strong nonlocality of its dielectric response in the vicinity to its epsilon-near-zero frequency.

In contrast to local uniaxial materials, nonlocal metamaterial supports not two but at least three waves, two of which have identical TM polarization. The light incident on the nanowire slab couples into both TM polarized modes. In this work we demonstrate that the two TM-polarized modes result from strong coupling between between plasmon-type electron oscillation perpendicular to metallic wires and polariton-type mode propagating along the wires. We further develop quantitative description of this coupling, mapping the solution of Maxwell equations to the coupled-oscillator model. This process yields analytical description of dispersion of optical modes inside nonlocal metamaterial.

Finally, we use homogenization of Maxwell equations at the metamaterial scale to develop a set of additional boundary conditions describing the coupling between plane-wave-type modes propagating in nanowires and in surrounding media. The results of the developed nonlocal transfer-matrix formalism are in agreement with finite-element 3D solutions of Maxwell equations.

8806-8, Session 2

Control of Förster energy transfer with density of photonic states

Thejaswi U. Tumkur, John K. Kitur, Carl E. Bonner Jr., Norfolk State Univ. (United States); Evgenii E. Narimanov, Purdue Univ. (United States); Mikhail A. Noginov, Norfolk State Univ. (United States)

We show that media with high densities of photonic states such as metals and metamaterials serve as platforms to control the rate of Förster energy transfer. Moreover, the same high density of photonic states-environments which enhance spontaneous emission, inhibit Förster energy transfer between donor and acceptor molecules. Our finding supports the possibility of controlling Förster energy transfer by metamaterials, cavities and plasmonic environments.

8806-9, Session 2

Characterization of the optical topological transition in 1D (multilayer) and 2D (nanowire) hyperbolic metamaterials

Ward D. Newman, Srikrishna Bodepudi, Minchang Zhang, Ryan Starko-Boes, Huan Hu, Jonathan Atkinson, Ilya A. Utkin, Robert Fedosejevs, Ray G. DeCorby, Sandipan Pramanik, Zubin Jacob, Univ. of Alberta (Canada)

In this work, we present the first unified approach to the design, fabrication and characterization of both 1D (multilayer) and 2D (nanowire) hyperbolic metamaterials (h-MMs). We discuss some of the common problems with reliable fabrication of multilayer and nanowire h-MMs and finally show experimental extraction of multilayer and nanowire effective medium parameters from reflection and transmission measurements.

Our approach to extracting the effective medium parameters relies on isolating the poles and zeros of the dielectric tensor predicted by effective medium theory (EMT). We show the existence of a Reststrahelen band for propagating waves and anti-Reststrahlen band for evanescent waves in the theoretical EMT response and experimental data.

An optical topological transition (OTT) in h-MMs occurs when the topology of the iso-frequency surface transitions from a closed ellipsoid to an open hyperboloid. We experimentally characterize the OTTs

in h-MMs which occurs at the epsilon-near-zero crossing and study the lifetime, absorption spectrum and emission spectrum of organic dye molecules (Alq3 and R6G) near h-MMs. 1D multilayer h-MMs are realized by fabricating alternating nanoscale layers of silver (15nm) and silica (30nm) via electron-beam evaporation. 2D h mms consist of a well-ordered array of vertically oriented silver nanowires embedded in an anodic aluminum oxide (AAO) matrix. Such structures are synthesized by combining an electrochemical self-assembly process with electrodeposition technique. Structural parameters of such 2d h mm s can be tuned by the self-assembly parameters and for this study nanowire diameter is ~30nm, length ~ 500nm and inter nanowire spacing is ~60nm.

8806-10, Session 2

Control of spontaneous emission spectra by hyperbolic metamaterials

Lei Gu, Thejaswi U. Tumkur, Guohua Zhu, Mikhail A. Noginov, Norfolk State Univ. (United States)

High density of photonic states in metamaterials with hyperbolic dispersion is known to enhance spontaneous emission rates. At this time, we demonstrate that hyperbolic metamaterials can control emission spectra as well. Experimentally, DCM and R6G dyes were embedded into lamellar metal/dielectric metamaterials. The observed ≈18 nm blue shift of emission is explained by strong dispersion of the density of photonic states. On the other hand, practically no spectral shifts were observed in the excitation spectra of the same dyes. This implies different effect (or an absence of the effect) of the density of photonic states on absorption than on emission.

8806-11, Session 3

Optic spin hall effect at metasurfaces *(Invited Paper)*

Xiang Zhang, Univ. of California, Berkeley (United States)

The relativistic spin-orbit coupling of electrons results in intrinsic spin precessions and therefore spin-polarization-dependent transverse currents, leading to the observation of spin Hall effect (SHE) and the emerging field of spintronics. The coupling between charge's spin degree of freedom and its orbital movement is essentially identical to the coupling of the transverse electric and magnetic components of a propagating electromagnetic filed. To conserve total angular momentum, an inhomogeneity of material's index of refraction can cause momentum transfer between the orbital and the spin angular momentum of light along its propagation trajectory, resulting in a transverse splitting in polarizations. Such a photonic spin Hall effect (PSHE) was recently proposed theoretically to describe the spin-orbit interaction, the geometric phase, and the precession of polarization in weakly inhomogeneous media as well as the interfaces between homogenous media. Here we demonstrate experimentally the strong interactions between the spin and the orbital momentum of light in a thin metasurface ? a two-dimensional electromagnetic nano-structure with designed in-plane phase retardation over the wavelength scale. In such an optically thin material, the resonance-induced anomalous “skew-scattering” of light destroys the axial symmetry of the system and we observed PSHE even at the normal incidence. In stark contrast, for conventional interfaces between two homogeneous media, the spin-orbit coupling does not exist at the normal incidence.

8806-12, Session 3

Device applications of metafilms and metasurfaces *(Invited Paper)*

Mark Brongersma, Geballe Lab. for Advanced Materials (GLAM) (United States)

Many conventional optoelectronic devices consist of thin, stacked films of metals and semiconductors. In this presentation, I will illustrate how one can improve the performance of such devices by nano-patterning the constituent layers at length scales well below the wavelength of light. The resulting metafilms and metasurfaces offer opportunities to dramatically modify optical transmission and reflection properties and enhance light-matter interactions. To illustrate these points, I will show how nanopatterned metals and semiconductor layers can be used to enhance the performance of photodetectors and solar cells.

8806-13, Session 3

Holographic metasurfaces *(Invited Paper)*

Patrice Genevet, Harvard School of Engineering and Applied Sciences (United States); Jiao Lin, A*STAR (Singapore); Jean Dellinger, Benoit Cluzel, Univ. de Bourgogne (France); Mikhail A. Kats, Harvard School of Engineering and Applied Sciences (United States); Frédérique A. de Fornel, Univ. de Bourgogne (France); Federico Capasso, Harvard School of Engineering and Applied Sciences (United States)

Plasmonic gratings and plasmonic lenses are routinely used to convert free-space beams into propagating surface waves and vice versa. So far, this approach has been limited to simple light beams, such as plane waves or Gaussian beams. I will present a powerful generalization of plasmonic structures to couple more complex wavefronts. This approach is based on the principle of holography: the coupler is designed as the interference pattern of the incident vortex beam and focused SPPs. We have integrated these holographic plasmonic interfaces into commercial silicon photodiodes, and demonstrated that such devices can selectively detect the orbital angular momentum of light. We also introduced, the cosine-Gauss beam, which does not diffract while it propagates in a straight line and tightly bound to the metallic surface. The generation of this highly localized wave is shown to be straightforward and highly controllable, with varying degrees of transverse confinement and directionality, by fabricating a plasmon launcher consisting of intersecting metallic gratings. By analogy to the three dimensional optical bottle beams, we introduce a two dimensional surface wave which features oscillating dark focuses surrounded by regions of higher intensity. This beam is a created by superposing the two-dimensional nondiffracting cosine-Gauss beam, characterized by a constant on-axis slow phase velocity, and a quasi-plane wave. This approach might find interesting applications in plasmonic trapping, by creating two dimensional arrays of intensity hot spots in the close vicinity to metallic interfaces.

8806-14, Session 3

Experimental validation of a new bianisotropic parameter retrieval technique using plasmonic metasurfaces made of V-shape antennas

Jingjing Liu, Amr M. Shaltout, Purdue Univ. (United States); Xingjie Ni, Purdue Univ. (United States) and Univ. of California, Berkeley (United States); Vladimir M. Shalaev, Alexander V. Kildishev, Purdue Univ. (United States)

We report on an experimental and theoretical study of Babinet's principle for v-shape antenna metasurfaces at optical frequencies. Large dimension arrays of nano-voids are fabricated using electron beam lithography. Experiments demonstrate that angular positions of diffracted cross-polarized light are the same for the regular and Babinet-inverted design. Furthermore, the Babinet-inverted design greatly increases the extinction ratio. Also, each antenna element with a discrete phase shift is modeled by a homogenous bianisotropic film to represent the optical response. We find a complementary relationship in the effective permittivity. This relationship gives a correspondence between the spectral positions of the eigenmodes and the positions of the effective permittivity resonances. It also explains the observations that the best performing wavelength of cross-polarized scattered light is blue shifted for the complementary design compared to its regular counterpart. Since the effective bianisotropic parameters of each antenna element produce the same response to incident plain waves as the full-wave simulations, theoretically we could unite different elements to compose a patch antenna array which forms a metasurface capable of bending the light abnormally. It provides a shortcut to observe the coupling effects between adjacent antennas and to simulate the response of the whole device. Simulations show that two adjacent antennas will couple with each other so that the final design does not have the same local response as a single antenna. The experiments also show that the device has a high extinction ratio when the coupling effect is weak.

8806-15, Session 4

Graphene metamaterials *(Invited Paper)*

Javier García de Abajo, ICFO-Institut de Ciencies Fotoniques (Spain)

Graphene offers great opportunities as a novel platform for electrically tunable, ultrathin metamaterials. We will review recent advances and opportunities in the field of graphene metamaterials, including applications to optical modulations and sensing.

8806-16, Session 4

Time domain modeling of metasurfaces with graphene *(Invited Paper)*

Ludmila J. Prokopeva, Alexander V. Kildishev, Naresh K. Emani, Purdue Univ. (United States); Alexandra Boltasseva, Purdue Univ. (United States) and Technical Univ. of Denmark (Denmark)

Graphene is an interesting elemental material due to the properties of its dielectric function. Permittivity of graphene depends on chemical potential and temperature and can be electrically controlled by the applied bias voltage, [1-3]. Thus, the transmission of a bare graphene sheet can be changed by approximately 1% by applying a gate voltage, see [2-3]. Further, it has been shown that with local field enhancement the induced change can be as high as 30% for resonance frequency of bowtie antenna metasurface [2]. A time-domain phenomenological parametric model of the tunable dielectric function of graphene is imperative for accurate numerical simulations of time-resolved multiphysics, including studies of nonlinear optical response of grahene-based tunable photonic devices with metamaterials or metasurfaces. However, precise time domain modeling of graphene is complicated with the integral expressions of dielectric function. Integrals have to be accurately approximated and effectively evaluated numerically for broadband wavelength operation within desired ranges of tunable parameters such as chemical potential and temperature.

In this paper an accurate causal broadband time domain model for optical response of graphene, consisted of the Drude term and a number of critical point terms, is presented [4]. The model can be used for time domain simulations with FDTD, FETD, FVTD Maxwell's solvers. Example applications of time-domain modeling of the graphene-based tunable devices are discussed.

8806-17, Session 4

Time-domain multiphysics of silver nanowires-graphene transparent conducting electrodes

Jieran Fang, Suprem R. Das, Ludmila J. Prokopeva, Vladimir M. Shalaev, David B. Janes, Alexander V. Kildishev, Purdue Univ. (United States)

It has been already shown that transparent conducting electrodes (TCE) constructed of silver nanowires (SNW) co-percolated with a single-layer graphene (SLG) cover have higher optical transparency and lower sheet resistance than commercially-available ITO and are comparable to the best reported results in TCEs [1]. Numerical analysis of the multiphysics of SNW-SLG electrodes is built on the broadband 3D FDTD simulations, coupled to auxiliary equations describing the optical responses of the SLG cover and a layer of randomly distributed SNW.

To approximate the dielectric function of SLG we fit the Drude – Continuous Critical points (DCCP) model [2] to the experimental transmittance and reflectance data from SLG samples. The numerical implementation of the individual terms of the DCCP model follows [3].

Bare and SLG-covered random SNW layers are simulated using the spectral averaging of the FDTD transmittance and reflectance data from individual indiscriminately selected frames [4]. Numerical simulations are done for a number of frames until a convergent set of averaged spectra is obtained. Details and future trends of these experiment-fit simulations are discussed.

Molding Optical Wavefronts: Flat Optics Based on Metasurfaces

Federico Capasso, Harvard School of Engineering and Applied Sciences (United States)

Metasurfaces based on sub-wavelength patterning have major potential for realizing arbitrary control of the wavefront of the diffracted light by achieving local control of the phase amplitude and polarization. We discuss novel devices based on this technique; a salient feature is the ability to create often with a single digital mask an arbitrary analog phase profile. A variety of flat optical components, including lenses, polarizers, vortex plates, coatings, holograms and couplers with polarization invariant coupling efficiency will be presented.

8806-301,

From Photonic Metamaterials to Metadevices: Exploiting Forces and Fields at the Nanoscale

Nikolay I. Zheludev, Univ. of Southampton (United Kingdom) and Nanyang Technological Univ. (Singapore)

Metamaterials, artificial electromagnetic media achieved by structuring on the subwavelength scale, were initially suggested as negative index

media for the "superlens" and for transforming electromagnetic space to control propagation of waves. The research agenda is now shifting to achieving tunable, switchable, nonlinear and sensing functionalities using metamaterails. We show how engaging the changing balance of forces, structural transformation, light confinement and quantum effects at the nanoscale bring about the emerging field of metadevices. We define metadevices as devices with unique and useful functionalities achieved by structuring of functional matter on the subwavelength scale.

8806-302,

Recent Progress in Photonic Crystals

Susumu Noda, Kyoto Univ. (Japan)

I will talk about recent progress in photonic crystals. First of all, I will discuss on the progress in 2D photonic crystals, where the focus is on the thermal emission control which is important for energy harvesting. Next, I will discuss about on-demand 3D guiding of photons in 3D photonic crystals, which have been a long dream. Then, I will describe the other interesting topics, including ultrahigh-Q nanocavities, stopping light, ultra-small Si Raman lasers, SiC photonics, unique 2D lasers, etc.

8806-18, Session 5

Low-loss localized surface phonon polariton modes in silicon carbide nanopillars: beyond plasmonics *(Invited Paper)*

Joshua D. Caldwell, U.S. Naval Research Lab. (United States); Yan Francescato, Imperial College London (United Kingdom); Orest J. Glembocki, U.S. Naval Research Lab. (United States); Nicholas Sharac, Univ. of California, Irvine (United States); Francisco J. Bezares, U.S. Naval Research Lab. (United States); Vincenzo Giannini, Imperial College London (United Kingdom); James P. Long, Jeffrey C. Owrutsky, Joseph G. Tischler, Igor Vurgaftman, U.S. Naval Research Lab. (United States); Stefan A. Maier, Imperial College London (United Kingdom); Virginia D. Wheeler, Loretta Shirey, Nabil D. Bassim, U.S. Naval Research Lab. (United States); Richard Kasica, National Institute of Standards and Technology (United States); Chase Ellis, U.S. Naval Research Lab. (United States)

Over the past decade, significant effort has been focused on the field of plasmonics and its applications in enhanced spectroscopy, light emitters, waveguides, and absorbers for photodetectors. However, while plasmonic systems have attracted attention for their ability to achieve extreme sub-diffraction limit confinement with large concentrations of optical energy, they are severely limited by the inherent ohmic losses due to the high carrier densities within metals. Therefore, it is desirable to identify new materials capable of supporting electromagnetic modes below the diffraction limit without excessive loss. We report on the observation of localized surface-phonon (SPhP) polariton resonances in 800-nm-tall nanopillars fabricated from semi-insulating 6H- and 4H-silicon carbide with diameters of 150-260 nm and 1 µm, respectively. These localized SPhP resonances exhibit exceptionally narrow linewidths of 7-24 cm< sup>-1< /sup>, corresponding to quality factors in the 40-140 range. Such high Q-factors, coupled with the small modal volumes that are 15-50x smaller than the incident wavelength, result in what is to our knowledge the highest potential Purcell factors reported to date for nanoscale resonators, with values between (2-7)x10< sup>5< / sup>. These exceptional properties are the result of the long lifetimes of the optical phonons supporting these oscillations. The performance of these initial structures point to what is possible with SPhP systems. With SiC in particular, these resonances should prove useful for military and commercial applications because they occur in the 8-12 µm, infrared atmospheric window, which also overlaps the spectral band of a wide array of molecular vibrations.

8806-19, Session 5

Non-Hermitian plasmonics *(Invited Paper)*

Pavel Ginzburg, Anatoly V. Zayats, King's College London (United Kingdom)

Optical properties of plasmonic nanostructures may exhibit counterintuitive manifestations of the dissipative dynamics of the inherently lossy electron system of a metal. Their dissipative evolution can be described within non-Hermitian formulation of quantum mechanics. Here, we will overview recent theoretical approaches to dissipation in plasmonic systems. Based on these non-Hermitian theories, we will discuss plasmonic analogues of some quantum effects and their applications in photonics, concentrating on quantum Hanle effects due to dissipative coupling in plasmonic metamaterials, and non-Markovian dynamics of plasmonic dark modes. In the standard quantum Hanle effect, time-reversal symmetry is broken by a static magnetic field. We will show that similar effect in plasmonics could be achieved by introducing dissipative level crossing of localized surface plasmons due to nonuniform losses, designed using a non-Hermitian formulation of quantum mechanics. Such metamaterial has been shown to exhibit strong circular birefringence and circular dichroism which depends on the value of loss or gain in the metal-dielectric nanostructure. It will also be shown that the dynamics of the weakly coupled to radiation (dark) modes of subwavelength plasmonic nanostructures may be strongly nonexponential and their lifetime can be overestimated by conventional exponential relaxation time obtained in the standard Markovian approximation.

8806-20, Session 5

Optical metamaterials based on plasmonic nanoparticle chains *(Invited Paper)*

Koray Aydin, Northwestern Univ. (United States)

Metal nanostructures support localized plasmon resonances at optical frequencies that can be controlled by changing their size, shape and dielectric permittivity of the environment. The field of plasmonics is dedicated to the study of optical properties of various metal nanostructures including chemically synthesized metal nanoparticles (bottom-up), as well as top-down fabricated metallic gratings, antennas and nanostructure arrays. Similarly, optical metamaterials are composed of metal nanostructures with unique geometries, therefore facilitating localized electric and/or magnetic resonances. Initially, the fields of plasmonics and metamaterials progressed as two separate disciplines with little overlap. However, after the realization of optical metamaterials using plasmonic (gold and silver) nanostructures, the interactions between these two fields of nanoscience increase drastically. In this talk, I will describe novel metamaterial building blocks that are composed of gold nanoparticles rather than top-down fabricated conventional metamaterial elements. Comparisons will be made with conventional metamaterials and nanoparticle based metamaterials. Our simulations predict drastic red-shift of metamaterial resonances of optical-antenna and split-ring resonator shaped nanoparticle chains due to increased effective inductance. Nanoparticle chain metamaterials operate at a broader wavelength range, are much smaller than corresponding continuous metal-bar shaped resonators, are less lossy and have higher localized electric fields, making them attractive for a variety of applications including sensing, light-trapping, and optical filters.

8806-21, Session 5

Functional nanostructures for plasmonic sensing and energy applications *(Invited Paper)*

Wei Ting Chen, Ming Lun Tseng, Yao-Wei Huang, Pin Chieh Wu, National Taiwan Univ. (Taiwan); Kuang-Yu Yang, Academia Sinica (Taiwan); Chia Min Chang, National Taiwan Univ. In this talk, we give some practical applications such as molecular sensing, and photocatalytic water splitting that based on plasmonic nanostructures. The plasmonic nanostructures can be achieved via fs-laser direct writing and laser induced forward transfer techniques with high-throughput [1]. We demonstrated the surface-enhanced Raman scattering measurement (SERS) of molecules on Ag nanostructures and shown the high intensity that resulting from fine plasmonic enhancements and identical plasmonic hotspots, the processed AgOx thin films exhibit broad-band enhancement of optical absorption and effectively function as active SERS substrates. Probing of the plasmonic hotspots with dyed polymer beads indicates that these hotspots are uniformly distributed over the treated area [2]. We will also show that the AgOx thin film treated by fs-laser, which can be used as plasmonic layer to enhance the efficiency of photocatalytic process [3]. The photocurrent of ZnO/Ag plasmonic photoelectrode shows an 85 % enhancement in comparison with the photocurrent of ZnO photoelectrode only. Both localized surface plasmon resonance in metal nanoparticles and plasmon polaritons propagating at the metal/semiconductor interface are available for improving the capture of sunlight and collecting of charge carrier. Furthermore, in-situ X-ray absorption spectroscopy was performed to monitor the plasmonic-generating electromagnetic field upon the interface between ZnO/Ag nanostructures as well. This can reveal inducing vacancies on conduction band of ZnO, which allow effectively separating charge carriers and improve the efficiency of hydrogen generation. Plasmon-induced effects simultaneously enhanced the photoresponse, by both improving optical absorbance and facilitating the separation of charge carriers. These results offer a low-cost and high-efficiency approach to develop plasmonic nanostructures for sensing and energy applications.

Applications of plasmonic nanostructures for linear and nonlinear optics *(Invited Paper)*

Augustine M. Urbas, Vitaliy Pustovit, Dean P. Brown, Air Force Research Lab. (United States)

Abstract- Metamaterials in optical frequencies have a tremendous range of application, many of which require large area materials with fine features. Self assembly can provide an efficient route to fabricating structured optical metamaterials. From enabling fundamentally new effects, such as optical magnetism, to creating tailored absorption and transmission spectra, designing optical properties through structure offers a new mechanism for manipulating light. These systems require nanometric features on structures frequently below 100nm in size in order to gain the desired properties set. Various approaches can be used to create these structures and incorporate active materials into them for device applications. Self assembled systems can be used either directly as metamateials or as templating structures to create ordered arrays of meta-atoms. In addition, these techniques can be applied at the unit cell level to create complex, structured and active metamaterials. In this presentation, I will describe efforts to utilize self assembly techniques to create optical metamaterials. Systems designed to control fluorescence, nonlinear properties and optical absorption will be discussed. Based on the properties and local field control offered by these structures, I will also explore applications which can benefit from optical nanostructures, such as enhanced detectors

8806-23, Session 5

Raman plasmons in metal nanostructures

Andrey K. Sarychev, Institute for Theoretical and Applied Electrodynamics (Russian Federation); Sergei O. Boyarincev, Moscow Institute of Physics and Technology (Russian Federation)

We consider local optical field in the systems of metal nanoparticles. In particular, we are interested in the local electric field in the metal clusters and aggregates that have fractal structure. The metal fractals are formed, for example, in the semicontinuous metal film and in colloidal suspensions of metal nanoparticles. The light excites surface plasmons in the metal fractal and the system operates as a set of plasmon nanoantennas. Localization of plasmons results in giant fluctuation of the local electric field. Consider the Raman active molecules deposited on the metal particles. The molecules are excited by plasmons and operate as incoherent sources of the secondary electromagnetic field, which frequency is different from the frequency of the prime field by the Stokes shift. Thus, we obtain the surface enhanced Raman scattering (SERS) but also the plasmons excited by the dipoles of the Raman molecules. We use the original computer method to calculate the field of Raman plasmons in various fractals. It appears that the Raman plasmon is localized near the fractal. The fluctuations of the Raman local electric field are even larger than fluctuations of the primary field. Moreover, the spatial correlation functions of the Raman plasmons in the metal fractals are different from that of the prime plasmons. We find the distribution of the Raman plasmons in semicontinuous metal films and metal aggregates and show that these plasmons can be observed in the nearfield experiment.

Electric and magnetic dipole radiation in hyperbolic metamaterials *(Invited Paper)*

Alexander N. Poddubny, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation) and Ioffe Physical-Technical Institute (Russian Federation); Pavel A. Belov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Yuri S. Kivshar, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation) and Australian National Univ. (Australia)

Hyperbolic medium is a uniaxial medium where the longitudinal and transverse dielectric constants are of opposite signs. Its distinct feature is the hyperbolic surface of the wavevectors, corresponding to the extraordinary mode of given frequency. Specific properties of such hyperbolic materials include giant enhancement of the spontaneous emission and light-matter interaction due to the (ideally) diverging density of photonic states.

Here we focus on the Purcell enhancement of the spontaneous emission rate for both electric and magnetic dipole sources embedded in hyperbolic metamaterials. It is shown that the Purcell effect is strongly sensitive to the emitter type and orientation. We analyze different metamaterial realizations, including layered metal-dielectric structures, wire medium and arrays of split-ring resonators. Analytical estimates and numerical answers are provided for structures operating in both microwave and optical spectral ranges.

We also present comprehensive analysis of the electromagnetic Green function in hyperbolic metamaterials. Spatial distribution of the Green function has a peculiar cone-like shape. Validity of the local effective-medium approximation is examined. Additional spatial modulation of the point source emission pattern, arising due to nonlocality, is demonstrated. Interplay between the Purcell enhancement of spontaneous emission from single emitter and the Foerster resonant energy transfer between two quantum emitters is investigated for hyperbolic medium.

8806-25, Session 6

Angular distribution of emission from hyperbolic metamaterials

Lei Gu, J. E. Livenere, Guohua Zhu, Thejaswi U. Tumkur, Norfolk State Univ. (United States); Sharka M. Prokes, U.S. Naval Research Lab. (United States); Brian Wells, Viktor A. Podolskiy, Univ. of Massachusetts Lowell (United States); Cristian L. Cortes, Zubin Jacob, Univ. of Alberta (Canada); Mikhail A. Noginov, Norfolk State Univ. (United States)

Metamaterials with hyperbolic dispersion have high density of photonic states and can control spontaneous emission of molecules or quantum dots deposited on the top or embedded inside these materials. Until now, most of the studies in this area have been devoted to emission kinetics and spontaneous emission rates. At this time, we report on theoretical and experimental studies of angular distribution patterns of spontaneous emission from metamaterials with hyperbolic dispersion.

8806-26, Session 6

Collective spontaneous emission effects in semiconductor hyperbolic metamaterials

Prashant Shekhar, Zubin Jacob, Univ. of Alberta (Canada)

We show strong coupling between intersubband transitions (ISBTs) and the high-k modes of a semiconductor hyperbolic metamaterial (HMM). These high-k modes, modes with large wavevectors normally evanescent in conventional materials, can propagate in the semiconductor HMM leading to novel collective absorption and emission effects. We analyze a metal- dielectric multilayer structure consisting of a highly doped n+-InGaAs layer as the metal. Each dielectric layer consists of an Al0.35Ga0.65As and GaAs multiple quantum well slab acting as an active dielectric layer. Strong coupling and characteristic anticrossing with a maximum vacuum rabi splitting (VRS) energy of up to 104 [meV] was observed between the high-k mode of the semiconductor HMM and the ISBT, a value approximately 21 times greater than the ISBT linewidth. Strong coupling is achieved with multiple high-k modes forming a series of 'high-k-ISBT polaritons'. It is found that the magnitude of the VRS energy decreases with increasing high-k mode number and can also be tuned on and off completely by modulation of the semiconductor electron density. The spectral location of the anti-crossing behaviour, can also be pre-tuned during fabrication via control of the ISBT transition energy through the quantum well and barrier thicknesses as well as the semiconductor doping density. This scalability and tunability of the VRS energy available in semiconductor HMMs have potential applications in quantum well infrared photodetectors and tunable intersubband light-emitting devices. Our work lays the foundation for semiconductor based collective spontaneous emission and absorption processes in hMMs.

8806-27, Session 6

Optical properties of metal-dielectric based epsilon near zero metamaterials

Ganapathi S. Subramania, Sandia National Labs. (United States) and Univ. of New Mexico (United States); Arthur J. Fischer, Sandia National Labs. (United States); Ting S. Luk, Sandia National Labs. (United States) and The Ctr. for Integrated Nanotechnologies (United States)

Epsilon near zero(ENZ) materials are metamaterials where the effective dielectric constantis close to zero for a range of wavelengths resulting in zero effective displacement field (D) and displacement current. ENZ structures are of great interest in many application areas such as optical nanocircuits, supercoupling, sub-diffraction imaging, cloaking, emission enhancement etc. Effective ENZ behavior has been demonstrated using cut-off frequency region in a metallic waveguide where the modal index vanishes. Here we demonstrate the fabrication of ENZ metamaterials operating at visible wavelengths (lambda~ 640nm) using an effective medium approach based on a metal-dielectric composites. This structure is more suitable where a bulk ENZ material is required such as for etching grooves to create optical connecting 'wires' for optical nanocircuits. The structure consists of a multilayer stack composite of alternating nanoscale thickness layers of Ag and TiO2. Optical spectroscopy shows transmission and absorption response is consistent with ENZ behavior and matches well with simulations. We will discuss the criteria necessary in the design and practical implementation of the composite that better approximates a homogenous effective medium. We will also discuss techniques such as the subwavelength gratings that minimize the effect of optical losses to boost transmission. The potential for hosting gain media in the gratings to address losses as well as emission control will be discussed.

Sandia National Laboratories is a multi-program laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000.

8806-28, Session 6

Power emitted by a two-dimensional periodic array of sources at the surface of a hyperbolic metamaterial

Caner Guclu, Salvatore Campione, Filippo Capolino, Univ. of California, Irvine (United States)

Hyperbolic metamaterials (HMs) exhibit hyperbolic iso-frequency wavevector dispersion and theoretically host an unbounded spatial spectrum of waves that can propagate within the HM. However, practical realizations of HMs impose a maximum transversal propagating wavenumber. Recently, many studies demonstrated that one can achieve a propagating spectrum in HMs much wider than the spectrum of propagation in free space by using subwavelength-thick alternating layers of metals and dielectrics at infrared and optical frequencies. This unusually wide spectrum achieved in a wide frequency band is shown to enhance the emitted power by a single imposed dipole in proximity of HMs, as well as the scattered power by a nanosphere located on top of HMs. In both cases, most of the power is directed toward the HM itself. Previous experimental work showed that placing many scatterers on HMs may lead to unprecedented absorption properties. We develop here a theoretical framework to assess the capabilities and limitations of using HMs in such designs. Indeed, it is of utmost importance to model the effect of numerous sources or scatterers for the enhancement of emitted or scattered power and its redistribution toward the HM, which might lead to novel absorber designs. In this work, we investigate the power emitted by a two-dimensional periodic array of impressed sources in proximity of HMs by using an analytic approach that employs Green's functions and spectral theory. The results drawn in this study are of key importance for future work related to a periodic set of scatterers on top of HMs.

8806-30, Session 6

Enhancement of scattered power by microscatterers and near-field absorption at the surface of graphene-based hyperbolic metamaterial

Mohamed A. Othman, Caner Guclu, Filippo Capolino, Univ. of California, Irvine (United States)

Hyperbolic metamaterials (HMs) are recently studied for the enhanced absorption of near-fields generated at their surface, taking advantage of the propagating spatial spectrum in HMs which is much wider than the propagating spectrum in free space. Practical realizations of HMs at optical frequencies utilize subwavelength-thin metal-dielectric layers for enhancing the scattered power by passive nanoparticles in the vicinity of HMs, where most of the power is directed toward the HM side. Recently, graphene-based HMs comprising graphene-dielectric layers are proposed at far- and mid-infrared frequencies, taking advantage of graphene as a low loss inductive constitutive layer offering a great opportunity for controlling the hyperbolic dispersion properties via biasing with static fields, and thus designing tunable HMs. In this work, we explore the scattered power enhancement by passive microscatterers at the surface of graphene-based HM, and power absorption by the HM. Moreover we investigate the tunability of the dispersion characteristics of the graphene-based HM using both electrostatic and magnetostatic biasing, and we report the control of the scattered power enhancement. The key parameters on the HM design with graphene are discussed and their impacts on the tunability and absorption capabilities of the metamaterial are quantified. The effective parameters of the multilayers are derived for the graphene-based HM under bias and they are shown to predict the hyperbolic dispersion regime and near-field absorption features, in good agreement with the transfer matrix analysis.

8806-31, Session 6

Realistic electric field modeling of multilayered nanostructures by classic electrodynamics and first principles theory

Vladimir I. Gavrilenko, Alexander V. Gavrilenko, Norfolk State Univ. (United States); Ludmila G. Ilchenko, Vasyl V. Ilchenko, National Taras Shevchenko Univ. of Kyiv (Ukraine)

Typical metamaterial structures are composed from periodic pattern of conductive and non-conductive components. Efficient engineering of metamaterials involves modeling of electric field profiles around these structures. Realistic modeling of the electric field in metamaterials requires accurate knowledge of optical constants of the components for which traditionally the bulk values are taken. Further progress in the developing of metamaterials is characterized by a reduction of the pattern size, dimensions of single layers in multilayered structures etc. It has been understood that optical functions in low-dimensional and nano-sized materials substantially differ from their bulk values increasingly affecting by quantum processes.

In this work we develop a complex method for analytical modeling of electric field profiles in metamaterials including quantum processes in nano-sized multi-layered structures. In particular based on first principles density functional theory we obtained simple analytical functions allowing predictions the optical functions variations with the size reduction of single metamaterial components over a wide spectral region. It is shown that optical functions of nano-sized films substantially (by 50 percent and more) differ from those in bulk. The new calculated optical functions of the components are used for electric field profile modeling of nano-sized multilayered structures by nonlocal Green function technique including effects of spatial dispersion. Silicon, silicon dioxide, and water layers are used as an example. The method effectively incorporates real atomic structure reconstruction on surfaces and inner interfaces thus providing with a more realistic picture for modeling. By comparison with experiment it is demonstrated that our method predicts image potential of the nanostructures in better agreement with experiment than if using traditional classic electrodynamics approach neglecting the quantum effects. The results are discussed in comparison with literature

8806-32, Session 7

Mapping the properties of plasmonic and metamaterial structures in the near field *(Invited Paper)*

Uriel Levy, Avner Yanai, Meir Grajower, Boris Desiatov, Ilya Goykhman, Liron Stern, The Hebrew Univ. of Jerusalem (Israel)

In this talk we present our recent experimental results showing the mapping of plasmonic and metamaterial structures in the near field. For example, we will demonstrate strong heating of metallic and metallo-dielectric structures by probing the structures with a thermocouple tip in the near field. The experimental results will be explained by electromagnetic and heat simulations.

8806-33, Session 7

A characterization study of highly tailorable 3D metamaterials in the thermal infrared for selective emission behaviors

Bryan M. Adomanis, Air Force Institute of Technology (United States); D. Bruce Burckel, Sandia National Labs. (United States); Michael A. Marciniak, Air Force Institute of Technology (United States)

The spectral and directive behaviors of highly tailorable thermal infrared metamaterials were characterized between 6-20µm wavelengths and 0-50-degree incidence angles, through finite-difference time domain (FDTD) simulation and spectroscopic measurements. Sandia National Laboratories fabricated true 3-D metamaterial unit cells using the membrane projection lithography (MPL) phenomenology. The 1cm^2 samples consisted of gold bent dipoles evaporated inside 5µm cubic cavities on a 6µm pitch in an SU-8 photoresist substrate. Three samples contained bent dipoles with 5µm total length and upper/lower dipole fractions of 90/10, 50/50 and 20/80; samples with a purely vertical or purely horizontal dipole of 4µm each were also fabricated as the control. SEM images exposed significant cavity warpage in all samples, producing localized non-uniformity of the dipoles. Both measurement and simulation for multiple polarization/dipole orientation states confirmed the existence of dipole resonances, though fabrication errors led to spectral broadening and reduced intensity in measurements. For states with fields polarized parallel to the dipole moment, the dominant mode was a broad fundamental electrical mode, which compared well to simulations. A slightly weaker, sharper, higher-frequency plasmonic mode was clearly present in simulation for states with perpendicular polarizations, but was visible only in measurements which did not have dominant electrical modes. As incident angle increased, the modes shifted to longer wavelengths along the incident-angle/wavelength Bragg diffraction edge. Finally, the samples were heated to 150 degrees C and directional emittance was calculated from spectral radiance measurements, and found to be in good agreement spectrally with a Kirchoff emittance calculated from transmittance and reflectance measurements.

8806-34, Session 7

Directional thermal emission from a leaky-wave frequency-selective surface

Edward C. Kinzel, Missouri Univ. of Science and Technology (United States); James C. Ginn, Plasmonics, Inc. (United States); Eric Z. Tucker, Jeffrey A. D'Archangel, The Univ. of North

Carolina at Charlotte (United States); Louis A. Florence, U.S. Military Academy (United States); Brian A. Lail, Florida Institute of Technology (United States); Glenn D. Boreman, The Univ. of North Carolina at Charlotte (United States)

We designed and characterized a Frequency Selective Surface Metamaterial for directional emission at 9.8 µm. The design consists of an array of Au patch antennas and microstrips, both separated from a Au ground plane with a ZnS standoff. We patterned a 2x2 cm structure using lift-off and e-beam lithography so that the absorptance could be measured in the far-field using a hemispherical directional reflectormeter (HDR). These experimental results showed good spectral/directional agreement with Finite Element numerical simulations of the structure (Ansoft HFSS). The structure supports guided leaky-wave type modes with forward and backward propagating branches which couple to TM polarized radiation. These branches intersect at the design wavelength, where the surface has a broadside beam with 20° FWHM. The principle branches of the structure show near-unity absorptance. While the physics of the surface are similar in some respects to coherent emission from gratings, the field in the leaky-wave surface is well confined in guided modes bound in the standoff and is not based on diffraction. This makes the surface well suited to sensing applications as well as engineering the radiation heat-transfer properties of the surface.

8806-35, Session 7

Multiplex-bands spectral characteristics of infrared perfect absorber metamaterials

Yongqian Li, Lei Su, Binbin Wang, Yongjun Guo, Jinglong Wang, Northwestern Polytechnical Univ. (China)

Much of the work on the perfect absorber metamaterials focused on overcoming the narrowband limit through multi-resonance or broadband structures. The multiple structure mechanism and the multi-resonant structures have been experimentally demonstrated last decades, by creating unit cells that resonant responses occur at more than one frequency, using lumped resistance elements or exploiting higher order modes of a single resonant structure. These designs utilize single unit cell that resonates at different spatial areas or two structures resonating separately for different frequencies.

There are some furthermore mechanisms to develop such a multiplex resonance research of the metamaterials. In this research, the multiplex absorption metamaterials elements (such as asymmetric cross and metallic rectangle blocks arrays) at mid-infrared realm were investigated through the analysis of their optical parameters and the polarization incident configuration. The orthorhombic polarization configurations play a role of multiplex resonant wavelength contributor as well as a switcher. Similar with the perfect absorber metamaterials, the designed nanostructure consists of metallic cross (or square) structure and a metallic ground plane separated with a dielectric between them, as shown in Fig.1 (a). The strong multiplex resonances at infrared frequency (2µm -10µm) were interpreted through the physical modes and the experimental verification. We experimentally realized that there were multiplex narrow-band infrared absorption peaks in several types of perfect absorber metamaterials, such as that listed in Fig.2. Both the interpretations and the analysis mode of the electromagnetic permittivity and permeability for kinds of the perfect absorber metamaterials have been adopted to explain the consistence of the multiplex resonance wavelength and their optical parameters. Through the performing of the absorption measurements, we try to explain the multiplex-band resonant spectra of the PAMs through our models built, which may directly interpretate other interactions of the nanostructure tailoring the electromagnetic spectrum.

8806-36, Session 7

3D CMOS-compatible plasmonic and metamaterial structures

D. Bruce Burckel, Sandia National Labs. (United States)

Recently we have demonstrated membrane projection lithography (MPL) as a fabrication approach capable of creating 3D structures with sub-micron metallic inclusions for use in metamaterial and plasmonic applications using polymer material systems[1-3]. While polymers provide several advantages in processing, they are soft and subject to stress-induced buckling. Furthermore, in next generation active photonic structures, integration of photonic components with CMOS electronics is desirable. While the MPL process flow is conceptually simple, it requires matrix, membrane and backfill materials with orthogonal processing deposition/removal chemistries. By transitioning the MPL process flow into an entirely inorganic material set based around silicon and standard CMOS-compatible materials, several elements of silicon microelectronics can be integrated into photonic devices at the unit-cell scale. This paper will present detailed fabrication and characterization data of these materials, emphasizing the processing trade space as well as optical characterization of the resulting structures.

Supported by the Laboratory Directed Research and Development program at Sandia National Laboratories. 8806-37, Session 7

Negative differential thermal emitter

Mikhail A. Kats, Romain Blanchard, Shuyan Zhang, Patrice Genevet, Changhyun Ko, Shriram Ramanathan, Federico Capasso, Harvard School of Engineering and Applied Sciences (United States)

Thermal radiation is light that is spontaneously emitted from an object at a temperature above absolute zero. The spectrum and intensity of thermal radiation are a function of temperature and the emissivity of the object, which is frequency-dependent, as expressed in Planck's law. Integrating over all frequencies the Stefan-Boltzmann law of thermal radiation is obtained, which states that the total energy density emitted is proportional to the fourth power of temperature. This is congruent with every-day experiences that hotter objects emit more light, corresponding to a strictly positive differential thermal emittance.

We show that the differential thermal emittance can become negative in a geometry which exhibits an absorption resonance that can appear and disappear as a function of temperature. Our geometry involves a thin (~150 nm) film of vanadium oxide (VO2), a phase change material, on a sapphire substrate. Recently, we showed that a film of VO2 deposited on sapphire can operate as a temperature-tunable absorber. As absorptivity and thermal emissivity are related, such a structure is expected to have a temperature-dependent emissivity.

We measured the thermal emission from our VO2/sapphire samples over the 8-14 µm window, and observed that in the vicinity of the IMT the sample exhibits a large negative thermal emittance. Imaging with a thermal camera shows that the sample appears cooler even as it is heating up over the 73 – 85 °C range. This phenomenon can find uses in applications such as infrared camouflage and thermal tagging/identification.

8806-38, Session 7

Control near- and far-field thermal radiation with nanophotonic concepts *(Invited Paper)*

Shanhui Fan, Zongfu Yu, Nicholas P. Sergeant, Stanford Univ. (United States); Torbjorn Skauli, Norwegian Defence Research Establishment (Norway); Gang Zhang, Peking Univ. (China); Hailiang Wang, Eden Rephaeli, Aaswath P. Raman, Stanford Univ. (United States)

We present some of our recent works on using nanophotoinc concepts to control thermal radiation. In particular, we show that density-of-state engineering can lead to tremendous enhancement of far-field thermal radiation, far beyond the apparent blackbody limit, without violating the second law of thermodynamics. We also discuss the possibilities for thermal radiative cooling during daytime using nanophotonic design.

8806-39, Session 8

Magnetic light: visible resonant properties of high-refractive index dielectric nanostructures *(Invited Paper)*

Arseniy I. Kuznetsov, Yuan Hsing Fu, A*STAR - Data Storage Institute (Singapore); Andrey E. Miroshnichenko, The Australian National Univ. (Australia); Ye Feng Yu, Mohsen Rahmani, Zhenying Pan, Vytautas Valuckas, Boris S. Luk'yanchuk, A*STAR - Data Storage Institute (Singapore)

High-refractive index dielectric nanoparticles are novel and unique objects in nanophotonics, which can complement or even substitute metallic nanoparticles in the visible spectral range for various applications. According to theoretical predictions based on Mie theory [1] they can have strong resonant responses of both electrical and magnetic nature, which spectral positions are linearly scalable with particle sizes. Recently we have experimentally demonstrated strong magnetic and electric dipole resonances tuneable through the whole visible and near-IR spectral ranges in silicon nanoparticles with sizes ranging from 100 nm to 300 nm [2, 3]. We have also shown that these nanoparticles have unique far-field scattering pattern, which directivity can be controlled changing nanoparticle size and the light wavelength [4]. These optical properties arise due to simultaneous excitation and mutual interference of magnetic and electric dipole resonances inside a single nanosphere. Such behaviour is similar to Kerker's-type scattering by hypothetic magneto-dielectric particles predicted theoretically three decades ago [5]. For nanoparticles with sizes ranging from 100 nm to 200 nm, forward-to-backward scattering ratio above 6 has been experimentally obtained in our work. We will also discuss applications of unique optical properties of high-refractive index dielectric nanoparticle to design of novel low-loss optical nanoantennas and other nanophotonic devices.

Magnetic lenses of surface magnetoplasmons in INSB-glass waveguide arrays

Yung-Chiang Lan, Siang-Hao Wu, National Cheng Kung Univ. (Taiwan)

Magnetic lenses are devices to focus or deflect the charged particles by applying magnetic Lorentz force. Since optical beams are uncharged, the magnetic fields are of no effects on them. Recently, focusing lenses for surface plasmons (SPs) in metal-dielectric waveguide arrays (MDWAs) have been proposed and examined. In these MDWAs lenses, a gradient of thickness or refraction index in dielectric material is used to generate the phase difference of SPs in different channels. However, the functions of these lenses are inflexible and cannot be modulated. The dispersion relations of surface magnetoplasmons (SMPs) are manageable by applying external magnetic fields. Hence, it is possible to design devices to steer SMPs by using magnetic fields. In this work, the magnetic lenses for SMPs in InSb-glass waveguide arrays (ISGWAs) under Voigt configuration are proposed and investigated using simulations and theoretical analyses. The FDTD program, VORPAL, is adopted in this study with using the linear plasma dielectric model to represent the magnetized plasmons in InSb layers. The functions of the magnetic lenses of ISGWAs that can focus, deflect, or control the SMP beams are demonstrated. The operation frequency of incident beams is about 1 THz with the largest applied magnetic field of 1 Tesla. The Hamiltonian optics method is utilized to predict and analyze the trajectories of the incident beam. The relations between the focal length and the magnetic field profile in ISGWAs are also elucidated.

Hyperbolic dispersion of metamagnetics

Vladimir P. Drachev, Univ. of North Texas (United States); David Lyvers, Univ. of North Texas (United States) and UES, Inc. (United States); Dean P. Brown, UES, Inc. (United States); Mark A. Walker, General Dynamics Information Technology (United States); Alexander V. Kildishev, Purdue Univ. (United States); Augustine M. Urbas, Air Force Research Lab. (United States)

In a hyperbolic medium, the principal components of the permittivity have opposite signs causing the medium to exhibit a 'metallic' type of optical response in one direction, and a 'dielectric' in the other resulting in interesting applications. A nanolithography pattern was demonstrated with a hyperbolic slab made of many thin planar layers of a metal and dielectric [1]. Improving the radiative decay rate for dye molecules with hyperbolic metamaterials was shown with a similar multilayer structure by measuring their life time and quantum yield [2].

Here we study hyperbolic dispersion of metamaterials with magnetic response. Recently we explored the group delay dispersion of metamagnetic gratings by the multiphoton intrapulse interference phase scan technique [3], which enables their use for ultrafast pulse shaping. The metamagnetic films have properties of biaxial anisotropic materials. In contrast to uniaxial hyperbolic metamaterials, metamagnetics represent a more general example of indefinite media [4] where both permittivity and permeability components have opposite signs depending on the wavelength. This paper presents our findings on the dispersion of metamagnetic gratings.

Metamaterial-enhanced magnetoelectric effects in axionic media

Yong Zeng, Los Alamos National Lab. (United States)

The axionic electromagnetics describes how the presence of a nontrivial background of a putative axion field would modify standard electrodynamics. Recently, it is found that the axionic electromagnetics can be applied to describe low-energy topological insulators, especially the magneto-optical Kerr effect and Faraday effect.

In this talk, I will present a general three-dimensional numerical algorithm which can simulate arbitrary axionic system. I will also show that one can significantly enhance the axionic magnetoelectric effect by using metamaterials.

8806-43, Session 8

Magneto-induced anisotropy of Voigt effect and other magneto-optical phenomena in ordered metal-dielectric metamaterials

Yakov M. Strelniker, Bar-Ilan Univ. (Israel); David J. Bergman, Tel Aviv Univ. (Israel)

It is known that the Voigt, Faraday and other magneto-optical effects can be significantly enhanced in the vicinity of an electromagnetic resonance. One such resonance, which is currently under intensive study, is the surface plasma resonance. It is widely believed that this or similar resonances are responsible for the Extraordinary Light Transmission through a metal film, perforated by a periodic array of sub-wavelength holes, as well for other new phenomena recently found in photonic crystals. Application of a static magnetic field B0 to such systems induces strong optical and transport anisotropy and leads to the appearance of additional off-diagonal tensor components in the effective permittivity tensor and changes the frequency of the surface plasma resonance. Therefore, the application of a static magnetic field to a conducting system with dielectric islands or to a dielectric system with metallic islands should lead to the appearance of strong magneto-optical effects and to possibilities for the manipulation of light propagation.

We have studied analytically and numerically the rotation and ellipticity of polarization of the light propagating through a metamaterial film with periodic microstructure for arbitrary direction of the applied static magnetic field, including both Voigt (when the static magnetic field is in the film plane) and Faraday (when that field is perpendicular to the film) configurations. In the Voigt configuration we found a strong dependence of the above mentioned effects on the direction of the applied field.

8806-44, Session 8

Lattices of magnetoelectric point scatterers in front of an interface

Andrej Kwadrin, A. Femius Koenderink, FOM Institute for Atomic and Molecular Physics (Netherlands)

In the community of metamaterials it is common nature to strive for a simplified description of the artificial medium in terms of effective medium parameters. However, this approach potentially obscures the underlying nature of the material constituents, the meta-‘atoms’. This firstly concerns the electric and magnetic polarizability of each constituent, and secondly any higher order multipolar behavior relevant when studying phenomena involving distances comparable to the metamaterial building block size.

An excellent approach to study these properties is to understand the combined system formed by a metamaterial array and an interface. In our experiment, we collect normal incidence reflectivity and dark field spectra of lattices of split ring resonators (resonant in the near-infrared) for different lattice-interface separations, where the interface is a silver mirror. We compare our data to point dipole lattice sum calculations suitable for arbitrary magnetoelectric point scatterers and find deviations to common approximations such as treating the combined system in a Fabry-Pérot or image dipole model. We attribute this discrepancy to two effects. Firstly, a multilayer model in which each layer is described by its complex amplitude reflection and -transmission coefficients, r and t, cannot describe fields close to the lattice (separations << resonance wavelength). Secondly, the nontrivial local density of states introduced by the interface modifies the radiative damping of each individual scattering element.

8806-45, Session 9

Engineering the coherent, thermal, and quantum state of light using metamaterials *(Invited Paper)*

Zubin Jacob, Univ. of Alberta (Canada)

Nano-Energy: We show that engineering the poles and zeros of the dielectric function using artificial media leads to narrowband, tunable, spatially coherent thermal sources both in the far-field and near-field. We propose the use of high melting point plasmonic building blocks for metamaterials overcoming the critical roadblock for high temperature applications. Our proposed thermal sources can lead to highly efficient thermophotovoltaic energy conversion beyond the Shockley-Queisser limit.

Nano-Quantum: We show that metamaterials can allow control not only over the fields but also the field fluctuations. In particular, we develop the Rytov fluctuational electrodynamics of metamaterials with hyperbolic dispersion to show the enhanced thermal and zero point fluctuations in a prescribed broad bandwidth. One application of this phenomenon is enhancing the spontaneous emission in a broad spectral range for coupling to emitters such as nitrogen vacancy centers in diamond, not possible with cavity approaches.

8806-46, Session 9

Quantum plasmonics *(Invited Paper)*

Andrey K. Sarychev, Institute for Theoretical and Applied Electrodynamics (Russian Federation); Ilya A. Fyodorov, Moscow Institute of Physics and Technology (Russian Federation); Alexei Bogdanov, HGST (United States); Andrey N. Lagarkov, Institute for Theoretical and Applied Electromagnetics (Russian Federation); Gennady Tartakovsky, AS&T (United States)

Surface plasmon nanolasers, also known as SPASERs attract much attention in recent years due to the numerous potential applications in the plasmonics. In this work, we consider the metal horseshoe nanoresonator filled with the active dielectric medium. The size of the considered resonator is much less than the wavelength. On this scale, the plasmon field inside the nanoresonator behaves as a quantum object. The plasmon quantum field is subject of the random external force because of the quantum-mechanical process of the photon absorption in the active medium. Due to the small size of the resonator, the coupling between the plasmon field and an atom of the active medium is anomalous strong. The interaction cannot be considered as just emission or absorption processes. We develop the quantum dynamics of the plasmon field coupled with the active medium. Thus, we consider how the quantum fluctuations influence the process of the luminescence and find how the lasing threshold is changed. The coherence of the light emitted by the plasmon laser is also considered. We predict that the light beams, radiated from non-interacting plasmon nanolasers, could not give the interference pattern. The quantum properties of the nanolaser are important for many applications, such as transmitting and processing optical signals on a scale much smaller than the wavelength.

8806-47, Session 9

RF squid quantum metamaterials *(Invited Paper)*

Melissa Trepanier, Daimeng Zhang, Univ. of Maryland, College Park (United States); Oleg Mukhanov, HYPRES, Inc. (United States); Steven M. Anlage, Univ. of Maryland, College Park (United States)

We are developing active metamaterials capable of quickly tuning their electrical and magnetic responses over a wide frequency range. These metamaterials are based on superconducting elements to form extremely low insertion loss, physically and electrically small, highly tunable structures for the next generation RF electronics. The meta-atoms are RF superconducting quantum interference devices (SQUIDs) that incorporate the Josephson effect. RF SQUIDs are essentially a quantum version of the split-ring resonator in which the inductance now includes a contribution from the Josephson inductance of the junction. This inductance is strongly tunable with DC and RF magnetic fields and currents. We will present experimental and numerical results from the first generation samples, and discuss the degree of tunability of these new meta-atoms. This work is supported by the NSF-GOALI program through grant # ECCS-1158644, and CNAM.

8806-48, Session 9

Nonlocal modification and quantum optical generalization of effective-medium theory for metamaterials *(Invited Paper)*

Martijn Wubs, Wei Yan, Technical Univ. of Denmark (Denmark); Ehsan Amooghorban, Shahrekord Univ. (Iran, Islamic Republic of); Niels A. Mortensen, Technical Univ. of Denmark (Denmark)

A well-known challenge for fabricating metamaterials is to make unit cells significantly smaller than the operating wavelength of light, so one can be sure that effective-medium theories apply. But do they apply? Here we show that nonlocal response in the metal constituents of the metamaterial lead to modified effective parameters for strongly subwavelength unit cells. For infinite hyperbolic metamaterials, nonlocal response gives a very large finite upper bound to the optical density of states that otherwise would diverge [1]. Moreover, for finite hyperbolic metamaterials we show that nonlocal response affects their operation as superlenses, and interestingly that sometimes nonlocal theory predicts the better imaging [2]. Finally, we discuss how to describe metamaterials effectively in quantum optics. Media with loss or gain have associated quantum noise, and the question is whether the effective index is enough to describe this quantum noise effectively. We show that this is true for passive metamaterials, but not for metamaterials where loss is compensated by linear gain. For such loss-compensated metamaterials we present a quantum optical effective medium theory with an effective noise photon distribution as an additional parameter. Interestingly, we find that at the operating frequency, metamaterials with the same effective index but with different amounts of loss compensation can be told apart in quantum optics [3].

8806-49, Session 10

Dynamics of metamaterials with quantum gain *(Invited Paper)*

Ortwin Hess, Imperial College London (United Kingdom)

Nanoplasmonics and optical metamaterials have in the last 10-15 yeas emerged as a new paradigm in optics and nanoscience, enabling the efficient coupling of light fields to the nanoscale and paving the way for a multitude of classical and quantum nano-optics applications. However, metal optics suffers from inherent dissipative losses and only recently theoretical and experimental advancements have shown that it is realistically possible to overcome dissipative losses of nanoplasmonic metamaterials, even in the exotic negative-index regime [1]. If the gain supplied by the active medium is sufficient to overcome dissipative and radiative losses [2,3], the structure can eve function as a coherent emitter of surface plasmons over the whole ultrathin 2D area, well below the diffraction limit for visible light [4,5]. The talk will give an overview of recent advances in the field of gain-enhanced plasmonics and optical metamaterias and show that these constitute an exciting new frontier in nanophotonics and nanoscience, and are precursors towards active, intergrated quantum nano-optics [6]. Bringing gain to the nanoscale is anticipated to improve the performance of a host of active nano-components, such as electro-optic modulators and light sources, but also passive ones, such as plasmonic waveguides or sensors featuring intensified plasmonic hotspots for single-emitter spectroscopy.

8806-50, Session 10

Engineered metals for mid-IR plasmonics

Stephanie Law, Univ. of Illinois at Urbana-Champaign (United States); Christopher Roberts, Univ. of Massachusetts Lowell (United States); Jonathan R. Felts, Torin Kilpatrick, William P. King, Univ. of Illinois at Urbana-Champaign (United States); Viktor A. Podolskiy, Univ. of Massachusetts Lowell (United States); Daniel M. Wasserman, Univ. of Illinois at Urbana-Champaign (United States)

The ability to strongly confine incident mid-IR light to subwavelength geometries has the potential for significant impact in molecular sensing, thermal signature control, and IR optoelectronics applications. While plasmonics has been hailed as a route to subwavelength photonic systems at short wavelengths, the properties of metals at longer wavelengths results in very different optical behavior of plasmonic structures at these longer wavelengths, especially in the near-field. However, by replacing traditional plasmonic metals such as Ag and Au with engineered metals consisting of highly-doped semiconductor materials, strong confinement of mid-IR light becomes possible.

Plasmonic structures are fabricated using our heavily-doped semiconductor materials, in order to demonstrate subwavelength confinement and control of mid-IR light with engineered mid-IR plasmonic metals. First, micro-structures from single-layer doped InAs films are fabricated, and these structures' ability to support localized surface plasmon resonances in the mid-IR is demonstrated. The micro-particles are characterized by both near-field and far-field spectroscopic techniques and simulated by finite element methods. In addition, all-semiconductor plasmonic absorbers are fabricated from multilayer first growth samples and absorption of >98% observed at resonance, largely independent of our structure's lateral geometry. Our perfect absorbers are characterized by infrared microscopy and simulated using finite

difference time domain (FDTD) techniques and rigorous coupled wave analysis (RCWA).

In summary, we demonstrate the potential of engineered plasmonic metals for strong localization of long wavelength light. The ability to strongly confine mid-IR light to subwavelength geometries has the potential for integration into a new generation of sensing, thermal signature control, and optoelectronic structures and devices.

8806-51, Session 10

All-dielectric metamaterials: path to low losses and high spectral selectivity *(Invited Paper)*

Gennady B. Shvets, Nihal Arju, Institute for Fusion Studies (United States); Michael B. Sinclair, Igal Brener, Sandia National Labs. (United States)

Ohmic losses severely limit the performance of metamaterials. High-index semiconductors offer an attractive alternative. We review several meta-surfaces based on silicon and silicon carbide enabling infrared applications such as polarization manipulation and thermal emission. Non-metallic (dielectric or semiconductor) metamaterials present a unique opportunity for developing electromagnetically complex multi-resonant meta-surfaces while avoiding Ohmic losses. For example, Fano-resonant structures exhibiting sharp resonances caused by the interference between sub-radiant and super-radiant resonances can be designed and utilized for highly spectrally selective thermal emissivity, polarization manipulation, nonlinear optics, and full Stokes parameter hyper-spectral polarimetry.

I will also report the results of theory, design, fabrication, and optical characterization of large-area meta-surfaces (MSs) for thermal emission comprised of SiC antennas shown in Fig.2. The attraction of semiconductor-based thermal emitters is three-fold. First, optical properties of many semiconductors are essentially frequency-independent across broad spectral range, unlike those of plasmonic structures. Second, the ability to affect the refractive index of semiconductors by introducing free carriers enables either active or passive control of their optical properties. Third, high conductivity of doped semiconductors enables their electric heating.

8806-52, Session 10

Direct fs laser writing: principles and applications *(Invited Paper)*

Elmina Kabouraki, Ioanna Sakellari, Maria Vamvakaki, David Gray, Maria Farsari, Foundation for Research and Technology-Hellas (Greece)

We present a new method for increasing the resolution of direct fs laser writing by multiphoton polymerization, based on quencher diffusion. This method relies on the combination of a mobile quenching molecule with a slow laser scanning speed, allowing the diffusion of the quencher in the scanned area and the depletion of the multi-photon generated radicals. We use this method to fabricate dielectric, metallic and quantum-dot doped photonic crystals and we show that the results are comparable to those produced by direct laser writing based on stimulated-emission-depletion microscopy, the method considered today as state-of-the-art in 3D structure fabrication. We model the quencher diffusion and we show that radical inhibition is responsible for the increased resolution. Finally, we discuss applications of Direct fs Laser Writing in photonics, metamaterials, and biomedical Implants.

8806-53, Session 10

Bichromatic wave mixing to reach optically lossless semiconductors

Adil-Gerai Kussow, Yassine Ait El Aoud, Alkim Akyurtlu, Univ. of Massachusetts Lowell (United States)

Two-wave mixing in non-ohmic semiconductors with low dispersion to dramatically reduce optical losses is proposed. The optical losses in the probe mode are fully compensated due to the flow of energy from the support mode. The total-loss-suppression effect is derived from the solution of non-linear Maxwell equations combined with coherence conditions for two parametrically coupled waves. We provide a scenario which demonstrates that this scheme can be realized experimentally in bulk semiconductors, e.g. zinc telluride (ZnTe), within the mid-IR regime, and preliminary experimental results are discussed.

8806-54, Session 10

Low index metamaterials comprised of plasmonic dimers of aluminum doped zinc oxide

Hossein Alisafaee, Princess M. Cox, Michael A. Fiddy, The Univ. of North Carolina at Charlotte (United States)

The behavior of localized surface plasmon resonances (LSPR) of AZO nanoparticle dimers embedded in a host polymer medium is investigated for different dimer orientations with respect to the indicent electromagnetic wave. In doing this, the role of dressed polarizability to enhance and quench the plasmonic effects is also considered. The effects of the nanoparticles' relative size and the spacing between them are studied. The frequency of LSPR is found in the near infrared (NIR) spectral region. Understanding these resonances and their dependence on dimer orientations, provides a means to design metamaterial structures for use in the NIR region with epsilon-near-zero properties leading also to low index metamaterials. In our studies, we demonstrate how nanospheres with radii less than 100 nm that are distributed with an average spacing less than their diameter, can result in an effective medium with refractive index less than one. Since our study is in the NIR, where the resonant behavior of AZO nanoparticles is dominant, simple effective medium models such as Bruggeman's cannot be applied while the high particle density also prevents us from employing a Maxwell-Garnet model. Consequently, we utilize a full-wave frequency domain finite element method in conjunction with an equivalent-circuit model for the nanoscale dimers in order to describe the spectral response of the bulk low index properties. We also present a statistical analysis to obtain the effective refractive index for incident light having different polarizations. The results from our model are compared with those of the Bruggeman and Maxwell-Garnet effective medium approximations.

8806-55, Session 11

Tuning plasmon resonances by electrochemical potential control *(Invited Paper)*

Harry A. Atwater Jr., California Institute of Technology (United States)

Recently considerable attention has turned towards the relationship between plasmon excitation and the electrochemical potential associated with the electron gas in a conductor. In this paper, we explore this relationship in three contexts: 1) the plasmoelectric effect, a new physical phenomenon that relates resonant excitations in conductors to their electrochemical potentials and 2) field effect tuning of the electrochemical potential and plasmon resonances of graphene nanoresonators and 3) transport of plasmon-excited hot carriers across metal-semiconductor interfaces.

The plasmoelectric potential is an electrochemical potential induced by resonant optical absorption in plasmonic nanostructures. This electrochemical potential results from the dependence of the plasmon resonance frequency on electron density. We demonstrate experimentally the relationship between plasmoelectric potential and resonant optical absorption via three independent experimental methods: 1) electrochemical potential measurements made by Kelvin probe force microscopy observations of Au nanoparticles on conducting substrates 2) potential measurements between two photoelectrochemical cells connected by a salt bridge and 3) comparison of extinction spectra take under broadband 'white' illumination and scanned monochromatic excitation.

We report the gate-tunable resonant absorption in lithographically fabricated arrays of graphene ribbon plasmonic nanoresonators with cavity lengths in the 10-100 nm range. Resonant mid-infrared absorption features due to transverse and longitudinal plasmonic cavity resonances are observable, as are plasmonic features that couple to localized phonon modes in the underlying silicon dioxide substrate. The plasmonic dispersion relations for these resonators can be developed by variation of resonant energy with cavity length as a function of gate voltage. The relationship between cavity edge roughness and resonance linewidth will be discussed.

Recently considerable attention has turned towards finding a silver lining in the cloud of plasmonics by extracting energy from the inevitable optical losses resulting from plasmon decay. We assess the prospects energy conversion via hot electron injection from localized plasmon decay across a rectifying metal-semiconductor Schottky barrier junction. Of particular interest is the relationship between the injection current across the Schottky barrier and the polarization of the electric field used to excite the plasmon. We analyze the current injection in Au/Si Schottky barrier nanoantennas excited with fields polarized transverse and parallel to the heterojunction interface.

8806-56, Session 11

On the calculation of optical force and stress in metamaterials *(Invited Paper)*

Che-Ting Chan, Hong Kong Univ. of Science and Technology (Hong Kong, China)

We will talk about some calculations we have done on the light induced force and stress. We show that some special non-diffracting beams can attract particles with simultaneous electric and magnetic responses. For dielectric particles, such attractive forces happen in the Mie regime. For metamaterial particles with both electric and magnetic resonances, it is possible to attract particles even in the Rayleigh regime. In addition, we would like to show that attractive light forces that are strong in magnitude with a reasonable power of the incident light can be achieved. One possible configuration is to use a near field approach and employ the evanescent field of a plasmonic excitation. For example, we can use light to excite the plasmonic resonance of a configuration that is the counterpart of high-impedance "meta"-surfaces. We will discuss experimental effort in this area. We will also address the question of electromagnetic induced stress inside a metamaterial. This is a difficult problem both technically and conceptually, as it is not easy to distinguish between the material and the field part of the momentum density. We find that the usual effective permittivity and permeability parameters do not give sufficient information to determine the force density inside a metamaterial if the field penetrates the material and we show that the required additional parameters can be calculated semi-analytically using a multiple scattering formalism.

8806-57, Session 11

Modeling and understanding of effects of randomness in arrays of resonant meta-atoms *(Invited Paper)*

Sergei Tretyakov, Mohammad Albooyeh, Pekka Alitalo, Aalto Univ. School of Science and Technology (Finland); Andrei Andryieuski, Technical Univ. of Denmark (Denmark); Ali Culhaoglu, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany); Andrei V. Lavrinenko, Technical Univ. of Denmark (Denmark); Dmitry Morits, Aalto Univ. School of Science and Technology (Finland); Constantin Simovski, Aalto Univ. School of Electrical Engineering (Finland)

In this review presentation we will discuss approaches to modeling and understanding electromagnetic properties of 2D and 3D lattices of small resonant particles (meta-atoms) in transition from regular (periodic) to random (amorphous) states.

Nanostructured metasurfaces (2D) and metamaterials (3D) are arrangements of optically small but resonant particles (meta-atoms). The main focus of research of these structures has been on the case of periodical arrays of meta-atoms. However, most recently, random or amorphous metamaterials start to attract attention, due to novel technological possibilities to manufacture amorphous structures cheaply and on a large scale, and there is a need to develop predictive analytical tools for the design of amorphous metamaterials. We will present our results on analytical modeling of metasurfaces with periodical and random arrangements of electrically and magnetically resonant meta-atoms with identical or random sizes, both for the normal and oblique-angle excitations. We show how the electromagnetic response of metasurfaces is related to the statistical parameters of the structure.

Effective parameters of many metamaterials exhibit a so called anti-resonance, which is a nonphysical feature, in at least one of the parameters that are retrieved this way. Many previous works have either claimed or assumed that the anti-resonance is an effect caused by the periodicity of the composite material. Here we will discuss the question if the sample periodicity is indeed essential for appearance of anti-resonances in extracted material parameters. Our conclusion, supported by both numerical simulations and microwave experiments, is that both periodic and random arrays clearly show similar anti-resonance of the extracted material parameters. It means that the physical reason of the anti-resonant behavior of effective parameters is the resonant response of finite-size inclusions and unit cells, while the particular arrangement of these cells is not essential.

8806-58, Session 11

Trapping light by mimicking gravitational lensing

Hui Liu, Chong Sheng, Yi Wang, Shining Zhu, Nanjing Univ. (China); Dentcho A. Genov, Louisiana Tech Univ. (United States)

Recently, there is an increasing interest in light trapping in microstructures. Furthermore, it has been suggested that artificial optical materials and micro-structured waveguides may be used to mimick celestial phenomena such as light trapping in gravitational black holes, Hawking's radiation etc.. In astronomy, gravitational lensing, which was theoretically proposed by Albert Einstein, has become an important tool to map large scale structures such as gas clouds, dark matter halos in the galaxy and others. However, the stronger lensing effects in close proximity to ultra-compact objects such as black holes and neutron starts have not yet been observed.

In this paper, we propose a distorted waveguide around microsphere that mimics the gravitational lensing effects in close proximity to such compact objects and specifically those with asymptotic polytropic equation of state. Our methodology can be used to experimentally study, for a first time, strong gravitational effects such as light capture and existence of photon spheres around these objects. Other possible applications may be in energy harvesting devices due to the omnidirectional absorption properties of our system as well as for applications as high Q-factor optical cavities.

8806-59, Session 11

Experimental demonstration of metamaterial multiverse in a ferrofluid *(Invited Paper)*

Igor I. Smolyaninov, Univ. of Maryland (United States); Bradley Yost, Evan Bates, Vera N. Smolyaninova, Towson Univ. (United States)

Extraordinary light rays propagating inside a hyperbolic metamaterial look similar to particle world lines in a 2+1 dimensional Minkowski spacetime. Magnetic nanoparticles in a ferrofluid are known to form nanocolumns aligned along the magnetic field, so that a hyperbolic metamaterial may be formed at large enough nanoparticle concentration nH. Here we investigate optical properties of such a metamaterial just below nH. While on average such a metamaterial is elliptical, thermal fluctuations of nanoparticle concentration lead to transient formation of hyperbolic regions (3D Minkowski spacetimes) inside this metamaterial. Thus, thermal fluctuations in a ferrofluid look similar to creation and disappearance of individual Minkowski spacetimes (universes) in the cosmological multiverse. This theoretical picture is supported by experimental measurements of polarization-dependent optical transmission of a cobalt based ferrofluid at 1500 nm.

8806-60, Session 11

Solids in ultrafast and strong optical fields: new phenomena *(Invited Paper)*

Mark I. Stockman, Georgia State Univ. (United States)

We report theory and experimental results for a new class of phenomena in condensed matter optics when strong optical fields ?0.1-3 V/Å reversibly change the solid within an optical period [1-5]. Such fields, if adiabatic, cause phenomena such as the Wannier-Stark localization and anticrossings of adiabatic levels. During a single-oscillation strong optical pulse, a dielectric undergoes a reversible transition to a semi-metal, which follows the instantaneous optical field during time intervals on order of hundred attoseconds. Such a pulse drives currents in dielectrics and controls their properties, including optical absorption and reflection, and extreme UV absorption in a non-perturbative manner. Applied to a metal, such a pulse causes an instantaneous and reversible loss of the metallic properties. These are fastest phenomena in optics and offer potential for petahertz-bandwidth signal processing.

Plasmonic resonances, enhanced optical properties, and other optical phenomena in novel eutectic and nanoparticles-based composites *(Invited Paper)*

Dorota A. Pawlak, Marcin Gajc, Katarzyna Sadecka, Pawel Osewski, Andrzej Stefanski, Sebastian Turczynski, Andrzej Klos, Barbara Surma, Institute of Electronic Materials Technology (Poland)

Developments of the materials for plasmonics and metamaterials by two novel bottom-up manufacturing methods will be presented. These methods are based on: (i) directional solidification of eutectic composites and (ii) NanoParticles Direct Doping (NPDD) - doping dielectric matrices with plasmonic nanoparticles. In both cases we apply one of the crystal growth methods - the micro-pulling down method - to create the material. Materials with plasmonic resonances at visible and IR wavelengths will be presented, as well as their influence on photoluminescence or nonlinear properties of the materials. Our new approach may lead to novel manufacturing solutions for photonic applications.

8806-62, Session 12

THz metamaterial effects in phonon-polariton composite media *(Invited Paper)*

Maria Kafesaki, Foundation for Research and Technology-Hellas (Greece) and Univ. of Crete (Greece); Alexey Basharin, Charalambos Mavidis, Eleftherios N. Economou, Foundation for Research and Technology-Hellas (Greece); Costas M. Soukoulis, Foundation for Research and Technology-Hellas (Greece) and Iowa State Univ. (United States)

Polaritonic materials (i.e. materials showing phonon polariton modes) are becoming recently a more and more valuable component of THz metamaterials. This is due to the resonant permittivity response that they exhibit in the THz regime, involving a wide range of permittivity values, from high positive to near-zero and negative ones. Thus, polaritonic materials give the possibility, if properly structured, to obtain a rich variety of metamaterial related phenomena and capabilities. In this talk we will discuss polaritonic systems made of rods periodically placed in a host and we will describe the rich phenomena and capabilities that such systems can offer. These phenomena include negative permittivity, negative permeability and negative index response, indefinite media response leading to subwavelength resolution imaging capability (hyperlensing), backwards radiation leading also to subwavelength propagation, total transmission or reflection due to the excitation of Mie-resonant modes of the rods if the host permittivity gets epsilon-near-zero values, as well as sub-wavelength guiding based on such modes. The model systems that we will employ to demonstrate the above mentioned phenomena are systems of LiF rods in NaCl or KCl host. Besides the rich phenomena that can be observed in those systems, another great advantage of them is their easy realization possibility, through eutectics self-organization structuring.

8806-63, Session 12

Modeling and fabrication of Terahertz metamaterials

Mayer A. Landau, U.S. Air Force Research Lab. (United States)

Metamaterials are synthetic materials with periodic electromagnetic inclusions. The interactions between inclusions can fundamentally alter the macroscopic response of the material to electromagnetic radiation. Simulating this response is costly in computer resources due to the sheer number of cell elements involved in a 3D material. It would be ideal to have macroscopic constituitive parameters that capture the essense of the material's response, as index of refraction and impedance do for natural materials. But metamaterials are highly dispersive and their lattice constant is on the cusp of being too large to model effectively with macroscopic constituitive paramaters. Recently (2010) Andrea Alu at UT Austin derived a new metamaterial homogenization theory of macroscopic material parameters (permittivity and permeability) that are dispersion independent. We use these dispersion independent parameters to simulate scattering from finite slabs. These results are compared to FDTD simulations. We also compare to actual experiments with metamaterial filters, i.e. slabs, built to operate at W band and at 1THz. We find the Alu constituitive parameters give good agreement with experiment and provide much faster scattering calculation compared to standard FDTD.

8806-64, Session 12

Modified bow-tie antenna with strong broadband field enhancement for RF photonic applications

Shiyi Wang, Qiwen Zhan, Univ. of Dayton (United States)

We present a novel design of a subwavelength modified bow-tie antenna that is capable of generating strong broadband field enhancement in its extended feed gap. This modified bow-tie antenna is comprised of a conventional bow-tie antenna with capacitive extended bars attached to the apex points of bow-tie. The feed gap between the two capacitive bars is separated with a deep subwavelength width for the generation of enhanced local electrical field. Three-dimensional finite element method model is utilized to systematically explore the properties of this antenna design. Through adjusting the bow-tie geometry and the substrate properties, the antenna structure is optimized with a central resonant frequency at 100 GHz. Highly enhanced electrical field is created between the extended bar under radio frequency (RF) illumination. With the optimized design, numerical simulations show that a uniform field enhancement of more than 200 through the entire feed gap with a bandwidth of 40 GHz can be achieved. The strongly enhanced RF field within the gap can be applied to directly modulate guided optical wave propagating in a waveguide embedded in the substrate underneath the feed gap. This work builds up a bridge between devices in the RF and optical frequency regimes that may find many potential applications in RF photonic devices and systems.

Polarization properties of 2D and 1D metamaterial lenses

Duncan A. McGillivray, Univ. of Virginia (United States); Robin L. Cravey, Kenneth L. Dudley, Erik Vedeler, NASA Langley Research Ctr. (United States); Mool C. Gupta, Univ. of Virginia (United States)

The unique properties of metamaterials present an opportunity for many novel sensor applications and nondestructive evaluation devices. The polarization properties of metamaterials have not been significantly investigated, in particular in the context of sensors and nondestructive evaluation. This study examines the polarization properties of a split ring resonator and rod (SRR+R) metamaterial array.

The array is configured into a 2-D metamaterial lens and the results are compared to 1-D lens configurations. The polarization properties of the lens configurations were investigated through experiment and FDTD modeling.

It was found that, at resonance frequency of 3.63 GHz, the transmission response of SRR+R metamaterial structures is highly sensitive to the polarization state of the incident microwave. This sensitivity is due to the coupling mechanisms between the incident radiation and the metamaterials constituent elements. For transverse-electric (TE) incident polarization, the 2-D lens alters the polarization state of the incident radiation into elliptical polarization with a tilt along the principal axis, where the ellipticity changes with incident polarization angle. Transverse-magnetic (TM) incident polarization is unaffected by the 2-D metamaterial lens.

The 1-D lens does not affect the polarization of the incident microwave radiation. However, drastic changes in the transmission profile and effective index of refraction were found. These changes are due to the incident polarization state (TE and TM) coupling with the metamaterials constituent elements.

The control over the polarization state of the incident microwave radiation allows to tailor the transmission, which can be leveraged towards novel transmission based microwave metamaterial sensors.

Filament-based virtual hyperbolic metamaterials for microwave guiding

Zhaxylyk A. Kudyshev, Natalia M. Litchinitser, Univ. at Buffalo (United States)

One of the major challenges in transmitting microwaves in air is that as any electromagnetic beams they diffract. Therefore, in order to be able to receive the signal at a certain distance, one has to counteract this diffraction broadening. In the last few years various types of filament-based waveguides were proposed for channeling microwaves [1-3]. Filamentation of an intense laser pulse is a phenomenon originating from self-focusing. Guiding of microwaves with filaments over 16 cm was experimentally demonstrated by Chateauneuf using a 100 TW laser system to produce a cylindrical array of filaments 45mm in diameter [4]. The detected signal was increased by a factor of ~ 6 compared to the free propagation case.

We propose ordered filament-based photonic structures to reduce microwave beam divergence and route beams around the obstacles. In particular, we design and optimize virtual hyperbolic metamaterials formed from filaments in air. One possible realization of hyperbolic metamaterials is a set of wires with negative dielectric constant in a background medium with a positive dielectric constant [4]. These wires are formed by multiple filaments with a fix fill-fraction of filaments and air. Our proof-of-concept results confirm that microwave beam divergence can be controlled using the proposed metamaterial structure.

Advanced solitonic metamaterial waveguide structures under external magnetophotonic control and peregrine creation *(Keynote Presentation)*

Allan D. Boardman, Peter Egan, Univ. of Salford (United Kingdom)

Metamaterial research is an extremely important global activity that promises to change our lives in many different ways, including making objects invisible and having a very dramatic impact upon the energy and medical sectors of society. Behind all of the applications, however, lies the design of metamaterials but this can be led by elegant routes that include nonlinearity, and waveguide complexity, associated with optical device formats and coupling to soliton behaviour. A range of devices will be considered here but a particular interest will be in the use of solitonic Y-junction waveguides and soliton beam and pulse interactions. It will be shown that particular metamaterial environments will completely change everything and open up a dramatic influence on the kind of nonlinear superposition of spatial solitons needed for this application. The implications for planar waveguide sensors are immense and some will be discussed in detail to show how loading, or interacting, them with certain types of metamaterial will lead to measurement outcomes with considerably enhanced sensitivities. All of these discussions will focus upon the need for special metamaterials, or combinations of them, many of which will be hyperbolic and some of which will use interacting metaatoms and magnetoinductive waves. The control of a solitonic metamaterial waveguides through external influences, like magnetooptics, under the general heading of magnetophotonics will also be investigated. In addition, vortex formation will be critically assessed with a view to using metamaterials to enhance the addition of angular momentum to special light beams. In the final section of the presentation, the absolutely fascinating possibility of generating Peregrine solitons, involving localization in both space and time, will be addressed. These solitons are named after Professor Peregrine but also have the same name as the well-known high-speed falcon. This type of soliton is like the rogue hydrodynamic wave that causes so much global damage. It has only recently been observed optically and it will be shown here that the introduction of metamaterials opens up a vast spectrum of opportunities so that the soliton can be used in either a positive, or a negative, way with much more flexibility.

8806-68, Session 13

Graded-index metamaterials: from linear to low-intensity nonlinear optics *(Invited Paper)*

Natalia M. Litchinitser, Zhaxylyk A. Kudyshev, Fatema Alali, Univ. at Buffalo (United States); Ildar R. Gabitov, The Univ. of Arizona (United States); Andrei I. Maimistov, Moscow Institute of Physics and Technology (Russian Federation)

We discuss recent progress in the field of linear and nonlinear light propagation in transition metamaterials, a class of artificial graded-index materials with dielectric permittivity and magnetic permeability gradually changing between positive, zero and negative values. Our initial studies predicted strongly polarization sensitive anomalous field enhancement near the zero refractive index point under oblique incidence of the plane wave on a realistic, lossy transition metamaterial layer, potentially enabling a variety of applications in microwave, terahertz, and optical metamaterials, including subwavelength transmission and low-intensity nonlinear optical devices. In this talk, we compare the phenomenon of resonant field enhancement in the cases of planes wave, Gaussian and Hermite-Gaussian beam propagation in transition metamaterials and demonstrate that in the case of Gaussian beam resonant enhancement occurs for both normal and oblique incidence due to the fact that the beam is composed of a combination of plane waves, each with a different angular vector. We investigated various graded-index structures and predicted a possibility of field enhancement in both positive-zero-negative index structures and positive-zero-positive index profile case. Moreover, we demonstrate that more complex refractive index distributions with, for example, two zero-index crossings, may result in a formation of tunable resonant cavities. Finally, we report our first studies of the effect of resonant enhancement in the transition layer with quadratic nonlinearity enabling enhanced efficiency of second harmonic generation and providing a promising route to low input power nonlinear optical devices.

8806-69, Session 13

Plasmonic enhancement of third order nonlinearity: practical limitations *(Invited Paper)*

Jacob B. Khurgin, Johns Hopkins Univ. (United States); Greg Sun, Univ. of Massachusetts Boston (United States)

Plasmonic structures and metamaterials allow very high degree of concentration of electro-magnetic fields in the vicinity of metal nanoparticles. This effect is known to enhance optical nonlinearities and thus has been suggested as the basis for all optical switching, frequency conversion and other applications. At the same time, being a strongly resonant phenomena, plasmonic enhancement is always impeded by losses in the metal. We show that indeed the effective third order nonlinearity in plasmonic nanostructures can be increased by as much as 5-6 orders of magnitude, but only for weak pumps and signals. This makes nonlinear nanoplasmonics an excellent platform for sensing applications. At the same time, the more relevant figure of merit, the maximum total phase shift attainable in the device cannot exceed a few percent, thus rendering all optical switching and frequency conversion in nanoplasmonic structures extremely inefficient.

8806-70, Session 13

Quantum mechanical modeling of nonlinear surface plasmon polaritons

Fan Wang, Dafei Jin, Nicholas X. Fang, Massachusetts Institute of Technology (United States)

Surface plasmon polaritons (SPP) are coupled collective excitations of electrons and photons at the metal-insulator interface. When the characteristic size of interest shrinks to the order of one nanometer (for example, around a sharp metal tip or across a thin dielectric spacer), the classical treatment will break down; the quantum nature of electrons, such as the tunneling through potential barrier and the interference around structural defect, start to take place. When the deposited energy is sufficiently high, the nonlinear phenomena due to SPP-SPP collision will show up as well. In this work, we adopt coupled nonlinear Schrodinger equation and Maxwell's equations to study the behavior of SPPs in the extreme-quantum and high-energy regime. We calculate the excitation spectrum under various geometric and electrostatic configurations, and investigate the evolution and interaction of SPP vortices in real time. Our work can give a good insight into the underlying physics of this system and may be helpful for designing sub-nanometer plasmonic devices.

8806-71, Session 14

Active metamaterials based on strong coupling to semiconductor excitations *(Invited Paper)*

Igal Brener, Sandia National Labs. (United States)

Planar metamaterials (MM) offer many desirable properties for modulation, filtering and control of the emission of light. The optical response of metallic metamaterial resonators is very scalable through most of the infrared spectrum. Strong coupling between these resonators and optical excitations in semiconductors offers a viable path for tunable and nonlinear optical response.

First, I will present recent results on the strong coupling between metamaterials and intersubband transitions (IST) in semiconductor quantum wells. We can maximize this interaction by proper design of the MM resonators and the semiconductor heterostructure. Our designs lead to a Rabi splitting that can reach 15-20% of the fundamental frequency. Furthermore, this coupling occurs in a deep subwavelength volume. Then, I will describe the strong coupling between MM resonators and epsilon near zero (ENZ) waves present in thin highly doped semiconductor layers. Finally, I will discuss the control of this strong coupling using an external bias.

This work was performed, in part, at the Center for Integrated Nanotechnologies, a U.S. Department of Energy, Office of Basic Energy Sciences user facility. Sandia National Laboratories is a multi-program laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000.

8806-72, Session 14

Optical switching with phase-change metamaterials *(Invited Paper)*

Kevin F. MacDonald, Jianfa Zhang, Behrad Gholipour, Jonathan S. Maddock, Daniel W. Hewak, Univ. of Southampton (United Kingdom); Nikolay I. Zheludev, Univ. of Southampton (United Kingdom) and Nanyang Technological Univ. (Singapore)

The next phase of the photonic technological revolution will be driven by switchable and nonlinear metamaterials, with properties surpassing those of natural media, as a functional platform for nanoscale 'meta-devices'. We report here on recent advances in the development of versatile, planar photonic metamaterial solutions to provide a new generation of all-optical switching and memory devices.

8806-73, Session 14

Reconfigurable gradient index using VO2 memory metasurface

Michael D. Goldflam, Univ. of California, San Diego (United States); Tom Driscoll, Duke Univ. (United States) and Intellectual Ventures (United States); Daniel Barnas, Omar Khatib, Univ. of California, San Diego (United States); Matthew Royal, Nan M. Jokerst, David R. Smith, Duke Univ. (United States); Bong-Jun Kim, Electronics and Telecommunications Research Institute (Korea, Republic of); Giwan Seo, Univ. of Science & Technology (Korea, Republic of); Hyun Tak Kim, Electronics and Telecommunications Research Institute (Korea, Republic of) and Univ. of Science & Technology (Korea, Republic of); Dimitri N. Basov, Univ. of California, San Diego (United States)

We have demonstrated the creation of spatial gradients in the optical properties of a metamaterial device through tuning of a hybrid metamaterial. Such metamaterials are formed through the combination of tunable substrates with standard metamaterial structures. Our device consists of a vanadium dioxide (VO2) layer that interacts with an array of lithographically fabricated split ring resonators. Application of a transient electrical pulse across the metamaterial-VO2 system leaves persistent changes in the properties of the metamaterial due to the hysteresis of the insulator-to-metal transition in VO2. We demonstrate that through modification of the spatial and temporal distribution of current, we can obtain increased control over the shape of gradients in these devices. Spatial control is achieved through geometrical design of contacts fabricated on the device. Using these methods, we are able to write spatially sharp gradients with ~50 percent change in the index of refraction over length scales of only a few wavelengths as observed through diffraction limited terahertz spectroscopy. Furthermore, we assess the potentials for applications of such gradients in beam-steering.

8806-88, Session 14

Smart metamaterial based on elastic crystals

Dongheok Shin, Yonsei Univ. (Korea, Republic of); Yaroslav A. Urzhumov, Duke Univ. (United States); Youngjean Jung, Kyoungsik Kim, Yonsei Univ. (Korea, Republic of); David R. Smith, Duke Univ. (United States)

We introduce a theory of a smart metamaterial that obtains own electromagnetic properties automatically from given mechanical deformations. Based on transformation optics and solid mechanics, we found the connection between electromagnetic and elastic properties that makes our elastic crystal sample to perform as smart metamaterial. With this concept, we build and experimentally test a transformation optics device - "carpet cloak" – whose functionality derives from quasi-conformal coordinate transformations. The smart metamaterial cloak self-assembles these transformations automatically from an essentially arbitrary deformation of the cloak boundary, eliminating the need to manufacture a large variety of metamaterial unit cells.

8806-84, Session PWed

Modeling of carpet cloak with angle dependent constitutive parameters for terahertz frequency band

Egor A. Gurvitz, Mikhail K. Khodzitsky, Anna V. Vozianova, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

Today, metamaterials (structures with unusual properties) become widely known hot topic of applied science [1]. Using metamaterials it can develop new types of waveguide structures, filters, detectors, super resolution imaging devices, antennas, etc. One of the most popular and exotic application of metamaterials is design of cloaking devices to hide objects. In the most cases, transformation optics was used to control of light and hiding of an object [2]. The invisibility effect is achieved by using special spatial distribution of constitutive parameters of cloak which acts as transformation medium. There are three main types of transformation optics cloaks such as spherical, cylindrical and carpet designs[2-4]. The most practicable design is carpet which allows e.g. to hide an object from security systems in terahertz frequency range. Our work is devoted to investigation of THz radiation control using carpet cloak with angle dependent constitutive parameters. The metric tensors of constitutive parameters were obtained for such design. The invisibility effect in such structure was verified by numerical simulation using COMSOL Multiphysics software [5].

Achieving multifrequency cloaking with a single shell of multiple plasmonic constituents

Youwen Liu, Yunji Meng, Nanjing Univ. of Aeronautics and Astronautics (China)

Researches on metamaterial cloaking become very active because of exciting potential applications in various scientific fields. The scattering cancellation cloaking, which exploits negative or low-positive permittivity of homogeneous and isotropic plasmonic layers to cancel the scattering of an object, can be more easily extended to multifrequency operation. As successfully shown, increasing the number of plasmonic layers that provides extra degrees of freedom in the design of the cloak would allow the possibility of drastic scattering reduction simultaneously at multiple frequencies. In this contribution, we proposed a single cloaking shell with different plasmonic composites, which possesses required permittivity properties to reduce the scattering of a given object at multiple frequencies. The results based on the Mie theory, which is verified with numerical simulation, show that extra degrees of freedom for MF cloaking

can be also provided by simply increasing the number of plasmonic constitutes of the thin shell without changing its total thickness. A special design has also been proposed, showing its great feasibility in the practical application.

Band-gap structure for n-fold layers inside bilayer cell of photonic crystal for THz frequencies

Alaudi K. Denisultanov, Sergey A. Ozerov, Mihail K. Khodzitsky, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

Recent years photonic crystals are very promising and attractive structures for control and manipulation of electromagnetic waves. They can find applications as filters, waveguides, polarization changers, superlenses, superprisms, etc [1]. In particular, photonic crystals are of very interest for terahertz applications as THz components for THz spectroscopy and tomography of biological objects [2]. However for qualitative THz components design there is an actual problem of exact definition of frequency position of center and edges of N-stopband of photonic crystal [3]. So this paper is devoted to theoretical and experimental investigation of band-gap structure for N-fold layers inside bilayer cell of one-periodical (1D) photonic crystal. The band-gap analysis was carried out using the transfer matrix method [4] and CST Microwave Studio software [5]. The formulas for calculation of exact frequency position of centers, edges and width of N-stopband were obtained for four values of multiplicity of layers inside of PC bilayer cell. The verification of these formulas was shown in the experiment in the frequency range from 0.1 to 1 THz.

A dual-band pass filter based on a Zeonor substrate in the THz regime

Jeong Min Woo, Min-Sik Kim, Jae-Hyung Jang, Gwangju Institute of Science and Technology (Korea, Republic of)

There is a growing need for research to control EM waves in the THz regime as such work offers great potential in the bio-medical, agriculture, and chemical fields. The characteristics of metamaterials (MMs) have fulfilled these needs, showing good performance as a frequency selector within a modulator, absorber, and filter. In this study, a dual-band pass filter based on a Zeonor substrate (23 ?) in the THz regime is studied. The transmittance level of the Zeonor substrate was 0.83~0.99 and the refractive index was 1.6 at 1 THz. Due to its good characteristics as a filter substrate, the dual-band pass filter designed here was demonstrated on it. Meanwhile, the metal-deposition step to demonstrate MMs on a Zeonor substrate failed, showing weak adhesion between the metal (Ti/Au=20/200 nm) and the substrate. We deposited a thin silicon-dioxide (SiO_2) layer (3 nm, 10 nm) before the metal-deposition step to change the surface condition from hydrophobic to hydrophilic, resulting in better adhesion between the metal and the substrate. THz time-domain spectroscopy was carried out to measure the transmittance of filters. The insertion losses were 0.56 dB and 0.58 dB and the stop-band attenuations for the first resonance were 22.44 dB and 22.42 dB; the corresponding second resonance values were 24.69 dB and 23.07 dB for filters with pre-deposited SiO2 of 3 nm and 10 nm, respectively. The SiO2 deposition did not limit the good transmission characteristics of the Zeonor substrate as a filter substrate, and it enabled the MMs to stand on the substrate.

8806-89, Session PWed

The optical limiting effect in suspensions astralens

Rimma Zatrudina, Vitaliy Kuzmenko, Volgograd State Univ. (Russian Federation)

A new form of fullerene-conformable nanostructures – the astralens [1] –was investigated. The astralens represent polyhedral multi-shell toroidal carbon nanoparticles a typical dimentions about 150 nm. They have optical strength and thermal stability more than fullerenes, and they have high chemical stability. The astralens are not soluble in any solvent, but they form a stable suspension. The astralens absorption spectrum is monotonous decreased from 400 nm to 1200 nm.

Nonlinear absorption of astralens aqueous suspension was measured using the Nd3+-glass laser at 1064 nm in Q-switching and short-term resonant modulation of losses [2] regimes. The duration of the pulse generation in these regimes makes 100 ns and 1 ns, respectively. The dependence of the transmittance of astralens aqueous suspension versus the incident radiation intensity in the range 100 kW/cm2 – 1 GW/cm2 was measured. Nonlinear transmission appears at the value of intensity about 10 MW/cm2. At the intensity 1 GW/cm2 the initial transmittance is decreased in 4 time. The relaxation time was about 15 ns. Comparison of the obtained experimental results with theoretical calculations showed that the optical limitation is caused by the resonant mechanism of reverse saturable absorption, and nonresonant mechanism of the nonlinear scattering.

Quantum theory of the plasmonic nanolaser

Ilya A. Fyodorov, Moscow Institute of Physics and Technology (Russian Federation); Andrey K. Sarychev, Institute for Theoretical and Applied Electrodynamics (Russian Federation); Alexei Bogdanov, HGST (United States); Andrey N. Lagarkov, Institute for Theoretical and Applied Electromagnetics (Russian Federation); Gennady Tartakovsky, Innovative Optical Solutions (United States)

Surface plasmon nanolasers, also known as SPASERs attract much attention in recent years due to the numerous potential applications in the plasmonics. In this work, we consider the metal horseshoe nanoresonator filled with the active dielectric medium. The size of the considered resonator is much less than the wavelength. On this scale, the plasmon field inside the nanoresonator behaves as a quantum object. The plasmon quantum field is subject of the random external force because of the quantum-mechanical process of the photon absorption in the active medium. Due to the small size of the resonator, the coupling between the plasmon field and an atom of the active medium is anomalous strong. The interaction cannot be considered as just emission and absorption processes. We develop the quantum dynamics of the plasmon field coupled with the active medium. Thus, we consider how the quantum fluctuations influence the process of the luminescence and find how the lasing threshold is changed. The coherence of the light emitted by the plasmon laser is also considered. We predict that the light beams, radiated from non-interacting plasmon nanolasers, could not give the interference pattern. The quantum properties of the nanolaser are important for many applications, such as transmitting and processing optical signals on a scale much smaller than the wavelength.

8806-91, Session PWed

Design of polarization splitter through phase transformation based on transformation optics

Wenyan Yan, Weixing Shu, Hunan Univ. (China)

Within the past a few years transformation optics has been arousing great interest. It provides a general method to manipulate electromagnetic waves by materials. Using it a host of striking electromagnetic devices has been demonstrated, mainly focused on controlling the path of light ray or on molding the phase, such as phase transformers. In that regard we proposed a general method of phase transformation between any two wavefronts through a compact slab (Phys.Rev.A 85,063840:2012). Meanwhile, less work has been devoted to manipulating the polarization.

In this work we will show it is possible to control the polarization through phase transformation based on transformation optics and present a theoretical design of polarization splitter. Usually the polarization splitter is constructed by optically anisotropic media. Being limited by the material parameter values, the split angle is restricted in conventional media and the direction of the output waves can only be tuned by the optical axis or the geometrical shape of the media. In contrast, our present scheme will keep a planar configuration, while the exit wave direction and shape can be manipulated.

In details we firstly realize a phase transformer that is able to deflect a wave into any direction and shape prescribed. For TE and TM waves we choose distinct deflection angles and obtain two sets of material parameters. Since the two sets are independent of each other, they can be fulfilled in a single anisotropic slab that will implement a polarization splitter. The results are further confirmed by numerical simulations.

8806-92, Session PWed

Nanopatterned multilayer hyperbolic metamaterials for spontaneous light emission control

Dylan Lu, Lorenzo Ferrari, Zhaowei Liu, Univ. of California, San Diego (United States)

Light emission process near the metallic surface has been modified through the Purcell effect, but it relies on the matching between spontaneous emission spectra and surface plasmon resonances which are limited by existing metal properties. In this work, we propose nanopatterned multilayer hyperbolic metamaterials (MHMs) for enhancing emission decay rates with improved radiative emission into the far field. By investigating Purcell effect on flat metallic films, flat and nanopatterned MHMs, we demonstrate tunable Purcell enhancement on MHMs across the visible spectrum through the engineering of hyperbolic material properties based on a theoretical model for dipole emitter's interaction with multilayer substrates and confirmed by full-wave electromagnetic simulations. The distribution of three decay channels, radiative emission, plasmonic modes, and lossy-wave component, is also analyzed by varying the emitter-substrate distances and emission wavelengths. The non-radiative nature of dominating plasmonic-mode component in flat MHMs leads to low radiative emission and external quantum efficiency. Nanopatterning into MHMs out-couples plasmonic modes into the far field for increased radiative emission, enabling far-field detection of strong Purcell enhancement. The promise in achieving light emission with both high decay rates and brightness has potential applications in light-emitting devices, single molecule detection, and surface-enhanced Raman spectroscopy.

Extending the scaling limit of artificial magnetism using vertical split ring resonator array

Fan Zhou, Chen Wang, Biqin Dong, Cheng He, Cheng Sun, Northwestern Univ. (United States)

Sub-wavelength split ring resonators (SRRs) has attracted much attention in creating artificial magnetism beyond the gigahertz range. However, the breakdown of linear scaling was found at the frequency above 100 THz. The contribution of self-inductance of electrons becomes ineligible when reduce the dimension of the planar SRRs. To overcome this issue, we developed a new route to fabricate vertically aligned SRR array consists of 1D array of metallic nanowires with U-shaped cross-section. Such a vertical SRRs exhibit two unique advantages: 1) it can be excited simultaneously by both the electric and the magnetic field of light at normal incidence; 2) The dramatically increased cross-section area effectively reduces the self-inductance of electrons and the Ohmic loss, successfully extending the scaling of artificial magnetism to the visible spectrum. The numerical simulation confirms the magnetic induced resonance at 408 THz and electrically induced resonance at 571 THz.

The U-shaped SRR array is fabricated using nanotransfer printing (nTP) process. The master mold consists of 1D grating of 150 nm width and center to center distance of 300 nm, based on which elastomeric stamps are prepared by NIL. Then 30 nm Au layer is coated on the elastomeric stamp by two subsequent angular depositions to form the U-shaped cross-section. It is then transferred to an epoxy-coated substrate via selective nTP, forming isolated and upright U-shaped grating structures. The reflectance and transmission spectrum of the SRR array are characterized by optical spectroscopy and the experimental results are in good agreement with numerical simulations.

8806-96, Session PWed

The influence of period between u-shaped resonators on metasurface response at terahertz frequency range

Mikhail K. Khodzitskiy, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Yury E. Terekhov, Lomonosov Moscow State Univ. (Russian Federation); Yaroslav V. Grachev, Egor A. Sedykh, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

Last years there has been intense research on metamaterials, which novel electromagnetic responses aren't available in natural materials. Especially there has been an increasing focus on practical applications for metamaterials in the terahertz frequency range [1-3]. Particularly, terahertz wave filters will be key components in the implementation of future terahertz (THz) communications systems, for terahertz sensing of biological and chemical samples, etc. However, for practical applications in industry, the tunability, simplicity, and low cost of THz filters are more favorable and widely demanded. In this paper we study the influence of the period between U-shaped split-ring resonators (SRRs) on the transmission/ absorbtion properties and refraction index of metasurface in THz frequency range (0.1-1 THz) using experiments and numerical simulations. The metasurface are formed by copper element arrays such as U-shaped SRRs. The metasurface is divided on nine parts with different values of the period between resonators. The period varies from 63 to 300 mkm. We fabricated the metasurface on the ZERODUR substrate by the use of ion-vacuum evaporation (the thickness of substrate is of 0.55 mm). Finally, the arrays of split-ring resonators were formed by laser engraving technique. The metasurface electromagnetic responses were characterized by terahertz time-domain spectroscopy. The experimental results reveal the shift in the transmission spectra for the metasurface response and the tuning of absorbtion intensity when the period between U-shaped SRRs changes. The notable change in the

metasurface refractive index produced by plasmon-polariton resonance for period alteration is shown. The experimental results are in consistence with finite-element simulations using COMSOL Multiphysics.

All-dielectric nanoantennas and metamaterials *(Keynote Presentation)*

Yuri S. Kivshar, The Australian National Univ. (Australia) and National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Andrey E. Miroshnichenko, The Australian National Univ. (Australia); Pavel A. Belov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

Recent experimental demonstrations of strong magnetic response of silicon nanoparticles in the visible range suggest a novel approach to many problems of nanophotonics where magnetic resonances of all-dielectric nanoparticles can be employed in addition or instead of electric resonances of metal nanoparticles in plasmonic structures. The basic physics of the excitation of magnetic response in high-index dielectric nanoparticles is quite different to that of conventional metallic nanoparticles and split-ring resonators. A magnetic Mie resonance originates from the excitation of a particular electromagnetic mode inside the nanoparticle with a circular displacement current of the electric field. This mode is excited when the wavelength of light is comparable to the particle’s diameter, and it has an antiparallel polarization of the electric field at the opposite sides of the particle

In this talk, we demonstrate novel effects for the interaction of electromagnetic waves with the structures composed of high-index dielectric nanoparticles due to the excitation of the magnetic Mie resonances. We demonstrate interplay of magnetic and electric resonances in such structures, and also discuss several examples including all-dielectric nanoantennas, oligomers of high-index dielectric nanoparticles, and all-dielectric metamaterials, and present several proof-of-principle experiments for the microwave and optical wavelength range. In particular, we predict and describe a novel type of Fano resonances originating from the optically-induced magnetic dipole modes of individual high-dielectric nanoparticles, and compare our results with the corresponding results for plasmonic structures.

8806-75, Session 15

Dielectric resonators for metamaterials *(Invited Paper)*

Aditya Jain, Iowa State Univ. (United States); Philippe Tassin, Iowa State Univ. (United States) and Chalmers Univ. of Technology (Sweden); Thomas Koschny, Costas M. Soukoulis, Iowa State Univ. (United States)

Metamaterials can achieve media with properties unattainable in nature, such as negative index of refraction or giant chirality. Many metamaterials are made out of metallic constituents, but they are plagued by dissipative loss due to conversion of energy to heat in the metal. It has been suggested to replace metallic electric circuits by Mie resonances in dielectric particles, but in general it is difficult to make such particles much smaller than the subwavelength, resulting in periodicity effects. In this talk, we present a novel type of metamaterials consisting of dielectric rather than metallic building blocks and we demonstrate that this can reduce dissipation in metamaterials significantly. We present our experimental work concerning a dispersion-engineered metamaterial based on a meta-atom made from alumina. This metamaterial possesses a resonance with a much larger quality factor than what is normally observed in metal-based metamaterials. We also show how our dielectric meta-atom can be used to create metamaterials with negative permittivity or negative permeability. The resulting structures can be modified to obtain metamaterials with a variety of properties.

8806-76, Session 15

High-contrast meta-structures for sub-diffractional light control *(Invited Paper)*

Jingjing Li, Univ. of Illinois at Chicago (United States)

The peculiar properties of metamaterials and their capability in making various devices, such as superlenses, sub-wavelength sized cavities, etc., are attracting a great deal of research interests. Currently, in the optical frequency domain, metamaterials are usually constructed from plasmonic inclusions, but the related ohmic loss has been a crucial factor limiting the performance of many of the devices. We show that the resonant phenomena related to dielectric structures of relatively high refractive index (such as silicon, n~3.5) can be harnessed to realize many of the devices once assumed to be only possible on metamaterials. The devices that will be discussed in the presentation include dielectric superlens with sub-diffraction focus; Optical cavities and waveguides of sub-wavelength mode size with the optical field staying in open space, thus freely accessible by particles and other agents. We show that optical antennas designed from some of the cavities can be coupled to a radiating dipole and distribute the radiation to the endfire direction. Some of the devices are designed through parallel stochastic optimization based on genetic algorithm which will also be introduced in the presentation.

8806-77, Session 15

Transformed cladding waveguides: confining light with all-dielectric metamaterials

Saman Jahani, Zubin Jacob, Univ. of Alberta (Canada)

Massive efforts over the last decade have been driven by miniaturization and integration of electronics and photonics on the same platform. Plasmonic waveguides suffer from absorption while photonic crystal waveguides and slot waveguides suffer from huge cross talk between closely spaced waveguides.

Here, we introduce a new class of metamaterial waveguides capable of dense photonic integration. We show that all-dielectric metamaterial claddings (epsilon > 1, mu = 1) can strongly confine light inside conventional low-index dielectric waveguides. To design the metamaterial claddings, we introduce the concept of transforming optical momentum for controlling evanescent waves. We show that these transformations lead to a class of metamaterials with dual electric and magnetic anisotropy along with giant birefringence which provide the ideal quasi-transverse electromagnetic mode propagation inside a glass core. However, magnetism at the telecommunication wavelength is a major challenge and we show that strong confinement of the electric energy of a waveguide mode can be achieved with lossless semiconductor metamaterials. The proposed practical lossless Transformed Cladding Waveguides show an order of magnitude decreased cross-talk as compared to conventional waveguides making them suitable for multiple applications in dense photonic integration and nanophotonic devices. Finally, we propose practically achievable all-dielectric metamaterial waveguides using lossless semiconductors with increased power confinement in the core for dense photonic integration

8806-78, Session 15

Probing the transition between the long-wavelength and the short-wavelength regimes of light propagation in all-dielectric metamaterials

Eric Cassan, Institut d'Électronique Fondamentale (France) and CNRS-Fonctions Optiques pour les Technologeis de l'information (France); Jean Dellinger, Univ. de Bourgogne (France); Xavier Le Roux, Khanh Van Do, Charles Caer, Institut d'Électronique Fondamentale (France) and CNRS-Fonctions Optiques pour les Technologeis de l'information (France); Frédérique A. de Fornel, Benoit Cluzel, Univ. de Bourgogne (France) and CNRS-Fonctions Optiques pour les Technologeis de l'information (France)

The transition between the long-wavelength and the short-wavelength regimes of light propagation in all-dielectric metamaterials is experimentally investigated using a hyperspectral near-field scanning microscope technique applied to a strong index contrast graded photonic crystal structure. Our measurements lead to an invariant quantity "λ/n" of only 1.78 times the photonic crystal lattice period as the criterion for the possible application of homogenization theories. Fourier decomposition of the photonic crystal Bloch waves allows interpreting the observed sudden transition between the two light regimes as a wavevector shift of the main partial plane wave at the crossing of the wavevector path with the first Brillouin zone of the photonic crystal. As a whole, these findings indicate the robustness of the homogenization approach of all-dielectric metamaterials and also suggest that the sharp transition between the two light propagation regimes could be profitably combined in graded optical artificial materials.

8806-97, Session 15

Fishnet metamaterial with broadband double negative refractive index in visible spectrum

Shiwei Zhou, Xiaodong Huang, RMIT Univ. (Australia); Qing Li, The Univ. of Sydney (Australia); Yi Min Xie, RMIT Univ. (Australia)

By optimizing the shape and scale of the perforated holes as well as the depth of metal-dielectric-metal layers, we designed a double fishnet metamaterial exhibiting 253 nm bandwidth of negative refractive index covering from 640 to 893 nm in wavelength, the widest one has even been reported. In visible spectrum, it spreads red and infrared regimes which are equivalent to 140 nm bandwidth. Moreover, the permittivity and permeability of this novel metamaterial are simultaneously negative from 647 to 755 nm, 5.7 times larger than formerly reported 19 nm in visible range. This pattering technique can be readily extended to other promising systems.

8806-79, Session 16

Recent experimental progress on quadruple-helix based metamaterials *(Invited Paper)*

Johannes Kaschke, Justyna K. Gansel, Joachim Fischer, Michael Thiel, Martin Wegener, Karlsruher Institut für Technologie (Germany)

Metamaterials based on metal helices have been introduced as broadband circular polarizers. For arrays of single helices however, the end of the helix wire together with the helix center defines a direction in space that breaks the rotational symmetry and leads to polarization conversion. Based solely on symmetry considerations we show that recovering four-fold rotational symmetry with N=4 intertwined helices circular polarization conversions can be eliminated. However, the operation mechanism is fundamentally different from single helices and without absorption of the constituent metal no circular polarization capability can be seen. The analysis is only based on four-fold rotational symmetry and time-reversal symmetry. The symmetry with respect to inverting the direction of propagation is not considered and a substrate will not change the analytical results. We compare these analytical findings to extensive numerical calculations.

Furthermore, we present current progress in the fabrication of N-helix metamaterials. We create polymer templates for subsequent electrochemical deposition of gold using STED inspired direct laser writing (STED-DLW). The major drawback of STED-DLW however, is the lack of a positive-tone photo-resist. We employ a negative-tone photo-resist instead by writing part of the complementary structure. Using STED-DLW, a highly enhanced aspect ratio can be achieved and with the increased axial resolution these inverse structures become feasible. The obtained hollow tubes are subsequently filled with gold by electro-chemical deposition during which a transparent indium-tin-oxide layer on the glass serves as the cathode.

8806-80, Session 16

Rotational optomechanics of metamaterials *(Invited Paper)*

David A. Powell, Mingkai Liu, The Australian National Univ. (Australia); Mikhail Lapine, The Univ. of Sydney (Australia); Ilya V. Shadrivov, Yuri S. Kivshar, The Australian National Univ. (Australia)

Development of nonlinear metamaterials have received new momentum with the recent emergence of structural nonlinearity, which opens rich opportunities by enabling new degrees of freedom in metamaterial design. For example, magnetoelastic metamaterials have demonstrated a nonlinear interaction between mechanical and electromagnetic subsystems, providing unusual patterns of nonlinear response. Alternatively, conformational nonlinearity has been achieved by designing a link between the electromagnetic, mechanical and thermal responses in helical metamaterial elements. Our most novel approach - metamaterials with internal rotation - is based on exploiting an easily controllable and highly sensitive mechanical feedback: twisting of an elastic wire. By using this feedback scheme, we have been able to provide a direct coupling between electromagnetic torque, induced by the incident waves in the system of split-ring resonators, and the mutual angle between them, which dynamically changes through their mutual rotation, until balanced by the elastic torque. This nonlinear mechanism results in a strongly nonlinear response and leads to a very pronounced bistability. We provide a complete analytical and numerical evaluation of the properties of this system, and confirm our findings with the proof-of-principle microwave measurements. We were able to obtain a robust bistable behaviour in experiments, showing an excellent agreement with theoretical predictions. Importantly, the general logic of our design is scalable across frequencies, implying that the corresponding nonlinear mechanism can be implemented in a wide frequency range. We believe that our results provide a valuable inspiration for the emerging area of metamaterial optomechanics, and are important for its further development.

8806-81, Session 16

Complex chiral plasmonics *(Invited Paper)*

Mario Hentschel, Harald W. Giessen, Univ. Stuttgart (Germany)

We demonstrate a strong chiral optical response in stacked arrangements of plasmonic nanostructures. We show that three-dimensional arrangements of plasmonic "meta-atoms" only exhibit a chiral optical response if similar plasmonic "atoms" are arranged in a handed fashion as we require resonant plasmonic coupling. Moreover, we demonstrate that such particle groupings, similarly to molecular systems, possess the capability to encode their three-dimensional arrangement in unique and well-modulated spectra, making them ideal candidates for a three-dimensional chiral plasmon ruler. Furthermore, we discuss

the onset of a broadband chiral optical response in the wavelength regime between 700 nm and 3500 nm upon charge transfer between the nanoparticles. We show in experiment and simulation that this response is due to the ohmic contact between adjacent particles which causes a strong red-shift of the fundamental mode. The geometrical shape of the resulting fused particles allows for efficient excitation of higher order modes. Calculated spectra and field distributions confirm our interpretation and show a number of interacting plasmonic modes. Finally, we will discuss plasmonic diastereomers which consist of multiple chiral centers. We find that the chiral optical response of the composite molecules can be traced back to the properties of the constituting building blocks. We demonstrate that the optical response of complex chiral plasmonic systems can be decomposed and understood in terms of fundamental building blocks, offering simple and straightforward design rules for future applications such as chiral optical elements and enantiomer sensors.

8806-83, Session 16

Effect of rotational symmetry on the optical rotation of using asymmetrical nanostructures

Y. L. Hor, W. K. Phua, A*STAR Institute of High Performance Computing (Singapore); Yanjun Liu, Eunice S. P. Leong, S. Wu, A*STAR Institute of Materials Research and Engineering (Singapore); Iftikhar Ahmed, Ching Eng J. Png, Eng Huat Khoo, A*STAR Institute of High Performance Computing (Singapore)

In this paper, we rotate an array of asymmetrical gammadion to investigate its effect on the chirality and sensitivity detection of biomolecular structures. The gammadion structure is made up of gold material on a glass structure and immersed in water. The gammadion array has a pitch of 700 nm with square arrangement and has right handed direction. The chirality of the un-rotated array is first determined by measuring the circular dichroism (CD) spectrum. The spectrum shows three resonance CD modes, which represent Bloch period mode and surface plasmonic resonance modes (SPR). The array is then turn to different angles with respect to the horizontal axis. It is observed that the CD spectra at different angles are different. The Bloch mode is red-shifted to longer wavelength while the SPR mode is blue-shifted. This is due to the rotation of array, which changes the optical axis, optical symmetry and arrangement from square to hexagonal. We also compare with the case where each asymmetrical gammadion is rotated and with fixed period, instead of turning the whole array. In the second case, the rotated gammadion resulted in larger wavelength shift of the CD spectra. In addition, the CD also increases by an average of 20%, given a larger absorption difference between the left and right handed circular polarized light. The results play an important role in the identification of biomolecules structures, synthesizing drug with required handedness and wide application to different class of protein molecules.

8807-1, Session 1

All-semiconductor plasmonics for mid-IR applications *(Invited Paper)*

Thierry Taliercio, Vilianne Ntsame Guilengui, Laurent Cerutti, Jean-Baptiste Rodriguez, Eric Tournié, Univ. Montpellier 2 (France)

Surface plasmon polaritons result of the strong coupling between an electromagnetic wave and the collective oscillation of free electrons of a metal. They are generated at the interface between a metal and a dielectric. They present actually a great interest because of their potential applications in the fields of metamaterial or metasurfaces, enhanced photonic devices properties, nanophotonics integrated circuits and nano-bio-photonics. All these applications rely on the use of gold resonators. Because of the need to integrate plasmonic functionalities to semiconductor devices and to keep high field exaltation at the metal/dielectric interface for mid-IR application, it is really attractive to use highly doped semiconductors. The plasma frequency as the magnitude of the permittivity of the highly doped semiconductor can be controlled via its doping level. We propose experimental study of stripe arrays of doped and encapsulated in un-doped semiconductors. The samples consist of a layer of 50 or 100 nm of lattice-matched InAsSb (Si at 1020 cm-3) grown by Molecular Beam Epitaxy (MBE) on a GaSb substrate. InAsSb arrays are realized by holography and wet or dry etching. The typical grating period is 540 nm and the width of InAsSb stripes varies from 210 to 90 nm. The encapsulating layer of GaSb is performed by MBE on the InAsSb grating. Angular dependent reflectance experiments with polarized light allowed identifying localized surface plasmon. Adjusting the doping level and the stripe's geometry allows controlling the wavelength of localized surface plasmon resonances.

8807-2, Session 1

On the detection of characteristic optical emission from electronically coupled nanoemitters

David S. Bradshaw, Jack S. Ford, David L. Andrews, Univ. of East Anglia Norwich (United Kingdom)

Optical emission from an electronically coupled pair of nanoemitters is investigated, in a theoretical analysis prompted by experimental work on oriented semiconductor polymer nanostructures. Three physically distinct mechanisms for photon emission by such a pair, positioned in the near-field, are identified: emission from a pair-delocalized exciton state, emission that engages electrodynamic coupling through quantum interference, and correlated photon emission from the two components of the pair. Each possibility is investigated, in detail, by examination of the emission signal via explicit coupling of the nanoemitter pair with a photodetector, enabling calculations to give results directly tailored for experiment. The analysis incorporates both near- and far field properties (determined from the detector-pair displacement), so that the framework is applicable not only to a conventional remote detector, but also a near-field microscope setup. The determined results are found to be strongly dependent on geometry and selection rules. This program of work paves the way for investigation of pairwise coupling effects in the emission from nanoemitter arrays.

8807-3, Session 1

NIR emitting gold nanorods: mechanism underlying the principle of emission in a metal-metal hybrid nano system

Lakshmi V. Nair, Ramapurath S. Jayasree, Sree Chitra Tirunal Institute for Medical Sciences & Technology (India)

Gold quantum cluster (GQC) and gold nano rods (GNR) are two different nanostructures of one of the most fascinating noble metals. These two nanostructures have exclusive optical properties which is attributable either to its size or shape. Gold quantum clusters are widely accepted for its extremely smaller size (~ atomic size) and the inherent fluorescence property due to quantum confinement effect. Gold nanorods, on the other hand attribute certain additional properties like NIR absorption because of the anisotropic nature and hence is an ideal candidate for photo thermal ablation.

Metallic gold impart fluorescence quenching of fluorochromes when they are in close proximity, where as metal enhanced fluorescence is exhibited at nanocluster scale where free electron model of metallic behaviour is predicted. Moreover, gold clusters are more stable and non photo bleachable.

We have developed a hybrid system of GQC and GNR, without compromising their individual properties. Glutathione protected quantum cluster with emission around 750 nm and GNRs with different aspect ratios whose absorption cross section overlaps with that of the emission of clusters were synthesized. A combined system was developed which exhibits fluorescence in the near infrared region leaving the rod structure intact. This was achieved by tuning the reaction conditions during the development of the GQC-GNR system. We discuss the mechanism underlying the fluorescence exhibited by the hybrid system in the context of the reaction conditions. This is the first report on a metal-metal combined nano system which can be used for FRET studies based on the donor-acceptor interaction.

8807-4, Session 1

Molecular nature of PbS nanoclusters attached on the silica spheres

Kwang Sun Kang, Kyungil Univ. (Korea, Republic of)

Abstract

The mixture of phenyltrimethoxysilane (PTMS) and mercaptopropyltrimethoxysilane (MPTMS) has been covalently bonded to the surface of the monodisperse silica spheres to attach the PbS nanoclusters. The Fourier transform infrared (FTIR) spectra of the modified silica spheres (MSSPh) with PTMS and MPTMS clearly indicates the phenyl ring and carbohydrate absorption band. The FTIR spectra of MSSPh after attaching the Pb2+ and converting Pb2+ to PbS show the characteristic absorption peaks. The stopband of unmodified silica spheres located at 830 nm. However, the stopband disappears after surface modification and PbS formation due to the hydrophobic nature of the silica spheres. The field emission scanning electron microscope images of the MSSPh and MSSPh-PbS show similar surface texture. The compositions of the MSSPh-PbS obtained by energy dispersive spectroscopy include silicon, oxygen, carbon, sulfur and lead with the atomic ratio (weight ratio) of 33.34 (46.31), 32.60 (25.80), 32.90 (19.55), 0.40 (0.64) and 0.75 % (7.70 %), respectively. The photoluminescence (PL) spectrum shows several luminescence peaks between 600 to 840 nm. The PL results indicate that the PbS nanoclusters (NCs) may have molecular characteristics with this growth process. A precisely controlled growth can be achieved by extensive washing and centrifuge processes.

8807-5, Session 1

Ultracompact metamaterials-based polarization converter for photonics at telecom wavelength

Loïc O. Le Cunff, Alexandre Vial, Rafael Salas-Montiel, Sylvain Blaize, Aurélien Bruyant, Univ. de Technologie Troyes (France); Anatole Lupu, Institut d'Électronique Fondamentale (France); Gilles Lérondel, Univ. de Technologie Troyes (France)

Over the past decades, advances in fabrication and characterization techniques have allowed Nanophotonics to emerge, and we are now at a point where nanophotonic devices are making their way into common products. However, there is still a lot of research to be done in that field, especially on new components. New compact and efficient components for nanophotonics are thus of great importance. The studies presented here have been done as part of the ANR METAPHOTONIQUE project, which first purpose is to design metametarials-based structures operating at telecommunication wavelength and integrated with SOI technology (Silicon on Insulator).

We present results of 3D simulations, done through the FDTD method, of a device operating at 1.55 micron and which allows for the rotation of guided light's polarization. That device efficiency is quantified in the case where it is crafted on top of a planar waveguide, and we show that it can convert up to 30% of the energy over a length shorter than that wavelength, making it a compact and efficient device. The physics behind that polarization rotation and the limits of that device are discussed, and its behavior on a waveguide of finite width is presented.

8807-6, Session 2

Transparent conductive oxides for light emission, plasmonics, and metamaterials *(Invited Paper)*

Luca Dal Negro, Boston Univ. (United States)

Transparent conductive oxides (TCOs) are a broad class of organic and inorganic materials exhibiting both optical transparency and electrical conductivity simultaneously. Zinc oxide (ZnO) is the most promising candidate for optoelectronic applications due to its large band-gap, high refractive index, low cost, and Si compatibility. We propose ZnO as a novel material platform for telecom and bio-compatible optoelectronics, plasmonics and solar cell devices.

First, we demonstrate multiband near-IR emission of Er and Nd in Si-rich ZnO thin layers under optical and electrical injection. We have investigated the rare earth (RE) excitation mechanism, driven by energy transfer from the ZnO band-gap and its optical-active defect centers. Moreover, we introduce Si in the matrix, and we demonstrate and quantify efficient Si-mediated energy sensitization of the rare earth ions. Si influence on the RE emission lifetime is elucidated as well. A proof-of-concept electroluminescent device based on Er-doped Si-rich ZnO with very low injection current density and turn-on voltage will be shown [1].

In addition, Aluminum-doped ZnO (AZO) has been demonstrated as a transparent and conductive plasmonic material in the near-IR wavelength range. In this talk, I will address opportunities and advantages of AZO and other TCOs as a metal-free Si-compatible platform for novel metamaterials-based devices towards the engineering of enhanced light emitting devices and broadband absorbing solar cells.

[1] E. F. Pecora, T. I. Murphy, and L. Dal Negro, Appl. Phys. Lett. 101, 191115 (2012).

8807-7, Session 2

ZnO as an effective fluorescence sensor for nitroaromatic derivatives

Roy Aad, Univ. de Technologie Troyes (France); Vesna Simic, Commissariat à l'Énergie Atomique (France); Loïc O. Le Cunff, Univ. de Technologie Troyes (France); Corinne Sartel, Vincent Sallet, Alain Lusson, Univ. de Versailles Saint-Quentin-en Yvelines (France); Christophe Couteau, Gilles Lérondel, Univ. de Technologie Troyes (France)

Zinc Oxide (ZnO) is an interesting wide bandgap semiconductor with various applications in medicine, electronics, acoustics and optics. In particular, ZnO is extensively investigated as material for the detection of a great number of gases and vapors. Ongoing research primarily focuses on the study of changes in the electric and acoustic properties of ZnO in presence/absence of gases. However, few studies have addressed the quenching (i.e. decrease) of the ZnO luminescence as a transducing technique for sensing applications. We report on the luminescence quenching of ZnO nanowires for TNT vapor detection. Vertically aligned arrays of ZnO nano-wires, with a high aspect ratio (65 nm radius and 1.2 µm height) are grown by metalorganic chemical vapor deposition. Photoluminescence (PL) measurements were realized in the presence/absence of 2,4-Dinitrotoluene (DNT) vapor, an impurity found in TNT. The quenching response of the nanowires is compared to that of a ZnO thin film. While both the thin film and the nanowires exhibited a decrease in the PL intensity, the nanowires present a faster (50 % quenched in 40 s) and more efficient response (95% quenching efficiency) than the thin film (only 15% quenching efficiency). The difference between the quenching response of the nanowires and the thin film is interpreted using Monte-Carlo simulations taking the exciton diffusion length and mean free path as parameters. The experimental results along with the simulations show the importance of nanostructured materials for enhanced sensing response. Moreover, this study reveals the great potential of using ZnO nanowires for TNT vapor detection.

8807-8, Session 2

Infrared to green and red frequency upconversion of Er3+/Tb3+/Eu3+ co-doped Y2O3 nanocrsystals

Geraldo Sobral, UFAL (Brazil); Maria Gomes, UFS (Brazil); Geovana Webler, UFAL (Brazil); Jhon Avila, José Joatan Rodrigues Jr., UFS (Brazil); Jandir M. Hickmann, Márcio A. R. C. Alencar, UFAL (Brazil)

Rare earth-doped nanocrystals (REDN) are among the most promising systems for luminescent applications in nanoscale domain due to their capability of convert infrared excitation into new higher frequencies fluorescence. In this work, we produced yttrium oxide nanocrystals (Y2O3) co-doped with Er3+, Tb3+ and Eu3+ ions and characterized intense infrared to red and green upconversion (UC) emissions. observed when this system was excited by a Ti:Sapphire laser tuned in the range of 792 and 820 nm. The Y2O3 REDN were produced via PVA-assisted sol-gel route, in which polyvinyl alcohol is employed in the polymerization step. The resulting sol was calcined in a temperature range of 400 and 1000 °C for 5 hours. DTA/TG and XRD measurements were employed to investigate the formation of crystalline phase. The particles' size and morphology were investigated using a field-emission scanning electron microscopy. We observed that the sample calcined at 1000 oC was composed by crystals with 34.3 nm diameter. From the fluorescence measurements we identified green UC associated to Er3+ and Tb3+ transitions and red emission due to the Er3+ and Eu3+ transitions. We also observed that the intensities of green luminescence bands vary quadratically with the laser power, which indicates that a sequential two laser photons absorption process of Er3+ gives the main contribution to the observed green UC, while energy transfer mechanisms between Er3+- Er3+ and Er3+-Eu3+ ions are the main responsible for the observed red UC. Our results indicate that this synthesis method can produce efficient nanophosphors useful for luminescent photonic applications.

8807-9, Session 2

Structural, optical, and vibrational properties of ZnO nanorods embedded in polymer matrix

Udayabhaskar Rednam, Balasubramanian Karthikeyan, National Institute of Technology, Tiruchirappalli (India)

ZnO nanorods were synthesized by refluxing method. The prepared ZnO nanorods were carefully characterized using SEM, TEM, XRD and UV-visible and photoluminescence spectrophotometer. ZnO nanorods with hexagonal wurtzite structure were loaded into PVP matrix inorder to get polymer nanocomposite films. The properties of the as-prepared ZnO:PVP composite films are characterized by X-ray diffraction (XRD), thermo gravimetric analysis (TGA), Fourier transform infrared spectroscopy (FTIR), UV-visible and Photoluminescence studies. Band gap of wurzite ZnO gets affected after loading into PVP matrix. TGA studies given the information about thermal stability of these films. The interaction between PVP and ZnO can be understood from the FTIR studies. PL studies provides the details about different luminescence centers identified in the PVP:ZnO polymer nanocomposite films.

8807-28, Session PWed

Enhanced infrared absorption on metal nano clusters and structures

Jae Hong Park, National Nanofab Ctr. (Korea, Republic of)

The intensification of infrared-active vibration modes of molecules in close proximity to nanometer-thick metal films, commonly known as surface-enhanced infrared absorption (SEIRA), is receiving increased attention from both a phenomenological and practical viewpoint. The resonant excitation of Plasmon in metallic nanostructures can provide large field enhancements on the surfaces of metals, which in turn provide dramatic increases in the detected spectroscopic signals for molecules adsorbed on their surfaces. The most widely used surface enhanced spectroscopy (SES) is surface enhanced raman scattering (SERS), where the electromagnetic enhancement factor is proportional to the fourth power of the field incident on the molecule.

Recently there has been a resurgence of interest in another type of SES, surface enhanced infrared absorption. It has been widely applied to surface trace analysis, bio-sensing, electro sorption, and electro catalysis because of its significant amplification of surface signal and simple surface selection rule. The surface enhanced infrared absorption can be observed easily on metal island films prepared by vacuum evaporation or sputtering and electrochemical or electroless deposition. Metal colloids also support the enhancement. Like surface-enhanced Raman scattering (SERS), SEIRA is chiefly of electromagnetic origin, that is, due to an increase in the local optical field exciting the adjacent molecules.

Metal nano clusters much smaller than the wavelength of light facilitate the interaction of the infrared radiation with the metal and adsorbed molecules, resulting in the enhancement. It was explained that the enhancement is greatly affected by the size, and planer density of metal nano clusters compared with metal nano films. Phenomenological and theoretical difference of infrared absorption in broad ranges of wave length including near field to far field infrared rays between metal nano clusters and metal nano films.

8807-29, Session PWed

On a simplified analysis of the external photoelectric effect from quantum wells, wires, and dots of nonlinear optical and optoelectronic nanostructure materials

Subhamoy Singha Roy, JIS College of Engineering (India); A. Singha Roy, School (India)

It has been found taking quantum confined Hg1-xCdxTe, CdGaAs2 and In1-xGaxAsyP1-y lattice matched to CdS, InP and stressed InSb as examples that the external photoelectric effect exhibits plateaus as function of incident photon energy, which is vital from experimental point of view. The numerical results of quantum confined optoelectronic III-V degenerate semiconductors form the special case of my generalized analysis.

8807-30, Session PWed

Optical properties and aging of PbS quantum dots embedded in a porous matrix

Aleksandr P. Litvin, Peter S. Parfenov, Elena V. Ushakova, Anatoly V. Fedorov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Mikhail V. Artemyev, Anatoly V. Prudnikau, Belarusian State Univ. (Belarus); Ivan D. Rukhlenko, Monash Univ. (Australia); Alexander V. Baranov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

Close-packed nanocrystal systems based on lead chalcogenide semiconductor quantum dots (QDs) attract much attention due to the possibility to utilize them in a variety of optoelectronic devices, such as photovoltaic elements, LEDs and lasers, and photodetectors. We demonstrate a low-cost effortless method for creation of close-packed nanocrystal systems in porous matrix. The samples thus obtained demonstrate linear dependencies of optical density and luminescence intensity on the QDs concentration and perfect homogeneity. Optical properties of PbS QDs with diameter of 3–8.5 nm embedded in a porous matrix were studied using absorption and steady-state and time-resolved photoluminescence spectroscopy. Luminescence band demonstrate slight red shift increased with rising of QDs concentration, which can be caused by FRET between nominally monodispersed PbS QDs. Measured average room-temperature luminescence lifetimes are size-dependent, increase with decreasing of QDs size and lie between 435 and 58 ns for close-packed PbS nanocrystals systems with QDs of 3.0 and 7.4 nm in diameter, respectively. The aging behavior of PbS QDs in a porous matrix was explored for different sizes of QDs. Large blue shift in luminescence spectra accompanied by increasing of luminescence lifetimes for small and medium QDs after a month of storage indicates the oxidation and decreasing of QDs size. Close-packed nanocrystal systems made from PbS QDs larger than 5 nm are found to be stable in aerobic atmosphere.

8807-32, Session PWed

Spectroscopy of intraband optical transitions in an anisotropic semiconductor nanocrystals

Vadim K. Turkov, Anvar S. Baimuratov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Ivan D. Rukhlenko, Monash Univ. (Australia); Alexander V. Baranov, Anatoly V. Fedorov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

Nonspherical semiconductor nanocrystals may exhibit strongly anisotropic photoluminescence and absorption due to the intraband transitions, whose matrix elements depend critically on the envelope wave functions of the confined electrons and holes. We theoretically demonstrate that this anisotropy may be used as the basis for a new type of polarization spectroscopy, enabling one to reliably determine the shape and spatial orientation of individual nanocrystals, as well as providing important information on the symmetry of quantum states involved in optical transitions.

8807-33, Session PWed

Effect of temperature on photoexcited charge carrier dynamics in Si-NCs/SiO2 superlattices

Miroslav Korinek, Martin Kozak, Frantisek Trojanek, Charles Univ. in Prague (Czech Republic); Daniel Hiller, Andreas Hartel, Sebastian Gutsch, Margit Zacharias, Albert-Ludwigs-Univ. Freiburg (Germany); Petr Maly, Charles Univ. in Prague (Czech Republic)

At present most commercial electronic integrated circuits and devices are fabricated from bulk silicon. However, this material is not useful for fabricating photon emitters because of its indirect band gap. On the other hand, silicon nanocrystals (Si-NCs) have attracted attention over the last years for their efficient light emission. Si-NCs not only have potential applications for optoelectronic devices (silicon-compatible light sources), but also are one of the most promising materials for solar cells (non-toxic absorber material in third generation photovoltaics), biosensors and non-volatile memories. From the application point of view, one of the most suitable materials would be Si-NCs in a SiO2 matrix, which provides a stable and easily achievable surface passivation. The studied samples were prepared by evaporation of SiOx/SiO2 superlattices and subsequent thermally induced phase separation. The dynamics of photoluminescence (PL) was measured by a streak camera on microsecond time scale. The stretched-exponential PL decay with spectrally and temperature dependent coefficients was observed. The time-resolved measurements were completed by a standard time-integrated PL. We show a strong influence of temperature and excitation intensity on the PL spectrum. The results will be interpreted in terms of carrier trapping and compared with those reported on Si-NCs prepared by other techniques.

Nonradiative resonant energy transfer between PbS QDs in porous matrix

Elena V. Ushakova, Aleksandr P. Litvin, Peter S. Parfenov, Anatoly V. Fedorov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Sergei A Cherevkov, National Research Univ of ITMO (Russian Federation); Alexander V. Baranov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

Resonant nonradiative energy transfer (FRET) between lead sulfide quantum dots with different sizes embedded in porous matrix is observed. Information on the availability and efficiency of FRET in systems with different relative ratio QD-donor (QDD) and QD-acceptor (QDA) is obtained by analyzing the changes in donors and acceptors luminescence intensity in steady-state and time-resolved fluorescence experiments.

Quantum dots with size 4.8 nm (QDD) and 6.2 nm (QDA) are obtained by hot-injection method. Quenching of QDD PL and enhancement of QDA PL with increasing QDA concentration in the mixture of QDs caused by FRET are observed. At the same time, the relative QDA PL intensity decreases with increasing acceptor concentration in the matrix. It is concluded that the FRET efficiency depends on the molar ratio QD-donor/QD-acceptor and the energy transfer from the donor to the acceptor carries on several channels.

We observe biexponential PL decay with lifetimes of 155 ns and 80 ns, typical for the individual QDD and QDA in the matrix, respectively. With increase of the acceptor concentration in the matrix the contribution of the donor PL decay decreases. This indicates that the energy transfer in the studied systems is determined by static quenching, specific for direct contact between QDD and QDA in the close-packed ensembles of the QDs.

Tunable luminescent properties of AgInS2/ZnS and AgInS2/ZnS at ZnS core-shell particles

Théo Chevallier, Gilles Le Blevennec, Sonia De Sousa Nobre, Frederic Chandezon, Commissariat à l'Énergie Atomique (France)

AgInS2/ZnS (AIZS) nanoparticles are luminescent semiconductor nanocrystals that are good candidates for the development of new white light emitting diodes because of their low toxicity compared to CdSe quantum dots. Moreover, the optical properties of AIZS particles are easily tuned by changing the AgInS2/ZnS molar ratio. Indeed, the luminescence of AIZS is primarily induced by the defects in their structure leading to a donor-acceptor luminescence mechanism.

In this work, we present the recent results of our investigations of the electronic structure of these nanomaterials in order to optimize the photoluminescence quantum yield associated with their light conversion properties. XRD spectra and TEM images confirmed the successful synthesis of crystalized AIZS nanocrystals with a chalcopyrite structure. AIZS nanocrystals with various compositions were successfully synthesized leading to the evolution of their luminescence properties with composition. Donor-acceptor type emission was confirmed by stationary photoluminescence measurements. Absorbance, time resolved spectroscopy, UPS and ESR measurements were used to probe the electronic structure of AIZS particles with a close look at the influence of defects.

With the help of TGA measurements, the growth of a controlled layer of semiconductor on the already made particles was achieved. ZnS coated AIZS nanocrystals gave insights on the electronic structure of the surface defects and their specific role in the donor-acceptor emission. Moreover reliability and thermal stability of AIZS and ZnS coated AIZS particles were studied by incorporating them in a standard LED device.

Time-resolved pump–probe spectroscopy of intraband absorption by a semiconductor nanorod

Mikhail Y. Leonov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Ivan D. Rukhlenko, Monash Univ. (Australia); Anatoly V. Fedorov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

The employment of anisotropic nanoparticles offers novel degrees of freedom in fabrication of complex geterosystems on the nanoscale. Despite the many practical benefits associated with the nanoparticles' anisotropy, the physical properties and electronic dynamics of anisotropic nanoparticles are still poorly understood. This gap in understanding may be filled via the analysis of the nanoparticles' response measured using the time-resolved pump–probe optical spectroscopy. Such an analysis must rely on a solid theoretical foundation of this spectroscopic technique tailored to study anisotropic nanoparticles, and may eventually put an end to the long-lasting discussion on the dominant relaxation mechanisms of nanoparticle electronic subsystem. In this work, we develop a theory of pump–probe optical spectroscopy based on the pump-pulse-induced transient intraband absorption of the probe pulse inside an anisotropic semiconductor nanorod. Our theory assumes that the carrier frequencies of the pump and probe pulses are close to the resonances with interband and intraband transitions, respectively. The evolution of the electronic states of the nanorod is described using the density matrix formalism. We elucidate the experimental conditions under which the dependence of the absorbed energy on the delay between probe and pump pulses is given by an exponential function, with the exponent inversely proportional to the lifetime of the electronic state.

Hierarchical ZnO/MgO nanostructure for enhancing light emission of vertical light-emitting diodes

Byeong-Uk Ye, Ulsan National Institute of Science and Technology (Korea, Republic of); Buem Joon Kim, Jong-Lam Lee, Pohang Univ. of Science and Technology (Korea, Republic of); Jeong Min Baik, Ulsan National Institute of Science and Technology (Korea, Republic of)

Nanostructured vertical light-emitting diodes (V-LEDs) with a very dense forest of vertically aligned ZnO nanowires on the surface of N-face n-type GaN are reported with a dramatic improvement in light extraction efficiency (~3.0x). The structural transformation (i.e., dissociation of the surface nitrogen atoms) at the nanolevel by the UV radiation and Ozone treatments contributes significantly to the initial nucleation for the nanowires growth due to the interdiffusion of Zn into GaN, evident by the scanning photoemission microscopy (SPEM), high-resolution transmission electron microscopy (HR-TEM), and ultraviolet photoelectron spectroscopy (UPS) measurements. This enables the growth of densely aligned ZnO nanowires on N-face n-type GaN. This approach shows an extreme enhancement in light extraction efficiency (>2.8x) compared to flat V-LEDs, in good agreement with the simulation expectations (~3.01x) obtained from 3D finite-difference time-domain (FDTD) tools, explained by the wave-guiding effect. The further increase (~30%) in light extraction efficiency is also observed by forming a hierarchical ZnO/MgO Nanostructure as a form of 'needleleaf tree' on VLEDs. The growth mechanism of nanolscale needleleaf tree is also investigated.

Optical properties of two-dimensional (2D) CdSe nanostructures

Sergey A. Cherevkov, Alexander V. Baranov, Aleksandr P. Litvin, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Anatoly V Fedorov, National Research University of ITMO (Russian Federation); Anatoly V. Prudnikau, Mikhail V. Artemyev, Belarusian State Univ. (Belarus)

Until recently, a very little attention has been given a two-dimensional (2D) colloidal semiconductor nanocrystals or nanoplatelets (NPs), spatial quantization of excitons in which is only in one dimension. Most of studies to date were focused on the mechanisms of growth and morphology of the 2D-nanocrystals. Works devoted to the electronic and phonon structures, depending on the thickness of the NPs, are virtually absent. In this work, the resonant and non-resonant Raman spectra of CdSe nanoplatelets with thickness of 5, 6, and 7 monolayers with the fundamental exciton transition at 460, 515 and 550 nm, respectively, were obtained. Micro-Raman spectra of the CdSe NPs with different numbers of monolayers demonstrate characteristic peaks at frequencies of ~ 180, 203, 230, 370, 406 and 470 cm-1. Here peaks at ~ 180 cm-1 and 203 cm-1 are associated with the SO and LO phonon modes of the NPs where as the peaks at 370 cm-1 and 406 cm-1 with their overtones. It was found that the frequencies of the LO-phonon and its overtone bands monotonically decrease with the platelets thickness that was associated with the effect of spatial confinement of optical phonons like that for CdSe quantum dots.

8807-11, Session 3

Optical and vibrational studies of ZnO nanostructures with silver colloids

Udayabhaskar Rednam, Balasubramanian Karthikeyan, National Institute of Technology, Tiruchirappalli (India)

We report Optical and vibrational properties of Ag doped ZnO nanoparticles. Ag/ZnO is prepared by using simple room temperature sol gel synthesis and influence of silver on ZnO is studied. Structural and optical properties are characterized by X-ray diffraction, Fourier transform IR (FTIR), Micro Raman, UV-visible, and photoluminescence spectroscopy for both pure ZnO (0 % Ag) and Ag/ZnO (5 % ZnO) nanostructures. Morphology studies are carried out using SEM and TEM. Uv-Vis results shows absorption related to band gap of ZnO along with the SPR (surface Plasmon resonance) band related metallic silver nanoparticles. The intensities of fingerprint Raman lines of ZnO nanocrystals were increased remarkably due to Ag doping and it is attributed to Surface Enhanced Raman Scattering (SERS).

8807-13, Session 3

Well-ordered patterning of multi-functional ZnO by templated growth and self-organization technique

Romain Parize, Anna Rumyantseva, Hind Kadiri, Mathieu Tobori, Komla Nomenyo, Christophe Couteau, Anisha Gokarna, Gilles Lérondel, Univ. de Technologie Troyes (France)

Ordered arrays of 1D ZnO nanowires (NWs) are essential for applications in optoelectronic devices because of device performance improvement but they are also essential for advanced light-matter interaction control i.e. absorption and emission enhancement.

The aim of this work is to demonstrate selective, patterned growth of ZnO using low cost, easy-to-fabricate templates by the top-down and bottom-up approach. The bottom-up approach combines the fabrication of self-organized templates of functionalized polystyrene (PS) beads followed by the growth of ZnO using low temperature chemical bath deposition (CBD) method. ZnO nucleation layer is deposited on the PS beads prior to the synthesis of ZnO NWs. Formation of highly crystalline, luminescent ultra-narrow NWs with diameter lower than 10 nm are observed to be formed around the PS beads leading to a new kind of urchin-like ZnO. A second, novel, top-down approach using two-beam laser interference lithography for patterning silicon substrates is also reported. Large scale structuring of the substrate is performed using this technique. Well ordered, coalesced, crystalline nanorods of ZnO are observed to grow by the CBD technique in these well-defined arrays. These patterned templates will be further incorporated in various device applications.

8807-14, Session 3

A novel route for fabricating printable photonic devices with a high refractive index *(Invited Paper)*

Carlos Pina-Hernandes, abeam Technologies, Inc. (United States)

The nanopatterning of high refractive index optical films promises the development of novel photonic nanodevices such as optical integrated circuits, imaging sensors and solar cells. Here, we demonstrate state of the art printed photonic devices and discuss their optical performance. A novel strategy for patterning inorganic films at very high resolution

by combining inorganic synthetic chemistry and printing methods was developed. This technology allows for the direct printing of optically transparent films with unmatched resolutions over large areas.

Novel hybrid organic/inorganic printable materials were synthetized for crack free films with very high resolution patterns. Sub-10 nm resolution was achieved and defines state of the art for patterning functional films [1]. Optical properties of the printed nanostructures can be tuned over a wide range of values; a refractive index higher than 2.1 and an extinction coefficient close to zero was achieved in the visible wavelength range. The proposed approach promises to drastically simplify the fabrication of photonic devices and the development of novel nanophotonic structures, which are very difficult to achieve by conventional nanofabrication processes. A variety of photonic structures have been successfully printed into TiO2 films and their optical properties were measured.

Our technology opens an original route for fabricating novel printable photonic devices at low cost and high throughput.

This study is supported by the US Air Force under Contract No. FA9550-12-C-0055. Work at the Molecular Foundry was supported by the Office of Science and Office of Basic Energy Sciences of the United States Department of Energy under contract DE- AC02-05CH11231

UV photonic structures fabrication by top-down lithography

Komla Nomenyo, Christophe Couteau, Univ. de Technologie Troyes (France); David J. Rogers, Nanovation (France); Gilles Lérondel, Univ. de Technologie Troyes (France)

Although ultraviolet lasers and LED based on GaN are readily available, zinc oxide (ZnO) is still interesting due to its large exciton binding energy, efficient radiative recombination and simpler crystal-growth processes which are significant for lower costs ZnO-based devices. On the other hand, ZnO structuring on a nanometric scale (periodicity ≤120 nm), in order to realize photonic crystal slabs, has proved to be a critical issue that is faced up by the strong mechanical properties of ZnO, making of lithography one of the main challenges to confront for the fabrication of efficient ZnO lasers and LEDs. To date only a top-down process namely focusing ion beam, has allowed the spatial control of ZnO resonant photonic crystal (PhC).

In this work, we present PhC and microcavities fabrication by electron beam lithography (EBL) combined with inductively coupled plasma reactive ion etching (ICP-RIE). EBL combined with ICP-RIE allows for a faster structuring on larger surfaces. We will both address the EBL and ICP-RIE fabrication issues which mainly include sample charging due to the use of nonconductive substrate such as sapphire and organic and inorganic compounds formation and deposition after ZnO etching with C2F6 plasma. Resin metallization prior to EBL and O2 plasma cleaning integrated in the ICP-RIE etching process were found to be very efficient to overcome the above mentioned issues leading to ZnO PhCs and microdisks. resonant in the arrays and microdisks. Structures quality was assess through micro PL results obtained by measuring µPL of photonic crystals and microcavities.

8807-17, Session 4

Practical nanophotonic architectures for ultrafast all-optical switching

Brandon Born, Christopher M. Collier, Jonathan F. Holzman, UBC Okanagan (Canada)

The all-optical switch is the fundamental building block for optical fibre frontend systems. Operation in an all-optical format eliminates the electronic bottleneck to facilitate processing and routing at terabit-per-second data rates. The challenges of these ultrafast all-optical switching devices are addressed and overcome through a series of nanophotonic architectures.

It is shown in this work that nano-scale localization of signal and control beams can be used to enhance nonlinear beam interactions and simultaneously reduce all-optical switch recovery times. The concept of a photonic nanojet is applied first to create this nonlinear all-optical beam interaction at the intense focal region between a high refractive index microsphere and a semiconductor surface. A nano-scale plasma is preferentially photoinjected at the semiconductor surface and undergoes rapid surface recombination due to the high density of surface states. Practical all-optical switching device geometries are designed, fabricated and tested for various semiconductors, and it is found that the observed picosecond recovery times can be ten times shorter (20 ps for GaAs) than a standard bulk semiconductor switch. The process of enhanced surface recombination is then accentuated through the use of semiconductor nanoparticles. The dramatic increase in the density of surface states is found to greatly reduce the all-optical switch recovery times. A Si ultrafast all-optical switch shows a 20 ps switching time, being approximately a thousand times faster than its bulk counterpart. A SiC ultrafast all-optical switch shows a 5 ps recovery time, being approximately a million times faster than its bulk counterpart. The capabilities of these new ultrafast all-optical switches are discussed for emerging photonic systems.

8807-18, Session 4

Optical scale photonic devices using complex block copolymer morphologies

Scott W. Sides, Benjamin Cowan, Tech-X Corp. (United States)

We present a numerical method for the optimization of photonic devices created from block co-polymer (BCP) templates by coupling a code which calculates nanoscale morphologies with with a code for calculating optical properties of photonic crystals.

Making commercially viable photonic devices active at optical wavelengths is challenging due to the difficulty of controlling the structure of dielectric regions with characteristic sizes on the order of 10nm-100nm.

An attractive method for creating photonic materials with these small length scales is by using block copolymers (BCP). Complex BCP formulations have the potential to form nanoscale morphologies with efficient, solution based techniques.

Numerical self-consistent field theory (SCFT) is a method that transforms the Hamiltonian of a complex system into a field theory description, whose mean-field solution is amenable to analytic and numerical methods.

The advantage of the coarse-graining SCFT algorithm is that it enables large simulations of BCP systems within minutes or hours as opposed to classical or ab initio molecular dynamics (MD) that can take days or weeks.

Initial simulations are presented of BCP mixtures on patterned substrates using the SCFT code PolySwift++. The results of these simulations can be used to create templates for fabricating nanoscale photonic devices. We then use the data from PolySwift++ in the high-performance electromagnetic simulation code VSim to study the optical characteristics of the devices. This coupling will enable theoretical investigations of novel photonic structures not currently possible.

8807-19, Session 5

Plasmonic nanoparticle transducers studied using single-particle nonlinear optical spectroscopy *(Invited Paper)*

Kenneth L. Knappenberger, Florida State Univ. (United States)

Polarization-resolved second harmonic generation (SHG) measurements were performed on solid gold nanosphere (SGN) dimers at the single-particle level. The results indicated that single-particle SHG measurements could be used to characterize the localized electromagnetic surface fields that result from excitation of inter-particle plasmon modes. For several dimers, the polarization-resolved measurements revealed that the confined surface fields were chiral. Quantitative analysis of SHG line shapes obtained from single-particle continuous polarization variation (CPV-SHG) experiments confirmed that the chirality originated from non-zero magnetic-dipolar contributions to the SGN dimer nonlinear optical response. These findings demonstrate that plasmonic nanoparticle assemblies can function as transducers that amplify both electric and magnetic fields. Correlation of SEM images and single-particle SHG measurements obtained for several SGN dimers, as well as lithographically generated nanostructures, were used to demonstrate the structure sensitivity of the CPV-SHG method.

8807-20, Session 5

Modal analysis of LSP propagation in an integrated chain of gold nanowires

Ricardo Tellez Limon, Mickael Février, Univ. de Technologie Troyes (France); Aniello Apuzzo, Université de Technologie de Troyes (France); Rafael Salas-Montiel, Sylvain Blaize, Univ. de Technologie Troyes (France)

In recent years, it has been demonstrated that light can be propagated through a chain of metallic nanoparticles due to the Localized Surface Plasmons effect.

By making use of the Fourier Modal Method, in this work we study numerically the propagation of plasmonic Bloch waves in a periodic array of gold nanowires, and its interaction with a single-mode dielectric waveguide. When the size of the nanowires is modified, at the edge of the first Brillouin zone we clearly identify different LSP resonances involved in the wave propagation mechanism: one dipolar longitudinal for nanowires of short height, and a quadrupolar and a dipolar transversal for taller ones.

In the computed dispersion curves, it is possible to observe a match of the wave-vector, k, between the fundamental mode of a dielectric waveguide and those associated to the dipolar longitudinal and quadrupolar Bloch modes of the nanowires. Thus, when the dielectric waveguide approaches to the nanowires, a directional coupling can be achieved. On the other hand, even when the dipolar transversal Bloch mode of the nanowires is not matched with the dielectric waveguide mode, it is still possible to observe a strong interaction of the field between both structures.

The used numerical method allowed us to determine the transmission, reflection and absorption of the structure in a spectrum range from 400 nm to 1.5 µm, as well as near field maps of the electromagnetic field components.

The obtained results show that the designed structure can be used as an integrated optical sensor with a sensing efficiency which can be improved by adjusting the geometrical parameters of the metallic nanowires.

8807-21, Session 5

Matrix induced in-situ growth of crystalline Au nanoparticles for photonic applications

Christian Katzer, Friedrich-Schiller-Univ. Jena (Germany); Markus Westerhausen, Institute of Solid State Physics (Germany); Philipp Naujok, Friedrich-Schiller-Univ. Jena (Germany); Hendrik Bernhardt, Institute of Solid State Physics (Germany); Gabriele Schmidl, Wolfgang Fritzsche, Institut für Photonische Technologien e.V. (Germany); Andreas Undisz, Martin Drüe, Markus Rettenmayr, Otto Schott Institute of Materials Research (Germany); Frank Schmidl, Friedrich-Schiller-Univ. Jena (Germany)

In the past years different methods such as wet chemical synthesis where established to fabricate metal nanoparticles which can be used in biophotonic sensor devices. In order to overcome the multiple preparation steps and typical solution based problems like aggregation of particles, new in-situ methods of preparation directly on the substrate surface are highly favoured.

The authors present a novel in-situ method of fabricating gold nanoparticles by self-organization using two different matrices ($YBa_2Cu_3O_{7-\delta}$ and $SrTiO_3$) grown by a pulsed laser deposition technique. Thereby a thin gold layer self assembles into crystalline nanoparticles due to the elevated temperatures during the matrix deposition. Through a variation of the initial seed layer thickness we are able to influence the size and the distribution of the particles [1]. Furthermore by choosing a different matrix material and other deposition parameters, also the shape of the particles can be controlled [2].

As one might have to extract the nanoparticles or at least theirs tips from the surrounding matrix material to realise photonic applications we will show that this is easily possible in case of using $YBa_2Cu_3O_{7-\delta}$ as matrix material. But also when using $SrTiO_3$ one can achieve a dissolution of the surrounding matrix as we will present in first measurements. Furthermore several possibilities will be given to grow nanoparticles only at well-defined positions on the substrate. A spectral characterization of particles will be presented based on microspectroscopy.

8807-22, Session 5

Local surface plasmon polariton excitation controlled by magnetic particles

Rémi Vincent, Univ. de Technologie Troyes (France); Hugues Marinchio, Ecole Supérieure de Physique et de Chimie Industrielles (France); Juan José Sáenz, Univ. Autónoma de Madrid (Spain); Rémi Carminati, Ecole Supérieure de Physique et de Chimie Industrielles (France)

Surface plasmon polaritons are surface electromagnetic modes propagating along metal-dielectric interfaces. This last decade, renewed interest in surface plasmon polaritons (SPP) arises from advances in nanotechnology allowing to structure surfaces at an optical subwavelength scale. Nowadays, the search for active plasmonics components has become a central issue. Active plasmonics can be achieved, for instance, by the uses of ferromagnetic materials [1]. These materials exhibit magneto-optical response, i.e., an anisotropic dielectric response controlled by a static external magnetic field. For example we have shown recently the possibility of controlling fluorescence resonance energy transfer (FRET) using a magneto-optical nanoparticle to tune the donor-acceptor interaction with the external magnetic field as an external control parameter [2].

In the present work, we study the excitation of surface plasmon polaritons on a flat metallic surface by a magneto-optical nanoparticle placed at subwavelength distance from the surface, and illuminated by a linearly polarized plane wave. We show that the directivity of plasmon excitation can be controlled with the external magnetic field. Furthermore considering the well-known LMOKE signal, for subwavelength distance above the interface, we predict an unseen intensity for this signal.

Our study is based on exact numerical simulations, using an extended coupled-dipole and Green function method that we used previously for the study of purely metallic structures [3, 4]. The numerical results are analyzed qualitatively using a perturbative approach that provides physical insight and simple rules for the design of magnetoplasmonic components.

8807-23, Session 6

Characterization of single layer graphene using a tip-enhanced Raman spectroscopy *(Invited Paper)*

Mun Seok Jeong, Kyoung-Duck Park, Doo Jae Park, Young Hee Lee, Sungkyunkwan Univ. (Korea, Republic of)

Graphene is a promising nanophotonic material owing to its outstanding optical and electrical properties. For the synthesis of large area graphene, Chemical vapor deposition (CVD) method is widely used. However, defects on CVD grown graphene such as nucleation seeds, grain boundaries, and wrinkles are severe obstacles to fabricate high performance devices. To fabricate single layer graphene free from such defects, a thorough investigation of the physical and optical properties of those defects should be delivered in advance. We constructed an Au-tip based tip-enhanced Raman spectroscopy (TERS) system and characterized nanoscale defect structures of single layer graphene where TERS supplies a variety of multifunctional(structural, optical, and chemical) information with nanoscale resolution. The correlated information of topography, Rayleigh scattering, and Raman scattering give us interesting clues to investigate growth mechanism of nano defects of single layer graphene. We expect that our nano characterization results will be useful for controlling the quality of graphene.

8807-24, Session 6

Functional semiconductor interfaces for application in artificial photosynthesis *(Invited Paper)*

Ian Sharp, Lawrence Berkeley National Lab. (United States)

In order to sustainably meet global energy demands, it is necessary to devise new technologies capable of providing distributable power that is carbon neutral and renewable, yet price competitive. Artificial photosynthesis for direct energy conversion and storage has been proposed as a promising route for achieving these requirements. Despite the considerable effort that has been devoted to development of semiconductor photoelectrodes and solar-to-fuels catalysts, there remains a significant lack of knowledge regarding interfacial phenomena when these systems are brought into contact. Furthermore, there are few semiconductors that possess both the high efficiency and long term durability that are required for operation under harsh aqueous conditions. In order to address these challenges, we have investigated atomic layer deposited (ALD) thin films on semiconductor photoelectrodes as corrosion protection layers. Metal oxide films of a few nm thickness are capable of stabilizing semiconductors under photoelectrochemical operation and partially passivating electrically active interface states, yet simultaneously enabling efficient interfacial charge transport. However, these surfaces are not optimized for catalysing reactions associated with solar fuels generation. Therefore, we have also developed inorganic-organic systems composed of molecular hydrogen evolution catalysts covalently tethered to visible light absorbing semiconductor surfaces. Such hybrid interfaces provide models for future devices, which are expected to integrate molecular CO2 reduction catalysts for fuel formation. Surface sensitive spectroscopic methods, such as attenuated total reflection Fourier transform infrared spectroscopy and x-ray photoelectron spectroscopy are utilized to determine the specific structural and chemical properties of these interfaces at each stage of assembly. In addition, charge carrier dynamics in semiconductor photoelectrodes are investigated via transient absorption at sub-ps to ms timescales. These measurements, together with photoelectrochemical performance characterization, provide more complete understanding of the interfacial charge transfer processes and enable design improvements that are critical for achieving high efficiency solar fuel generation.

8807-25, Session 6

Theoretical research on the optical properties of magnetic fluid composed of rod-like shape nanoparticles and its micro-structure

Yong Zhao, Yu Ying, Ri-qing Lv, Northeastern Univ. (China)

In this paper, a new Molecular Dynamics model based on Rod-like magnetic nanoparticles was proposed, and it was represented in terms of translations of nanoparticles and rotations of magnetic dipole moments. Torques and forces were all considered simultaneously. In addition, the processes of cluster formation of magnetic fluid in time-varying magnetic field and stable magnetic field were compared. Different ramp rates of time-varying magnetic field were considered in the simulation analysis. For the research of optical properties of magnetic fluid, a mathematical model based on Monte Carlo (MC) method was presented and the transitivity of magnetic fluid may be computed.

In conclusion, through simulation it was found that when magnetic field was introduced in magnetic fluid, the magnetic nanoparticles suspended in carrier liquid were in translational motion and in rotational motion. In the end, the groups of magnetic nanoparticles agglomerated to form chains along the direction of magnetic field. In the simulation, the average kinetic energy of the magnetic nanoparticles decreased gradually from original state to equilibrium state. With the increasing magnetic field, the distance between magnetic columns increased and the diameter of magnetic columns decreased. In time-varying magnetic field, there were better tendency to form chains than that in constant magnetic field. The size of magnetic chains was proportional to the ramp of external magnetic field. The transitivity passed through the magnetic fluid would increase with the increasing magnetic field. The wavelength at the resonance peak of the transmission spectrum would change with different ramps of time-varying magnetic field.

8807-26, Session 6

Structural and spectroscopic characterization of glass-ceramics composed by barium titanate nanocrystals in rare earth-doped tellurite glasses

Fabio L. Oliveira, Israel Matos, Geraldo Sobral Jr., UFAL (Brazil); Elivelton Ferreira, Fabia C. Cassanjes, Gaël Y. Poirier, UNIFAL (Brazil); Jandir M. Hickmann, Márcio A. R. C. Alencar, UFAL (Brazil)

In this work, glass-ceramic samples, produced from tellurite glasses, with 99.9 (70TeO2 - 15 BaO - 15 TiO2) -0.1X2O3 (X = Eu ou Er) composition and submitted to single-step and two-steps heat treatment processes were investigated. X-ray diffraction measurements were performed and the diffraction patterns showed that, at all samples, different crystalline phases were present. Moreover, the kind of grown phases depends strongly with the employed rare-earth, heat treatment number of steps and time. For the Eu3+-doped, it was observed that samples, in which the presence of BaTiO3 was identified, showed the highest emission intensities, related to 5D1→7F1 (538 nm), 5D1→7F2 (556 nm), 5D0→ 7F0 (581 nm), 5D0→7F1 (593 nm), 5D0→7F2 (617 nm), 5D0→7F3 (654 nm) and 5D0→7F4 (702 nm) europium ions transitions, for excitation tuned at 395 nm. From absorption measurements, the oscillator strengths and the Judd-Ofelt parameters related to the electronic transitions of the Er3+-doped glass-ceramics were obtained and It was observed that these parameters were affected significantly by the presence of crystalline phases. Relatively intense infrared to green and red frequency upconversion was also observed for the Er3+-doped samples, when excited at 800 nm. Exploiting this green luminescence, we also verified that this material could be employed for optical temperature sensing, with a good sensitivity. Our results indicate that this structured material is a promising candidate for luminescent applications.

Nanoscale quantum-dot supercrystals

Anvar S. Baimuratov, Vadim K. Turkov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Ivan D. Rukhlenko, Monash Univ. (Australia); Alexander V. Baranov, Anatoly V. Fedorov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

We develop a theory of two-dimensional and three-dimensional supercrystals made of periodically arranged semiconductor quantum dots. The theory allows one to calculate the energy spectra and wavefunctions of the supercrystals' collective excitations, which are similar to the excitons in molecular crystals. We illustrate the developed theory by the example of two-dimensional supercrystals and the four-band model of the quantum dots' electronic subsystem. In this case, the supercrystal's energy spectrum can be found analytically for the five types of the Bravias lattices. Using analytical expressions for the energy spectra of supercrystals with different symmetries, we analyze the possibility of engineering their band structure. The engineering is possible owing to the multiple degrees of freedom associated with the changes in symmetry of the periodic lattice, variations in properties of the quantum dots or their environment, and alterations of the unit cell. We demonstrate that the variation of the supercrystal parameters enables an unprecedented control over the optical properties of the quantum-dot supercrystals and thus paves a way towards the development of new nanophotonics materials.

8808-1, Session 1

Light trapping and solar energy harvesting with photonic crystals *(Keynote Presentation)*

Sajeev John, Univ. of Toronto (Canada)

Photonic crystals are widely known for their light-trapping capabilities. This is often associated with the occurrence of a photonic band gap or other suppression in the electromagnetic density of states. An important new opportunity arises from light-trapping in the higher bands of a photonic crystal, where the electromagnetic density of states is enhanced rather than suppressed. This enables unprecedented strong absorption of sunlight in a material with weak intrinsic absorption. We describe designs of thin-film photonic crystal solar cells made of silicon, GaAs and dye-sensitized TiO2 that maximize the overall absorption of sunlight using a minimal amount of material. These crystals trap light through a parallel-to-interface negative refraction (PIR) effect and other optical resonances that occur over a broad angular and frequency range. With just one micron of silicon it possible to absorb 85% of all sunlight in the 400-1100 nm wavelength range. With 200 nm of GaAs, 95% of all available sunlight can be absorbed. Both of these exceed the Lambertian statistical ray trapping 4n2 limit. These photonic crystals offer additional opportunities for solar spectral reshaping to rival and possibly surpass the famous Shockley-Queisser power conversion efficiency limit.

8808-2, Session 1

Energy-related applications of photonic structures *(Invited Paper)*

Kai Ming Ho, Iowa State Univ. (United States)

I will present results from our recent efforts on integrating photonic structures into organic solar cells, OLEDS and transparent electrodes for windows and displays.

8808-3, Session 1

3D photonic crystals for photon management in solar cells *(Invited Paper)*

Stefan L. Schweizer, Alexander N. Sprafke, Martin-Luther Univ. Halle-Wittenberg (Germany); Ralf B. Wehrspohn, Martin-Luther Univ. Halle-Wittenberg (Germany) and Fraunhofer-Institut für Werkstoffmechanik (Germany)

Photovoltaic systems are improving their economic efficiency continuously. To reduce costs further a significant increase of the conversion efficiency from solar to electrical energy is necessary.

A promising route to improve the conversion efficiency is to increase the absorption probability by an optical light path enhancement. We present optical concepts for light management, focusing on purely dielectric structures: the potential of 3D photonic crystals for improved light trapping. The combination of spectral and angular selectivity and diffractive effects lead to optical properties which make 3D photonic crystals attractive for photon management applications.

Placed on top of a solar cell, a 3D photonic crystal structure can act as an ultra-light trapping device. It should exhibit high transmission in the direction pointing to the sun so that the photons can reach the solar cell. In all other directions the structure should be opaque to prevent the escaping of light that was not absorbed.

We present numerical calculations and give design rules for improved 3D photonic crystal ultra-light trapping.

Inverted opals integrated between the top and the bottom cell of a tandem solar cell combine reflective and diffractive properties simultaneously in one single functional layer. We show numerically and experimentally, that an increased efficiency is expected for 3D inverted opals compared to simple thin films or Bragg stacks.

Placed on the backside of a solar cell, 3D photonic crystals allow to combine the effects of a back-side mirror and a grating with much higher flexibility than the linear combination of both.

8808-4, Session 2

Light harvesting with photonic and plasmonic crystals *(Invited Paper)*

Rana Biswas, Iowa State Univ. (United States) and Ames Lab. (United States)

Long-wavelength red and infrared photons have long absorption lengths in silicon and organic solar absorber layers. We describe photon harvesting in thin film absorber layers using photonic and plasmonic crystal structures. The traditional approach has been to use randomly roughened back reflectors in thin film silicon cells that randomize the light within the absorber layer. In the Lambertian limit, the path length of photons is enhanced by the 4n2 factor.

Periodic photonic and plasmonic crystal back reflectors in conformal thin film solar cells show extraordinary broad band light harvesting. These photonic structures i) strongly diffract photons leading to waveguide resonances within the absorber layer and ii) generate large surface-plasmon field enhancements at the semiconductor metal interface. Waveguided and surface plasmon modes are coupled in these systems. These lead to enhanced absorption approaching the Lambertian limit with broadband solar absorption enhancement, exceeds 50% in a 1 micron thick nanocrystalline-Si layer[1], and 40% in organic layers. A rigorous scattering matrix approach is utilized for the simulations. The highest enhancements are obtained with an array of tapered nanocones and a conformal solar cell architecture. Experimental measurements on thin Si cells, demonstrate superior performance of the periodically patterned solar architectures than the randomly roughened one. Sources of losses and obstacles to achieving or exceeding the Lambertian limit will be discussed.

8808-5, Session 2

Simple cubic photonic crystal for light bending and for maximizing solar absorption *(Invited Paper)*

Shawn-Yu Lin, Ping Kuang, Rensselaer Polytechnic Institute (United States); Alexei Deinega, Univ. of Toronto (Canada); Mei-Li Hsieh, National Chiao Tung Univ. (Taiwan); Sajeev John, Univ. of Toronto (Canada)

Three-dimensional (3D) photonic-crystals possess photonic bandgaps that prohibit the propagation of light in certain wavelength range in all three directions. It is also of great interest for utilizing photonic crystals for photon management and visible light trapping. A recent theoretical study showed that 3D photonic-crystals could also greatly enhance the light trapping and absorption in thin film photonic crystals due to strong resonances by parallel-interface-refraction (PIR). Here, we report on a four-layer simple cubic woodpile photonic-crystal structure successfully fabricated at nanoscales with amorphous silicon (a-Si:H) and its enhanced absorption over an unpatterned a-Si:H thin film.

8808-6, Session 2

Photon extraction: the key physics for approaching solar cell efficiency limits *(Invited Paper)*

Owen D. Miller, Massachusetts Institute of Technology (United States); Eli Yablonovitch, Lawrence Berkeley National Lab. (United States) and Univ. of California, Berkeley (United States)

Photon management is a fundamental criterion for approaching solar cell efficiency limits. Counter-intuitively, the cell should be designed for maximum extraction of photons, at open-circuit. The voltage penalty for imperfect extraction is logarithmic in the external fluorescence yield, which is highly sensitive to both intrinsic material radiative properties as well as structural non-idealities. This explains in part the substantial gap between experimental efficiency records and theoretical limits. However, it also provides a mechanism for closing the gap, as there is a substantial reward in voltage and power from small improvements in extraction. Solar cells are an exception to the rule of diminishing returns; conversely, incremental enhancements can generate significantly improved performance.

It is well understood that enhancing photon absorption improves short-circuit current and solar cell performance. Here we assert that photon extraction is equivalently important to the open-circuit voltage, the other half of the solar cell output power P=I*V. Moreover, the refractive index asymmetry between the absorber and its surroundings increases the difficulty of extraction relative to absorption, further elevating its importance. Thus external fluorescence efficiency should be a key design driver as new concepts ranging from plasmonic resonances to carrier upconversion are suggested and tested.

Recently, the single-junction solar cell efficiency record dramatically improved from 26.4% to 28.8%, with a 90 mV open-circuit voltage increase demonstrating the importance of extraction. Looking forward, photon management will play an important role in materials selection, novel surface textures and nano-structures, and ultimately in which technologies emerge with breakthrough efficiencies.

8808-7, Session 3

Meta-infrared detectors *(Invited Paper)*

Sanjay Krishna, The Univ. of New Mexico (United States)

There is an increased emphasis on obtaining detectors with enhanced functionality at the pixel level. Meta-infrared detectors in which meta materials are combined with metamaterial structures are a promising way to realize this. The infrared region is appealing due to the low metallic loss, large penetration depth of the localized field and the larger feature sizes compared to the visible region. We will discuss approaches to realize multicolor detectors using these approaches.

8808-8, Session 3

All-semiconductor photonic-crystal route to absorption harnessing

G. Chinna R. Devarapu, Stavroula Foteinopoulou, Univ. of Exeter (United Kingdom)

We discuss a new mechanism enabling extra-ordinary absorption management, even within the Restrahlen band of a semiconductor. Our results suggest that absorption can be dramatically enhanced by appropriate manipulation of the energy velocity and its gradient at the photonic crystal interface. This recipe allowed the construction of a compact layered structure exhibiting twenty-fold absorption enhancement with respect to a homogeneous structure made of the absorptive material constituent.

8808-9, Session 3

Ultra-thin optical coatings based on strong interference effects in highly absorbing media *(Invited Paper)*

Mikhail A. Kats, Romain Blanchard, Patrice Genevet, Federico Capasso, Harvard School of Engineering and Applied Sciences (United States)

Conventional optical coatings, which consist of one or more films of dielectric materials, rely on Fabry–Perot-type interference, involving multiple optical passes through transparent layers with thicknesses of the order of the wavelength. Highly absorbing dielectrics are typically not used because usually light propagation through such media minimizes interference effects.

We show that under appropriate conditions strong interference can instead persist in ultrathin, highly absorbing films, and demonstrate a new type of optical coating comprising such a film on a metallic substrate, which selectively absorbs various frequency ranges of the incident light. These coatings rely on nontrivial phase shifts at interfaces between highly-absorbing materials, and as a result have a low sensitivity to the angle of incidence and can be as thin as 5–20 nm for visible light and down to 50 nm for the infrared.

As these wide-angle coatings can be designed to have a large degree of optical absorption within a film of deeply-subwavelength thickness, they can potentially be useful in a variety of applications from ultrathin photodetectors and solar cells to optical filters, to labeling, and even the visual arts. In this talk, we will focus on several material systems including germanium, amorphous silicon, and vanadium dioxide on various substrates and demonstrate color, anti-reflection, and dichroic coatings, perfect absorbers, among other phenomena and applications.

8808-10, Session 3

Absorption-band engineering using resonant nanostructured photonic materials *(Invited Paper)*

Koray Aydin, Northwestern Univ. (United States)

Nanophotonics, the emerging field of photon-material interactions at the nanoscale, poses many challenges and opportunities for researchers both in the basic and applied sciences. I will describe our efforts in designing, realizing and characterizing nanostructured photonic materials including metals, transparent conductive oxides and inorganic semiconductors. By shaping materials at the nanoscale, one can drastically increase absorption in and/or scattering from nanostructures that could provide significant performance enhancements in photodetection, solar energy conversion and conservation, light emission applications.

In this talk, I will discuss the research efforts for realizing broadband plasmonics absorbers enabled by nanophotonic light-trapping approaches in metal-insulator-metal resonators. By using reflective metals and transparent dielectrics, we have achieved significant absorption enhancement in the metallic parts opening routes for spectrally and spatially selective light-absorbing devices that could find use in thermophotovoltaics and hot-electron collection devices. Then, I will describe light-trapping in nanostructured inorganic silicon ultrathin films which results in drastic absorption enhancement over the entire solar spectrum and over the wide range of incident angles. This approach does not involve any plasmonic components and based solely on localized and delocalized resonances in semiconductor nanostructures. This novel resonant light absorption phenomenon in semiconductors could find use light absorption in thin-film solar cells and light extraction¬in inorganic LEDs. Finally, I will talk about our preliminary results on nanostructured transparent conductive oxide contacts, which is capable of light trapping over broad range of wavelengths. Nanostructured TCO contacts could benefit both organic and inorganic photovoltaic materials, offering significant absorption and short circuit enhancements.

8808-11, Session 4

Modeling active plasmonic response *(Invited Paper)*

Daniel Hannah, Montacer Dridi, George C. Schatz, Northwestern Univ. (United States)

This talk describes two recent projects where we have used a combination of experiments and theory to study the interaction of plasmons with excited states of organic molecules. In one project that was done with Emily Weiss, we considered the influence of ligands on the time-resolved absorption spectrum of few nm gold nanoparticles. Here we used electronic structure calculations to show that the ligands contribute significantly to the plasmonic density of states, and also influence the electron-phonon coupling strength. As a result it is possible to alter the rate of energy flow between electrons and phonons, and also the flow of energy to the surrounding solvent.

In the second project, we have collaborated with Teri Odom's group to study the time evolution of exciton populations in dye molecules that are near to plasmonic particle array structures. Here we modeled the dye excited states using a 4-level model that incorporates plasmon-enhanced fields that are obtained from FDTD calculations. We find that femtosecond pumping leads to inverted populations in the dye, and emission above an intensity threshold that is strongly coupled to lattice plasmon modes.

8808-12, Session 4

Enhancement of light extraction in silicon-rich oxide light-emitting diodes by one-dimensional photonic crystal gratings *(Invited Paper)*

Pablo A. Postigo, José M. Llorens, Instituto de Microelectrónica de Madrid (Spain); Joan Juvert, Ctr. Nacional de Microelectrónica (Spain); Alfredo González, Instituto de Microelectrónica de Madrid (Spain); Carlos Domínguez, Ctr. Nacional de Microelectrónica (Spain)

In this work we show the design, the simulation and the application of one-dimensional nanophotonic structures (photonic crystal gratings) for enhancement of light extraction in light-emitting diodes (LEDs) made of silicon-rich oxide with embedded silicon nanoparticles. The LED structure consists of a poly-silicon top layer 310 nm thick, a silicon-rich oxide layer with embedded nanoparticles 26 nm thick and the silicon substrate. The gratings are formed by grooves separated with periods ranging from 200 nm to 600 nm and widths 0.75 times the period engraved on the top layer. The height of the grooves has been varied from 460 nm to 310 nm. We have performed three dimensional finite-difference time-domain simulations to obtain the values for the internal and external quantum efficiency (EQE). The light extraction efficiency has been calculated as the light collected in the far-field within a cone of 1° around the normal and has been compared with the same structure without the nanophotonic pattern. The results show that it is possible to achieve a 10 times enhancement in the EQE for optimized gratings, as it is the case of 390 nm period and 60 nm height groove for wavelengths close to 460 nm.

8808-13, Session 4

The impact of morphology on absorption and luminescence processes in organic semiconductors *(Invited Paper)*

Jon A. Schuller, Univ. of California, Santa Barbara (United States)

Organic light-emitting and energy-harvesting materials typically self-assemble into highly ordered morphologies when processed from solution or physical vapor.

Here, we describe how structural anisotropies affect absorption and luminescence processes in organic optoelectronic materials. First, we show how light absorption in thin film organic photovoltaics can be greatly enhanced by orienting organic materials relative to plasmonic and gap-mode light trapping architectures. Subsequently, we demonstrate a novel method whereby we can resolve the orientation of luminescent excitons in layered materials. We show that the perylene derivative PTCDA exhibits luminescence from intra- and inter-molecular excitons with distinct spectra, dipole strengths, and temporal dynamics.

8808-14, Session 5

Nanolasers *(Invited Paper)*

Yeshaiahu Fainman, Univ. of California, San Diego (United States)

Dense photonic integration requires miniaturization of materials, devices and subsystems, including passive components (e.g., engineered composite metamaterials, filters, etc.) and active components (e.g., lasers, modulators, detectors). This paper discusses passive and active devices that recently have been demonstrated in our laboratory, including monolithically integrated short pulse compressor utilized with silicon on insulator material platform and design, fabrication and testing of nanolasers constructed using metal-dielectric-semiconductor resonators confined in all three dimensions.

8808-15, Session 5

How small can be a nanolaser? *(Invited Paper)*

Jacob B. Khurgin, Johns Hopkins Univ. (United States); Greg Sun, Univ. of Massachusetts Boston (United States)

In this talk we consider the prospective for development of sub-wavelength sources of coherent light involving metal-dielectric cavities and often referred to as spasers. In particular we show that being a single mode device the nanolaser does not exhibit a standard threshold behavior and one can confirm lasing only buy the line narrowing. Furthermore, we show that due to radiative time shortening caused by Purcell effect, the threshold pump power (or current) in realistic significantly sub-wavelength laser becomes prohibitively high, leaving one with two choices. The first choice is to settle on devices that are sub-wavelength in two dimensions but a few wave-lengths long in the third direction. The second choice is use incoherent plasmonic sources that are just as efficient and fast as spasers, yet can operate at realistically moderate pump powers.

8808-16, Session 5

Engineered pumping controls random lasers *(Invited Paper)*

Cefe López, Consejo Superior de Investigaciones Científicas (Spain); Marco Leonetti, Claudio Conti, Univ. degli Studi di Roma La Sapienza (Italy)

Random lasers (RL) have attracted much attention but they have been largely regarded as an academic topic with little or no technological interest. Being a system based on disorder, their performance is hard to subject to control. Their spectrum is defined by the scattering material which comprises innumerable modes of random shapes and energies filling the gain band of the lasing material. Engineering the scatterers permits tuning the broad band emission [1] into a nanometre-broad line in the intensity feedback regime.

Using a spatial light modulator (SLM) to create rays of amplified spontaneous emission in the dye bath surrounding and imbibing TiO2 nanoparticles clusters gives a large degree of additional control [2] that can select single subnanometre modes in the laser [3]. Interaction between modes allows to drive the RL between resonance or intensity feedback lasing. This allows their synchronisation by mode-locking [4]. We have observed that this interaction leads to a spreading of the energy and expansion of the modes whereby highly localized, distinct lasing modes end up covering the cluster when many modes are excited [5].

When many clusters form an ensemble two length scales are involved: that related to scattering within the lasing cluster (which is sub-micrometre) and that related to inter-cluster amplification by ASE in the dye bath. By controlling the chemistry of the solution where the clusters assemble it is possible profit from the interplay between both length scales without changing the net amount of scattering material [6].

8808-17, Session 6

Control of light with metamaterials and plasmonic structures *(Invited Paper)*

Yuri S. Kivshar, Isabelle Staude, Manuel Decker, Dragomir N. Neshev, The Australian National Univ. (Australia)

We review our recent experimental and theoretical results on the control of light emission and propagation with magnetic and electric resonances in metamaterials and plasmonic structures. We introduce a novel concept of polarization-dependent control of spontaneous emission of quantum dots through their coupling to magnetic metamaterials, analyse effects of the lattice symmetry on the properties of metasurfaces composed of periodic, random, and quasiperiodic lattices of metaatoms, and discuss novel strategies for active control of light with optical nanoantennas. We propose a novel hybrid fabrication approach combining direct laser writing with electron-beam lithography for realizing out-of-plane plasmonic nanostructures at the nanoscale.

We believe that our results open up a new way for designing plasmonic nanostructures for emission enhancement in e.g. biosensing applications, where mostly field localisation of small spherical nanoparticles is used to detect fluorescent molecules. Since higher-order modes in small nanoparticles are completely dark and even cause photoluminescence quenching, more complex structure designs, such as the split-ring resonator in our case, make higher-order plasmonic modes accessible for photoluminescence enhancement. This ultimately results in more efficient detection of quantum emitters and molecules leading to increased sensitivity. Our results also have important consequences for the design of plasmon-enhanced single photon sources.

8808-18, Session 6

Semiconductor nanowire photoluminescence: enhanced and directional emission through leaky/guided modes and Mie resonances

Ramon Paniagua-Dominguez, Consejo Superior de Investigaciones Científicas (Spain); Grzegorz Grzela, Tommy Barten, FOM Institute for Atomic and Molecular Physics (Netherlands); Yannick Fontana, Ecole Polytechnique Fédérale de Lausanne (Switzerland); Jaime Gómez-Rivas, FOM Institute for Atomic and Molecular Physics (Netherlands); Jose A. Sanchez-Gil, Consejo Superior de Investigaciones Científicas (Spain)

Photoluminescence from finite semiconductor nanowires have been theoretically and experimentally investigated. First, we have experimentally demonstrated the directional emission of polarized light from single semiconductor nanowires. The directionality of this emission has been directly determined with Fourier microphotoluminescence measurements of vertically oriented InP nanowires. Thus semiconductor nanowires behave as efficient optical nanoantennas [1], with emission characteristics that are not only given by the material but also by their geometry and dimensions. The theoretical analysis is based on a unified picture for infinite cylinders, including in a simple manner both the leaky/guided mode dispersion relation and the corresponding Mie extinction cross sections yielding related Mie resonances [2]. It is indeed shown that equivalent formulas yield leaky modes and Mie resonances alike. Light emission from finite nanowires is then numerically investigated in various scenarios with regard to Purcell factor enhancement and directionality; simple rules are deduced upon tuning leaky/guided mode coupling through dipole position/orientation and nanowire length, that allow us to predict their antenna-like behavior and thus to tailor photoluminescence at will [2]. We anticipate the relevance of these results for the development of nanowire photon sources with optimized efficiency and/or controlled emission by the geometry. Reciprocally, the same unified theoretical analysis is shown to yield physical insight onto enhancing light absorption at designed semiconductor nanowires through Mie resonances.

8808-19, Session 6

Spontaneous emission enhancement via guided resonance modes in GaN nanorod-array LEDs *(Invited Paper)*

Michelle L. Povinelli, The Univ. of Southern California (United States)

We examine the role of guided-resonance modes on the emission from GaN nanorod LEDs. Finite-difference time-domain simulations are employed to model incoherent emission from InGaN quantum wells in core-shell nanorod arrays. We show that high-intensity features in the far-field emission correspond to guided-resonance modes in the photonic band structure. The spontaneous emission rate is observed to peak near the guided-resonance mode frequencies. The nanorod array dimensions can thus be tuned to produce high emission at a desired wavelength. We present a nanorod array design with a Purcell factor twenty-six times higher than an equivalent slab.

8808-20, Session 6

Calibrating (non)radiative decay constants of fluorophores and the polarizability of metamaterial scatterers via the local density of photonic states

Andrej Kwadrin, A. Femius Koenderink, FOM Institute for Atomic and Molecular Physics (Netherlands)

We demonstrate the versatility of being able to create a controlled photonic environment that manipulates the local density of photonic states (LDOS) in two experiments: Firstly, as a tool to study the properties of photon emitters and secondly, to quantify the characteristics of plasmonics and metamaterials.

As photonic environment we use a mirror and a wedge-shaped dielectric spacer defined by a single gray-tone UV-lithography step. This geometry allows to perform a Drexhage experiment – studying the total decay rate as a function of emitter-mirror separation – on a single sample. In this way, we calibrate the radiative and non-radiative decay rate as well as quantum efficiency of emitters as we report for fluorescent dyes and quantum dots.

Further, we show that the unprecedented magnetic response of a metamaterial scatterer set by the scatterer's polarizability can be rigorously quantified through its dependence on a hitherto undescribed magnetic and magnetoelectric LDOS. A change in the LDOS, by variation of the scatterer-mirror distance, will cause a linewidth change of the scatterer's frequency dependent extinction cross section. For an archetypical metamaterial building block, a split ring resonator, we find a striking difference in the extinction linewidth for different split ring orientations. In our magnetoelectric point dipole model, we explain this observation by a thorough analysis of the phase relationship between the constituent electric and magnetic dipoles.

8808-21, Session 7

Graphene interaction with light *(Invited Paper)*

Andrea C. Ferrari, Univ. of Cambridge (United Kingdom)

No Abstract Available

8808-22, Session 7

Photoconductivity mechanisms in graphene *(Invited Paper)*

Marcus Freitag, IBM Thomas J. Watson Research Ctr. (United States)

We investigate the photoresponse of biased graphene on SiO2 and find that a multitude of mechanisms play a role. In particular we consider bolometric, photovoltaic, thermoelectric, and phototransistor responses. Some of these mechanisms have opposite sign, and we show that the dominating mechanism and thus the sign of the photocurrent can be switched by applying a gate voltage to the graphene transistor. When biased close to the Dirac point, where the transport current is minimized, the photovoltaic effect dominates and the photocurrent and transport current show the same sign. When biased far from the Dirac point, the bolometric effect dominates through the temperature dependence of the mobility, and the photocurrent is reversed. By modeling the various photoresponses, we are able to extract electron and lattice temperatures upon photoexcitation, and find that the electrons stay an order of magnitude hotter than the phonons.

8808-23, Session 7

Graphene-silicon heterojunctions for tunable, versatile, weak-incidence photodetection, photometry, and imaging *(Invited Paper)*

Fangze Liu, Swastik Kar, Northeastern Univ. (United States)

In this talk, we will present the results of our recent investigations of the photodetection properties of heterojunctions of silicon with graphene in the weak-incidence detection limit. We will show how the unique optical and electronic properties of graphene, coupled with the strong absorption of photons in the visible region of silicon can be utilized in conventional and unconventional methods to reach the forefronts of on-chip photodetection. In the photodiode mode, photovoltage responsivity exceeding 10^7 V/W has been achieved, with sub-picoWatt/Hz$^{1/2}$ noise equivalent power and millisecond response-times. With contrast sensitivity exceeding 10^6 V/W, these devices can potentially distinguish materials that transmit up to 99.95% of incident light, making them attractive for imaging and spectroscopy of ultra-transparent materials. In the second mode, which is a newly developed Quantum Carrier Reinvestment (QCR) Mode, the device utilizes the ultrafast carrier dynamics in graphene vis-à-vis the slow carrier recombination rate in silicon that results in extremely high quantum gain values with photocurrent responsivities obtained as high as 10^7 A/W. Layer thickening and doping of the graphitic laminae can lead to the development of solar cells with power conversion efficiency as high as 7.5%. These architectures are highly suitable for tunable and scalable, low-power, on-chip photodetection, imaging, photometry, millisecond-switching, and on-chip ultrasensitive spectroscopy; and can be further extended to low-cost photovoltaics.

8808-24, Session 7

Cavity enhanced graphene and intersubband detectors *(Invited Paper)*

Thomas Müller, Marco Furchi, Andreas Pospischil, Alexander Benz, Technische Univ. Wien (Austria); Stefan Schwarz, Technische Univ .Wien (Austria); Hermann Detz, Karl Unterrainer, Technische Univ. Wien (Austria)

In the first part of this talk we will demonstrate that graphene – a novel two-dimensional electron system comprised of a single layer of carbon atoms – shows a surprisingly strong photocurrent response and discuss the origin of its photoconductive behavior. Based on these findings we developed several concepts for graphene-based photodetectors. One of these concepts relies on the monolithic integrating of graphene with a Fabry-Pérot microcavity. These devices benefit from the large increase of the optical field inside a resonant cavity, giving rise to increased absorption. We demonstrate that the optical absorption can be 26-fold enhanced as compared to devices without cavity. In the second part, we present the design, fabrication and characterization of a metamaterial detector based on intersubband transitions in a THz quantum-cascade laser structure. The metamaterial is used to couple normal incidence radiation resonantly to the intersubband transitions. The metamaterial is formed directly by a structured top metal contact.

8808-25, Session 7

Carbon nanotube and graphene for photonic applications *(Invited Paper)*

Shinji Yamashita, Amos Martinez, Bo Xu, The Univ. of Tokyo (Japan)

Graphene and semiconducting CNTs have fast saturable absorption (SA), which fits for the laser mode locker for fs-pulse generation. It has been known that they also have high third-order nonlinearity. We usually use the thin (~1um) layer of CNTs/ graphene on optical fiber ends. For the high power applications, we sometimes use evanescent field interaction in CNTs using CNTs/ graphene-coated D-shaped or tapered fiber, to avoid the optical damage.

We have applied the CNT-based SA in many kinds of passively mode-locked fiber lasers. We have demonstrated that these lasers can easily generate high-quality nearly transform-limited pulses, regardless of the laser configurations. It can work not only in soliton mode-locked fiber lasers, but also in more advanced mode-locked fiber lasers, such as similariton or dissipative soliton mode-locked fiber lasers.

Compared with other SAs, CNT-based SA is small, low-loss, and compatible to fibers, which is good for short-cavity fiber lasers with high repetition rate. We have succeeded in generating pulses at up to 20GHz repetition rate from a 5mm-long fiber laser.

Graphene is more attractive than CNT because of its wavelength independence. We demonstrated that the optical deposition is also possible and that the mode locking properties are quite similar to the CNT-based one. We also realized short-cavity (1cm) high-repetition-rate (10GHz) graphene-based mode-locked fiber laser.

As for the nonlinear functional devices, we succeeded in wavelength conversion of 10Gb/s NRZ signal through four-wave mixing (FWM) in the CNT-coated D-shaped or tapered fiber.

8808-26, Session 8

Plasmonic nanoparticle based nanobiosensors and nanophotodetectors *(Invited Paper)*

Ekmel Özbay, Neval A. Cinel, Bilkent Univ. (Turkey); Serkan Bütün, Northwestern Univ. (United States)

Plasmonics mainly deals with light-matter interactions in metallic nanostructures. It has gathered interest since its discovery due to the benefits it provides when compared with photonics and electronics. It owes its popularity to the tremendous number of applications it serves for. Plasmonic nanoparticles have a wide variety of applications. In this talk, we will explain how plasmonic nanoparticles can be utilized in applications such as localized surface plasmon resonance based biosensing and enhancing performance of photodetectors. In the first part, EBL fabricated plasmonic nano-disks functioning as LSPR based refractive index sensors were implemented. In the second part, the integration of nano structures with MSM photodetectors were shown to increase the coupling of more light into the device and thereby increase the responsivity and photocurrent enhancement.

8808-27, Session 8

Aluminium plasmonics

Lifei Liu, Mark W. Knight, Rice Univ. (United States); Henry O. Everitt, Duke Univ. (United States); Naomi J. Halas, Peter Nordlander, Rice Univ. (United States)

Aluminum for plasmonic nanostructures has great potential to be used in many new applications, such as access to short wavelength regions of the spectrum, complementary metal-oxide-semiconductor (CMOS) compatibility, and the possibility of low-cost, sustainable, mass-producible plasmonic materials. Here we investigate the properties of individual Al nanorod antennas with cathodoluminescence (CL).[1] This method allows us to image the local density of optical states (LDOS) of Al nanorod antennas with a spatial resolution less than 20 nm and to identify the radiative modes of these nanostructures across the visible and into the UV spectral range. The results, which are in good agreement with finite difference time domain (FDTD) simulations, lay the foundations for precise Al plasmonic nanostructure design for a variety of applications.

Efficient optical trapping and manipulation of nanometer-scale particles with coaxial plasmonic apertures *(Invited Paper)*

Jennifer A. Dionne, Amr Saleh, Brian Baum, Hadiseh Alaeian, Stanford Univ. (United States)

Sculpted electromagnetic beams can serve as optical tweezers, allowing small objects to be accelerated, manipulated, or trapped with light . In this work, we theoretically and experimentally investigate plasmonic coaxial apertures as low-power optical traps for nano-sized specimens. When a particle interacts with the near field of a coaxial aperture illuminated with a linearly polarized plane wave, it experiences an optical trapping force. Unlike many prior plasmonic traps, the proposed coaxial structure traps particles at the surface of the aperture rather than inside it. Consequently, further manipulation and processing can be performed on the trapped particle.

We systematically examine this induced optical force using Maxwell stress tensor formalism and finite-difference time-domain simulations. We show that the induced trapping potential can stably trap dielectric particles smaller than 10 nm in diameter while keeping the trapping power level below 20 mW. By tapering the thickness of the coaxial dielectric channel, trapping can be extended to sub-2 nm particles. Our results also indicate that the trapped particle experiences a pulling force of the order of tens of pico-newton which can be utilized to apply localized forces on micro and nanoscale objects with nanometer precision. Experimentally, we investigate arrays of coaxial aperture traps in Au films, fabricated using focused ion beam milling. Semiconducting nanoparticles flow over the aperture and are selectively trapped at the resonant wavelengths of the aperture array. The nanoparticle fluorescence provides a direct probe of trapping of sub-10-nm particles. Our results demonstrate the potential of coaxial plasmonic apertures in enabling optical trapping and manipulation of dielectric particles ranging from single proteins to small molecules with sizes previously inaccessible.

Near-field thermal radiation at nanometer spacings *(Invited Paper)*

Jivtesh Garg, Poetro Sambegoro, Vazrik Chiloyan, Svetlana V. Boriskina, Massachusetts Institute of Technology (United States); Brian R. Burg, IBM Research Zurich Lab. (Switzerland); Wei-Chun Hsu, Jonathan Tong, Massachusetts Institute of Technology (United States); Keivan Esfarjani, Rutgers, The State Univ. of New Jersey (United States); Gang Chen, Massachusetts Institute of Technology (United States)

When the spacing between two surfaces is less than the dominant wavelength of thermal radiation, heat transfer between the two surfaces can significantly exceed the blackbody limit. Radiative heat transfer at small spacing is usually described by Rytov's fluctuating electrodynamics formulation, which is based on the macroscopic Maxwell equations and continuum descriptions such as dielectric functions. However, in the limit when two surfaces are in contact, heat transfer is described in terms of heat conduction and phonon transport. Today there is no unified theory that can describe the power transferred between two bodies as a function of their separation down to the zero gap contact limit. We develop an approach using lattice dynamics and the microscopic Maxwell equations to bridge the theories of conduction and radiation. Experimentally, we investigate near-field thermal radiation between two objects at extremely small separations using a sphere-plate geometry.

To measure near field thermal radiation from tens of nanometers down to direct contact, we fabricate and characterize a new type of cantilever that can decouple thermal and force signals to eliminate the parasitic deflection of the cantilever due to the force effect. Surface phonon-polariton and surface-plasmon contributions to near-field radiation heat transfer will be discussed.

This work is supported by DOE (J.G., P.S., S.B., V.C.) and UIUC MURI (W.C.H. and G. C.)

8808-30, Session 9

Quasi-coherent thermal emission from photonic crystal *(Invited Paper)*

Mei-Li Hsieh, National Chiao Tung Univ. (Taiwan); James A. Bur, Shawn-Yu Lin, Rensselaer Polytechnic Institute (United States)

We report a direct observation of a quasi-coherent thermal emission from a heated three-dimensional photonic-crystal (PhC) sample. While the sample is under Joule heating, we observed multiple oscillations in its emission interferogram and deduced a coherent-length of Lcoh ~ (20~40) um , 5-10 times longer than that of a blackbody at comparable wavelengths. The observed, relatively long coherent length is attributed to coupling of thermal emission into lossy Bloch modes that oscillate coherently over a distance determined by decay-length and the slow light nature of Bloch modes at the band edges.

8808-31, Session 9

Selective thermal emission from thin-film metasurfaces *(Invited Paper)*

William Streyer, Stephanie Law, Thomas Jacobs, Gino Rooney, Daniel M. Wasserman, Univ. of Illinois at Urbana-Champaign (United States)

The mid-infrared (mid-IR), as the spectral range where all finite temperature biological and mechanical objects emit thermal radiation, and where numerous molecular species have strong vibrational absorption resonances, is of significant importance for both security and sensing applications. The design of materials with engineered absorption resonances, which, by Kirchoff's Law, should give strongly selective emission at the design resonance upon thermal excitation, allows for the control of the spectral character of the material's thermal emission. Designed as a thin film coating, these structures can be applied to grey-body emitters to shift the grey-body thermal emission into predetermined spectral bands, altering their appearance on a thermal imaging system.

In this presentation, we will discuss two distinct selective thermal emitters. First, we investigate patterned metal antenna structures separated from a metallic groundplane by a thin dielectric layer. Here, the lateral dimensions of the patterning determine the resonant wavelength of the structure, while the thickness of the dielectric layer determines the strength of the absorption resonance. Samples with varying dielectric thickness and top metal pattern dimensions were fabricated for this work. In addition, we investigate a new class of selective thermal emitters based on thin-film, high-index lossless dielectric coatings on highly doped semiconductor designer metals. For both material systems, strongly selective thermal emission was obtained, and compared to blackbody emission at the same temperature. In addition, samples were characterized by reflection and emission spectroscopy, as a function of polarization, and emission angle. The strong spectral resonances as well as the ease of fabrication for these structures may offer a potential avenue towards thermal cloaking films and/or enhanced sensitivity mid-IR sensors.

8808-32, Session 10

Graphene plasmonics: tunability and active optical devices *(Invited Paper)*

Peter Nordlander, Rice Univ. (United States)

Graphene has emerged as an interesting material for optoelectronic applications due to its high electronic mobility and unique doping capabilities. Another interesting property of graphene structures is their remarkably narrow plasmon resonances which allows for strong coherent coupling with a nearby quantum emitter. [1] Such interactions can introduce highly nonlinear optical effects such as a plasmon blockade and saturable absorption. Due to its unique band structure, graphene can also serve as an efficient electron acceptor in active plasmonic applications. In a photodetector device, a gold nanoantenna sandwiched between two sheets can convert incident photons to hot electrons which can transfer into the graphene and be detected as an electric current. [2] Hot electrons generated from a plasmonic nanoantennas can also efficiently dope a nearby graphene sheet and create transient "optically induced electronics".[3] Finally, I will discuss some recent work on the tunability and quantum mechanical aspects of hybridized graphene plasmons in nanostructured rings and disks and rings [4]and in narrow graphene bowtie junctions.[5]

Graphene optoelectronics and photonics *(Invited Paper)*

Chee Wei Wong, Tingyi Gu, Nan Shi, Shu-Wei Huang, Hao Zhou, Felice Gesuele, Obafunso Ajayi, James F. McMillan, Columbia Univ. (United States)

Our team examines the precision, quantum, ultrafast, and nonlinear measurements of photons on-chip. In this talk we describe on our studies of optical nonlinearities and carrier dynamics in graphene, a massless linear dispersion material in a purely two-dimensional Dirac fermionic structure. Measurements on the graphene-silicon hybrid photonic crystals structure demonstrate enhanced nonlinearities such as degenerate four-wave mixing for optical signal processing, time-domain regenerative oscillations, as well as optical bistability. Ultrafast spectroscopy illustrate the dramatic third-order nonlinearities in graphene, enhanced by all allowed interband optical transitions. Quasi-equilibrium carrier Coulomb scattering as well as many-body interactions will be described.

8808-34, Session 10

Controllable optical negative refraction and phase conjugation in graphene

Hayk Harutyunyan, Argonne National Lab. (United States); Ryan Beams, Univ. of Rochester (United States); Lukas Novotny, Univ. of Rochester (United States) and ETH Zurich (Switzerland)

Recent advances in the field of metamaterials added a new dimension to the science of light-matter interaction. One of the remarkable new phenomena that arise from using materials with negative permittivity and/or permeability is the negative refractive index of the materials. In his seminal work Pendry suggested that a slab of such a material, e.g. silver,

can act as a “perfect-lens” and achieve super-resolution.

However, the main obstacle for using the negative index materials in standard imaging systems is the high losses which typically limit operation to narrow frequency bands.

Alternatively, it was proposed that two phase-conjugating surfaces placed in the close proximity of an object can reverse the phase of its optical fields and form a perfect image. We demonstrate negative refraction through time-reversal using graphene layers as a phase-conjugating surface. Two pump beams at 800nm write a holographic grating on grpahene that diffracts the signal beam of the same frequency at negative angles while reversing its phase. The effect can be described as a third order nonlinear wave-mixing process, with graphene acting as a source of high optical nonlinearity. The 2-dimensional character of the sample is crucial for observation of negative refraction and realization of supper-resolution imaging lens. The measurements show a narrow resonance at the angles corresponding to negative refraction confirming that graphene acts as a time-reversal lens.

We present the first experimental demonstration of optical negative refraction through phase-conjugation.

The scheme allows all-optical control of the negative refraction without need of sophisticated and costly fabrication techniques. Choice of graphene flakes as a nonlinear material provides a robust and easy way for future fabrication of superresolution imaging devices. The linear bandstructure of graphene and its small thickness ensure virtually unlimited bandwidth and low losses of the imaging device.

8808-35, Session 10

Reconfigurable THz devices using graphene *(Invited Paper)*

Huili Xing, Univ. of Notre Dame (United States)

The terahertz (THz) frequency range has recently become one of the most dynamic areas of scientific research. However, there is still a lack of devices efficiently manipulating THz waves, such as active filters, modulators, etc. The few devices demonstrated to date have presented severe tradeoffs between insertion loss, modulation depth, and switching speed. Graphene, in the infrared/visible range, has a tunable optical absorption of 2.3%. However, its optical conductivity dramatically increases in the terahertz range, leading to an efficient modulation by electrical control. Furthermore, the two-dimensional nature of graphene enables unprecedented integration possibilities, together with its remarkable mechanical, electrical, and optical properties, promising a myriad of attractive applications.

In this talk, I will review the first demonstration of broadband graphene THz modulators as well as our recent progress on reconfigurable THz devices using graphene. Single layer graphene is capable of efficiently tuning THz transmission meanwhile introducing negligible insertion loss [APL, 113104 (2011); Nat. Comms, 3:780 (2012)]. By combining active graphene layers with other passive structures, the control over THz waves can be greatly enhanced. THz wave reflectance modulators will be discussed, exhibiting superior tradeoff than the prior art in terms of modulation depth versus insertion loss [Nano Letters 12, 4518 (2012)]. Very efficient terahertz reconfigurable metamaterial devices can be constructed employing passive metallic frequency selective surfaces (FSSs) [Optics Express 20, 28664 (2012)]. Several applications of these devices will be presented and discussed, including arrays of graphene electro-absorption modulators as electrically reconfigurable patterns for terahertz cameras [Optics Express 21, 2325 (2013)].

Nonlinear time reversal in a wave chaotic system *(Invited Paper)*

Matthew Frazier, Biniyam Taddese, Thomas M. Antonsen Jr., Steven M. Anlage, Univ. of Maryland, College Park (United States)

Exploiting the time-reversal invariance and reciprocal properties of the lossless wave equation enables elegantly simple solutions to complex wave-scattering problems and is embodied in the time-reversal mirror. Here we demonstrate the implementation of an electromagnetic time-reversal mirror in a wave chaotic system containing a discrete nonlinearity. We demonstrate that the time-reversed nonlinear excitations reconstruct exclusively upon the source of the nonlinearity. As an example of its utility, we demonstrate a new form of secure communication and point out other applications.

See a Synopsis of the work at http://physics.aps.org/synopsis-for/10.1103/PhysRevLett.110.063902.

8808-38, Session 11

All-optical switching in PT-symmetric optical systems with balanced gain and loss *(Invited Paper)*

Andrey A. Sukhorukov, The Australian National Univ. (Australia); Sergey V. Suchkov, Russian Academy of Sciences (Russian Federation); Igor V. Barashenkov, Nora V. Alexeeva, Univ. of Cape Town (South Africa); Sergey V. Dmitriev, Institute for Metals Superplasticity Problems (Russian Federation); Yuri S. Kivshar, The Australian National Univ. (Australia)

Interest to the PT -symmetric systems in physics stems from Bender’s work [1], where it was shown that systems with non-Hermitian Hamiltonians can have an entirely real eigenvalue spectrum under parity-time symmetry constrain on the potential. In optics a complex refractive index can play a role of that potential [2]. Thus, optical systems with regions of balanced gain and loss can have eigenmodes which conserve their power on average. Recently PT -symmetric structures have been realized experimentally [3].

In the present work we reveal novel regimes of nonlinear wave interactions in a chain of optical PT -symmetric couplers with balanced gain and loss. The structure is governed by a system of discrete nonlinear Schrodinger equations with Kerr-type nonlinearity. We describe the interactions between different nonlinear modes: high-frequency and low-frequency solitons, soliton and breather, breather and breather [4]. We identify various scenarios of the interaction dynamics depending on model parameters and initial conditions. We also study the beam propagation in an array of optical waveguides with an embedded defect created by a pair of waveguides with gain and loss, and find that the incident high-amplitude beam can excite the mode localized at the PT – symmetric defect [5]. By exciting the localized mode of a large amplitude, it is possible to perform phase-sensitive control of beam scattering and amplification or damping of the localized mode.

Modulation phase and gauge field for photons *(Invited Paper)*

Shanhui Fan, Kejie Fang, Zongfu Yu, Stanford Univ. (United States)

We show that, in photonic structures undergoing dynamic time-dependent modulation, the phase of the modulation in fact introduces a gauge potential and gauge field for photons. Controlling spatial distribution of such modulation phase then leads to a rich set of novel optical physics effects, including one-way topologically protected edge states, as well as new mechanisms for controlling the flow of eletctromagnetic waves.

8808-40, Session 12

Novel phenomena in macroscopic photonic crystals *(Invited Paper)*

Marin Soljacic, Massachusetts Institute of Technology (United States)

Photonic crystals provide superb opportunities for tailoring of the photonic density of states. This ability can in turn be explored to control radiation into far-field, enhance fluorescent light emission, as well as optimize laser emission. In order to make these phenomena useful for large macroscopic devices, large-area nano-fabrication techniques have to be successfully implemented. In this talk, I will present some of our recent theoretical and experimental progress in exploring these opportunities.

8808-41, Session 12

Photonic Floquet topological insulators *(Invited Paper)*

Mikael C. Rechtsman, Technion-Israel Institute of Technology (Israel); Julia M. Zeuner, Friedrich-Schiller-Univ. Jena (Germany); Yonatan Plotnik, Yaakov Lumer, Technion-Israel Institute of Technology (Israel); Stefan Nolte, Friedrich-Schiller-Univ. Jena (Germany); Mordechai Segev, Technion-Israel Institute of Technology (Israel); Alexander Szameit, Friedrich-Schiller-Univ. Jena (Germany)

We present the first experimental observation of Photonic Floquet Topological Insulators. Topological insulators (TIs) constitute a new state of matter: they are insulators in the bulk, but conduct electrons on the surface. In two-dimensional TIs, propagating waves are unidirectional (no backward-propagating wave), and are completely immune to scattering by defects or disorder of any kind. Photonic TIs are TIs where the propagating waves are electromagnetic, rather than electronic - in our case, visible light. Beyond their fundamental significance, photonic TIs have also been suggested for a number of applications, including highly robust optical delay lines, on-chip optical diodes, and spin-cloaked photon sources. In TIs in the solid state, topological protection is achieved by virtue of the Kramers degeneracy, which does not apply to photons. Therefore, for non-fermionic TIs, another mechanism is required to achieve topological protection. Our system is composed of an array of helical waveguides arranged in a honeycomb lattice. The helicity induces a fictitious, time-varying electric field, and the structure becomes equivalent to a “Floquet TI”. By probing the diffraction of light through the lattice, we demonstrate topologically-protected edge states, scatter-free propagation around corners as well as upon encountering defects. Our setting can potentially allow for the study of mean-field interactions (through optical nonlinearities), and the effects of highly controllable disorder.

8808-42, Session 12

Dirac cone dispersions in photonic crystals and their implications *(Invited Paper)*

Che Ting Chan, Hong Kong Univ. of Science and Technology (Hong Kong, China)

Many unusual properties of graphene can be traced to its singular band structure near the Fermi level where two cones meet at one point. Such a dispersion is called a Dirac cone dispersion and the singular point the Dirac point. Dirac cone like dispersions are not unique to electronic graphene, but can also be found in many classical wave systems at the zone boundary as a consequence of lattice symmetry. In this talk, I will explore the consequence of having Dirac cone like dispersions at k=0. We show that Dirac cone like dispersions at k=0 can be obtained in classical wave systems using accidental degeneracy. If the photonic band dispersions originates from monopole and dipole excitations, such dispersions can be related to a double zero (zero permittivity and zero permeability) material at and near the Dirac point frequency in the sense that the system behave optically as if the refractive index is zero. From an effective medium point of view, such system has an infinite phase velocity but a finite group velocity. We will consider the extension of these ideas to from two dimensions to three dimensions and from periodic to aperiodic systems. We will also show that Dirac cone dispersions will lead to robust interface states and the origin of the robustness will discussed.

Anti-Hermitian plasmon coupling of gold antennas arrays for controlling light at the nanoscale *(Invited Paper)*

Shuang Zhang, The Univ. of Birmingham (United Kingdom); Xiang Zhang, Univ. of California, Berkeley (United States)

No Abstract Available

8808-44, Session 13

Ultrafast slow light control *(Invited Paper)*

Kobus Kuipers, FOM Institute for Atomic and Molecular Physics (Netherlands)

Photonic crystals are able to exert a huge control over light. Arguably one of their most interesting aspects is their ability to slowdown light. That they can achieve this feat over large bandwidths holds the promise of speeding up telecom and making it more energy efficient due to the effective enhancement of light-matter interactions.

We show that ultrafast manipulation of light is facilitated by this slowdown. Through an adiabatic control of the refractive index, we can control the properties of photonic eigenstates on (sub)-ps timescales. Light in these states can thereby be manipulated. Through changes of the refractive index in time but homogeneous in space we are able to change the frequency of the light [1]. By creating a perturbation that is not homogeneous in space we gain access to the wavevector of the slow light. By inducing frequency shifts that are wavevector dependent, we are able to tilt the photonic band structure. As a result we can spectrally compress the propagating light pulses and slow them down further [2]. With another spatial configuration of the perturbation of the eigenstates, we achieve an effective indirect photonic transition that can be used to create a delay line with which pulses can be continuously controlled in time by varying the intensity of the pump pulse [3].

Engineered SOI slot photonic crystal waveguides

Charles Caer, Xavier Le Roux, Laurent Vivien, Eric Cassan, Institut d’Électronique Fondamentale (France)

Inserting a trench along a photonic crystal waveguide allows adding new functionalities to silicon photonics. These features can rely both on the high optical confinement in the slot and the properties of the infiltrating material that can overcome some limitations of silicon (e.g. nonlinear losses, indirect bandgap). The strong dispersive properties of the photonic crystal provide a higher confinement that can be managed by engineering the dispersion diagram. We propose to engineer the dispersion by structuring the shape of the slot into a comb, i.e. forming a Comb Photonic Crystal Waveguide (CPCW). These waveguides have an ultra-small nonlinear effective area which is suitable for nonlinear optical devices. Our previous works showed that such waveguides support high group index bandwidth products while they enhance the localization of light by confining the light between the etched grooves. FDTD calculations validated our design and demonstrated a high coupling efficiency by using tapers and spot-size converters. Devices fabricated by state-of-art clean room processes enable measurements of slow light when placing the CPCW in an integrated Mach-Zehnder Interferometer. High amplitude interference fringes at high group indices show that losses are low, which is confirmed by cut-back measurements, reporting losses comparable to W1 PCW at high group indices and to refractive slot waveguides at low group indices. We expect these waveguides to provide novel functionalities to silicon photonics.

8808-46, Session 13

Slow light tuning in photonic crystals *(Invited Paper)*

Toshihiko Baba, Norihiro Ishikura, Keisuke Kondo, Yokohama National Univ. (Japan)

One attractive application of slow light is tuning the delay of optical pulses. It is achieved by controlling the chirping of photonic crystal waveguides whose photonic band exhibits a flat band sandwiched by the opposite dispersion characteristics. We call the so-obtained tunable slow light dispersion-compensated (DC) slow light. In these years, we have fabricated the devices using CMOS-compatible process, demonstrated the delay tuning of sub-ps pulses with a tuning resolution over 100, and applied it to varying the demodulation rate of DQPSK receiver. The other attractive application of slow light is enhancing the nonlinearity. It is achieved by the particular design of photonic crystal waveguides, which exhibits a straight photonic band with a small slope, producing low-dispersion (LD) slow light. We have demonstrated strong two-photon absorption (TPA), self-phase modulation and four-wave mixing in Si-based devices at fiber communication wavelengths. In this presentation, we demonstrate two advanced devices that utilize both DC and LD slow light. One is the on-chip optical correlator and the other is the all-optical ultrafast delay tuning. In the former, the delay scanner based on DC slow light and nonlinear-enhanced TPA photodiode based on LD slow light were integrated. The auto-correlator action was confirmed for ps pulses. In the latter, the delay of the DC signal pulse was tuned through the intensity and timing of the LD control pulse with a maximum tuning range and response time of 10 ps. It potentially achieves the retiming of disordered pulses by using LD pulses as a clock.

8808-47, Session 14

Nonlinear optical phononics: harnessing stimulated Brillouin scattering in nonlinear nanoscale circuits *(Invited Paper)*

Benjamin J. Eggleton, The Univ. of Sydney (Australia)

I will review our recent progress in developing nanoscale optical–phononic circuits that use nonlinear optical effects to efficiently interact phonons (sound) with photons (light), creating a new paradigm in information processing. The innovation is to exploit stimulated Brillouin scattering, the strongest nonlinearity for parametric coupling of light and sound, in highly nonlinear nanoscale circuits. The new level of control over the interaction between light and sound will result in optical–phononic circuits in which light can be spectrally controlled, amplified and processed in ways currently unachievable.

8808-48, Session 14

Ultrafast nonlinear optical mirrors for all-optical applications at visible wavelengths

James J. Hsu, Canek Fuentes-Hernandez, Alfred R. Ernst, Bernard Kippelen, Georgia Institute of Technology (United States)

All-optical applications at visible wavelengths have been limited by the lack of materials and devices with a strong nonlinear optical (NLO) response. Noble metals are known to have extremely large and ultrafast NLO response at visible wavelengths but little attention has been directed at utilizing their NLO properties to develop NLO devices. In this work, we will present advances in the optimization of the linear and NLO response of metallic thin films and introduce a novel mirror structure that allows all-optical control of its reflectance at visible wavelengths.

The NLO mirror structure consists of four thin-film layers and can be engineered to display strong reflectance changes with very broad spectral and angular bandwidths across the visible spectral region. Upon being excited by a femtosecond optical pulse, an improved change of reflectance up to 25 times was observed when comparing the NLO mirror with a single Au film, having the same Au thickness, on a glass substrate. The reflectance change of the NLO mirror is ultrafast. The linear and NLO properties of these NLO mirrors can also be engineered to present narrow spectral and angular bandwidths while preserving a strong NLO response. Potential applications of these novel nonlinear optical devices will be discussed.

8808-49, Session 14

Second order nonlinear susceptibility in silicon induced by inhomogeneous strain

Jörg Schilling, Clemens Schriever, Martin-Luther-Univ. Halle-Wittenberg (Germany); Federica Bianco, Massimo Cazzanelli, Lorenzo Pavesi, Univ. degli Studi di Trento (Italy)

Today active silicon photonic components (e.g. electrooptic switches/modulators) mainly rely on refractive index changes due to charge transport in/out of the waveguide devices. However to save energy, allow higher speeds and enable advanced optical functionality (e.g. opto-optic switching, wavelength conversion,) nonlinear optical properties have to be employed in silicon photonics. Unfortunately silicon lacks a dipolar second order nonlinear susceptibility (chi(2)) due to the centrosymmetry of its diamond lattice structure. To overcome this it was recently suggested to introduce a chi(2) into silicon nanostructures applying an inhomogeneous strain which breaks the centrosymmetry locally. In the earlier realizations of this concept [1,2] always a SiNx -straining layer on top of the silicon was employed so that it was not clear if the observed chi(2) is indeed caused by the inhomogeneously strained silicon itself or by a SiNx /Si interface effect.

Here we demonstrate second harmonic generation for pump wavelengths around 2200nm on silicon strip waveguides, which were inhomogeneously strained using SiO2 cladding layers as well as differently prepared (and differently stressed) SiNx layers. The strain field was checked by XRD reciprocal space mapping and local electron diffraction. The evaluation of the measured SHG-signal of the different samples reveals that the observed chi(2) is caused by both effects – a strain induced contribution, which increases with rising strain gradients and an interface chi(2,) which is caused by the Si/SiN interface and even appears for unstrained SiN-claddings. chi(2) values in the range of 10-40pm/V were estimated for maximum strained samples. These results show that dedicated strain engineering as well as interface effects can be employed to introduce a sizeable chi(2) into silicon paving the way for second order nonlinear processes like difference frequency generation in silicon photonics.

8808-50, Session 14

Si/chalcogenide glass hybrid waveguide design for efficient four wave mixing

Jörg Schilling, Peter W. Nolte, Christian Bohley, Martin-Luther-Univ. Halle-Wittenberg (Germany)

Although Si shows a sizeable optical third order nonlinearity, it also suffers from strong two photon absorption in the near infrared leading to a small overall nonlinear figure of merit (FOM). To overcome these limitations and be able to employ third order nonlinear processes in silicon photonics, we present here a novel design route for Silicon/chalcogenide glass hybrid slot waveguides. These hybrid waveguides allow FOM >1 and a maximum field concentration within the infiltrated material as well as a vanishing group velocity dispersion (GVD) at the same time.

Specifically, we theoretically investigated the nonlinear optical properties of slot waveguides which are infiltrated with the chalcogenide glass As2S3. Varying the waveguide width and height of the waveguides the FOM and the effective mode area was determined.

To achieve narrow band phase matching in four wave mixing processes the group velocity dispersion (GVD) must be zero. Here we propose to introduce a small periodic variation of the refractive index along the waveguide (e.g. be using the photorefractive properties of As2S3) which introduces a photonic band gap for the waveguide mode leading to band bending and a negative dispersion for the mode above the gap (second band). This negative second band dispersion compensates for the usual positive waveguide and material dispersion, so that GVD=0 can be reached for a specific frequency. Varying the periodicity of the refractive index between 300 - 400 nm allows to shift the GVD=0-frequency across the whole near infrared [1].

In conclusion the presented scheme demonstrates that the phase matching condition can be fulfilled independently from the wave guide cross section and the GVD = 0 condition can be easily tuned to the wavelength of interest allowing a flexible design of the hybrid photonic components.

Resonances with the vanishing width in periodic double arrays of dielectric cylinders and their application to the second harmonic generation

Friends R. Ndangali, Amherst College (United States); Sergei V. Shabanov, Univ. of Florida (United States)

Electromagnetic bound states in the radiation continuum are similar to bound states in the radiation continuum in quantum mechanics discovered by von Neumann and Wigner. They correspond to vanishing width resonances of the scattering amplitudes. In periodic double arrays of dielectric cylinders, these states are shown to exist at specific distances between the arrays in the spectral region where one or two diffraction channels are open. When the distance between the two arrays approaches a critical value at which a bound state in the radiation continuum is formed, the near field becomes significantly amplified in specific regions of the arrays. This amplification is explained by extending the quantum mechanical Siegert state formalism to Maxwell's theory of electromagnetism. The said amplification is used to control the second harmonic generation in periodic double arrays of dielectric cylinders with a second order nonlinear susceptibility. In particular, the conversion efficiency of the incident fundamental flux into the second harmonic flux is shown to be as high as 40% at a distance between the arrays as low as half the incident radiation wavelength. Moreover, this conversion efficiency is achieved systematically however small the second order nonlinear susceptibility of the dielectric material.

8808-61, Session PWed

Novel non-linear optical properties of alumina and silica nanocomposites

Valentin A. Milichko, Vladimir P. Dzyuba, Yury N. Kulchin, Institute for Automation and Control Processes (Russian Federation)

The results of study of optical properties of nanocomposites based on dielectric matrix and Al2O3 and SiO2 nanoparticles in weak optical fields are presented. Using z scan technique, we found that nanoparticles are responsible for unique nonlinear optical phenomenon in nanocomposites: The values of portions to nanocomposite refractive index and absorption coefficient increase to maxima, and then decrease to zero when the intensity of green and violet radiation changes from 1 to 500 W/cm2. Using the spectroscopic technique, we estimated the features of electron energy structures for nanoparticles dispersed in different liquid dielectric matrices (polymethylsiloxane, water, and isopropyl alcohol) and explained the influence of the matrix permittivity value on this structure, as well as the optical properties of nanocomposites.

8808-52, Session 15

Nonclassical light sources based based on quantum dots in optical nanocavities *(Invited Paper)*

Jelena Vuckovic, Stanford Univ. (United States)

A single quantum dot coupled to an optical nanocavity or a photonic molecule can be employed to generate a stream of nonclassical light (n-photon states) with high purity and efficiency. Such states are interesting for quantum communication, metrology, high resolution quantum lithography and sensing.

We have employed a platform consisting of a single self-assembled InAs QD in a GaAs PC cavity to study quantum optics and cavity QED. In particular, we have probed the ladder of dressed states of the strongly coupled QD-cavity system and studied the regimes of photon blockade and photon induced tunneling, as well as nonclassical light generation enabled by this ladder. The regime of photon blockade enables generation of a single photon stream, while the regime of photon induced tunneling enables generation of n-photon Fock states . . To enable generation of higher purity nonclassical states of light, without the need to dramatically improve fabrication of PC cavities and QD-cavity alignment, we are studying several new approaches, including:

- QD coupled to a photonic molecule
- QD coupled to a bimodal photonic cavity
- A multi-level quantum emitter (4-levels instead of 2) coupled to a photonic cavity

8808-53, Session 15

Harnessing light with photonic nanowires: from needles to trumpets *(Invited Paper)*

Julien Claudon, Mathieu Munsch, Nitin S. Malik, Emmanuel Dupuy, Adrien Delga, Joël Bleuse, Commissariat à l'Énergie Atomique (France); Niels Gregersen, Jesper Mørk, DTU Fotonik (Denmark); Philippe Lalanne, Institut d'Optique Graduate School (France); Jean-Michel Gerard, Commissariat à l'Énergie Atomique (France)

Photonic nanowires with an out-of plane orientation have recently emerged as an appealing platform for solid-state quantum optics. These waveguides, made of a high-index material, offer a broadband and an efficient spontaneous emission control for an embedded point-like emitter [1,2]. Moreover, the collection of the guided photons can be brought close to unity with a proper engineering of the wire ends. In particular a tapering of the upper end is mandatory to achieve a directive far-field emission. Two solutions are then possible, leading to a needle-like taper [3] or to a trumpet-like one. I will show that the second strategy features key assets: i) the taper offers a clean emission into a Gaussian beam, a key asset for a wide range of situations ii) the taper performances are robust against geometrical changes, which ensures a high robustness against unavoidable fabrication imperfections [4].

As a first application in the field of quantum optics, we report the realisation of an ultra-bright single-photon source. The device, a high aspect ratio GaAs photonic trumpet containing a few InAs quantum dots, demonstrates a first-lens external efficiency of 0.75 and an external coupling efficiency to a Gaussian beam as high as 0.58.

Photonic quantum technologies *(Invited Paper)*

Jeremy L. O'Brien, Univ. of Bristol (United Kingdom)

Quantum information science aims to harness uniquely quantum mechanical properties to enhance measurement, information and communication technologies, as well as to explore fundamental aspects of quantum physics. Of the various approaches to quantum computing [1], photons are particularly appealing for their low-noise properties and ease of manipulation at the single qubit level [2]. Encoding quantum information in photons is also an appealing approach to other quantum technologies [3], including quantum communication, metrology [4] and measurement [5]. We have developed an integrated waveguide approach to photonic quantum circuits for high performance, miniaturization and scalability [6–10]. We have begun to address the challenges of scaling up quantum circuits using new insights into how controlled operations can be efficiently realised [11], and demonstrated Shor's algorithm with consecutive CNOT gates [12] and the iterative phase estimation algorithm [13]. We have shown how quantum circuits can be reconfigured, using thermo-optic phase shifters to realise a highly reconfigurable quantum circuit able to perform almost any function on two photonic qubits [14], and electro-optic phase shifters in lithium niobate to rapidly manipulate the path and polarisation of telecomm wavelength single photons [15]. We have addressed miniaturisation using multimode interference coupler architectures to directly implement NxN Hadamard operations and the 'Boson sampling problem' [16], and by using high refractive index contrast materials such as SiOxNy, in which we have implemented quantum walks of correlated photons [17], and Si [18], in which we have demonstrated generation of orbital angular momentum states of light [19]. We have incorporated microfluidic channels for the delivery of samples to measure the concentration of a blood protein with entangled states of light [20]. We have begun to address the integration of superconducting single photon detectors [21] and diamond [22,23] and non-linear [24–6] single photon sources. Finally, we give an overview of recent work on fundamental aspects of quantum measurement, including a quantum version of Wheeler's delayed choice experiment [27].

8808-55, Session 15

Enhanced light-matter interactions in photonic crystal nanocavities for ultralow-power photonics *(Invited Paper)*

Masaya Notomi, NTT Basic Research Labs. (Japan)

Photonic crystals have enabled various wavelength-sized high-Q nanocavities. Such high-Q nanocavities are promising for enhancing light-matter interactions which are intrinsically weak, but it is highly important to appropriately design the structure and material to realize large enhancement. In this talk, we show how we have succeeded in observing large enhancement in nanocavities. First, we apply nanocavities to enhance emission rate in Si by combining high-Q Si nanocavities with Cu isoelectronic centers. We also show emission rate enhancement for single-photon emission at telecom wavelengths. Second, we apply nanocavities to enhance optical nonlinearity. We discuss the design strategy for nonlinear application. Finally, we discuss electro-optic device applications including lasers and photo-detectors.

8808-56, Session 15

Plasmon amplification by strong coupling in a layered structure

Aurore Castanie, Brahim Guizal, M. Antezza, Didier Felbacq, Univ. Montpellier 2 (France)

Using surface plasmon-polariton in devices, the so-called domain of "Plasmonics", poses the problem of the losses inherent to metals. Several methods have been proposed to overcome the losses, mainly by introducing active media in the vicinity of the metal. In this situation, the photon emitted by the active medium are hoped to couple the plasmonic field. However, little has been said on the microscopic aspects of the coupling between the light emitted by the active medium and the plasmon-polariton. In the present work, we propose a simple layered geometry for which we demonstrate the strong coupling between confined exciton-polariton and the plasmon-polariton. Interestingly the strong coupling induces a splitting in both the energy and the propagation constant, resulting in Rabi oscillations but also on spatial oscillations. Because of the spatial oscillations, the hybrid mode resulting from the strong coupling is geometrical concentrated in both the waveguide and the metal. This results into an automatic reduction of the spatial damping of the hybrid mode. Next, we investigate the amplification of the plasmon by adding gain into the waveguide. By following by continuity the propagation constant path in the complex plane with respect to the gain, we exhibit an inherent limitation in close connection to the situation encountered in PT-symmetric waveguides.

8808-57, Session 16

Chiral plasmonic films and nanoparticles *(Invited Paper)*

David J. Norris, ETH Zurich (Switzerland)

Plasmonic structures with chirality (or handedness) can exhibit interesting optical phenomena. This has recently been explored in patterned films, typically defined by electron beam lithography. An outstanding challenge has been to create chiral metallic nanoparticles that have only one handedness (i.e. all left-handed or all right-handed, which in molecular terminology is referred to as enantiomerically pure). Such nanoparticles can exhibit both strong circular dichroism in the visible spectral range as well as non-linear optical effects. These properties can open up applications for chiral metallic nanoparticles in sensing, separations, and optical signal processing. Here we report a novel route to enantiomerically pure chiral gold nanoparticles. Template stripping is applied to silicon wafers to prepare plasmonic films and nanoparticles with chiral shape of only one handedness. In general, template stripping utilizes the fact that coinage metals (e.g., silver, gold, and copper) will wet silicon substrates well but adhere poorly. Thus, by depositing such a metal on a patterned silicon wafer, the metal can be "stripped" off to reveal a smooth patterned film or structure that was templated by the silicon. We exploit this to develop a simple approach for obtaining chiral plasmonic structures. In particular, we demonstrate gold nanoparticles that are enantiomerically pure and have sizes controllable between 100 nm and 1 micron. Both experimental and simulated circular dichroism spectra from suspensions of the template-stripped chiral nanoparticles will be discussed.

8808-58, Session 16

Holographic fabrication of 3D optical metamaterials *(Invited Paper)*

Paul V. Braun, Univ. of Illinois at Urbana-Champaign (United States)

We have developed a genetic algorithm method for designing the diffractive optics used in phase mask lithography and performed exposures through this phase mask to realize various complex 3D structures, include optical metamaterials comprised of both dielectric and metallic constituents.

8808-59, Session 16

Synthesis of core-shell Y2O3 nanoparticles for enhanced luminescence efficiency

Ju H. Choi, Jae-Pil P. Kim, Ki H. Kim, Hye-Jeong Kim, Jeong-Ho Kim, Korea Photonics Technology Institute (Korea, Republic of)

Rare-earth (RE) ion doped core and core-shell Y2O3 phosphors have been extensively used in many applications due to the high stability and emission range and intensity. The core-shell Y2O3: (RE= Eu, Dy, Tb) nanoparticles are synthesized using a two-step process in which 100-150 nm Y2O3 core particles are synthesized using a molten salt synthesis and the shell is deposited using a sol-gel process. A shell layer, up to 10 nm thick, is controllable based on the RECl3 salt concentration. The core-shell architecture was designed for enhanced luminescence efficiency and a balanced white light appearance with long emission lifetimes. Specifically, a core-shell architecture was necessary to spatially separate the Eu3+ and Tb3+ within the phosphor to circumvent the energy transfer between them, passivate the surface quenching sites. First, the crystallinity of Y2O3 nanophosphors was characterized using X-ray analysis. RE-doped Y2O3 core nanoparticles have a good compositional homogeneity. We have also recorded absorption, fluorescence spectra and measured fluorescence lifetimes as a function of the each RE concentration in the core. After coating passive shell layer, absorption, fluorescence spectra and measured fluorescence lifetimes were compared with those from Y2O3 nanophosphor core system in order to assess the effectiveness of these core-shell phosphors. RGB combinations from each RE activator were used to produce white light. The synthesized Y2O3 nanophosphors doped with RE= Eu, Dy, Tb have high quality white light with improved emission lifetimes, suitable for application in white light LED devices.

8808-60, Session 16

Shear ordering of densely packed core-shell spheres in super viscoelastic medium for making 3D photonic crystals *(Invited Paper)*

Qibin Zhao, Andrew I. Haines, Univ. of Cambridge (United Kingdom); David R. E. Snoswell, Schlumberger Cambridge Research Ctr. (United Kingdom); Chris E. Finlayson, Aberystwyth Univ. (United Kingdom); Jeremy J. Baumberg, Univ. of Cambridge (United Kingdom)

Making photonic crystals on large scale remains highly problematic, despite their great utility for manipulating light. We have been developing routes to polymer opals, which are stretchable 3D photonic crystals comprised of densely-pakced ordered core-shell spheres. Here we demonstrate their fabrication on the kilometre-scale using a novel bottom-up bending-induced oscillatory shearing (BIOS) process.

Shearing has been widely studied yet not fully understood in both granular physics and colloidal science. Compared to most granular or colloidal systems which use a liquid inter-particle medium with low viscosity which thus has little influence, our shearing assembly works with densely-packed polymer spheres in a highly viscoelastic medium. The spheres, with a hard polystyrene core and a low Tg soft sticky polyethylacrylate shell, are pressed into thin films sandwiched between two rigid plastic foils, then sheared in the solid phase using BIOS technique. By banding the sandwiched film onto heated rollers and driving the film backward and forward repeatedly, oscillatory lateral is applied homogeneously across the whole film, and high quality flexible 3D photonic crystal films of length scale up to 1km are obtained. Optical reflection and transmission properties of the photonic crystals show the influence of processing in one direction (uni-axial BIOS) or two directions (bi-axial BIOS, 30° with respect to each other) for different numbers of passes. This is confirmed by using micro-radian x-ray scattering, which demonstrates how the in-plane and inter-plane arrangements of spheres evolves. Such polymer photonic crystals have a wide range of uses in healthcare, coatings and security applications.

8809-1, Session 1

Classical and quantum effects in graphene plasmonics *(Keynote Presentation)*

Javier García de Abajo, ICFO - Institut de Ciències Fotòniques (Spain)

We will review current results in graphene plasmonics and describe distinct features of these excitations that can only be understood from quantum theory.

8809-2, Session 1

All-color plasmonic nanolasers with ultralow thresholds *(Keynote Presentation)*

Yu-Jung Lu, National Tsing Hua Univ. (Taiwan); Jisun Kim, The Univ. of Texas at Austin (United States); Hung-Ying Chen, National Tsing Hua Univ. (Taiwan); Wen-Hao Chang, National Chiao Tung Univ. (Taiwan); Chih-Kang Shih, The Univ. of Texas at Austin (United States); Shangjr Gwo, National Tsing Hua Univ. (Taiwan)

We demonstrate that SPASER-enabled semiconductor nanolasers with 3D subwavelength sizes can emit light in the full visible spectrum (red, green, blue, etc.) by using single shape-controlled InGaN/GaN core–shell nanorods as gain media on epitaxial Ag films. The use of atomically smooth Ag films grown on Si substrates allows us to fabricate low-loss plasmonic cavities for ultralow-threshold (e.g., <10 W/cm2 for the blue nanolaser), continuous-wave (CW) nanolaser operation above liquid nitrogen temperature. Furthermore, the continuously tunable bandgap energy of the InxGa1-xN alloy makes it possible to realize all-color laser emission. Our results represent a significant step toward the realization of all-color, single-semiconductor-system nanolasers, which can become critical for display and bioimaging applications.

8809-3, Session 2

Light-induced liquid-vapor phase transitions: solar steam generation using nanoparticles *(Keynote Presentation)*

Naomi J. Halas, Rice Univ. (United States)

When an Au nanoparticle in a liquid medium is illuminated with resonant light of sufficient intensity, a nanometer scale envelope of vapor -a “nanobubble”- surrounding the particle, is formed. This is the nanoscale onset of the well-known process of liquid boiling, occurring at a single nanoparticle nucleation site, resulting from the photothermal response of the nanoparticle. We examine the steam generation process at metallic nanoparticle surfaces, and in particular at an individual metallic nanoparticle surface, in detail. Incipient nanobubble formation is observed by monitoring the plasmon resonance shift of an individual, illuminated Au nanoparticle, when its local environment changes from liquid to vapor. The temperature on the nanoparticle surface is monitored during this process, where a dramatic temperature jump is observed as the nanoscale vapor layer thermally decouples the nanoparticle from the surrounding liquid. These quantitative measurements call into question the conventional picture of macroscopic heat transfer as an appropriate description of this phenomenon. These studies provide the first direct and quantitative analysis of the evolution of light-induced steam generation by nanoparticles from the nanoscale to the macroscale, a process that is of fundamental interest for a growing number of applications. Based on both single-particle and ensemble measurements and theory, an increased understanding of the mechanism of vapor generation at liquid-immersed nanoparticle surfaces is emerging: our talk will focus on our current picture of this phenomenon as well as emerging applications based on this new solar energy harvesting approach.[1]

8809-4, Session 2

Plasmonic smart dust for probing local chemical reactions

Andreas Tittl, Xinghui Yin, Harald W. Giessen, Univ. Stuttgart (Germany); Xiang-Dong Tian, Zhong-Qun Tian, Xiamen Univ. (China); Christian Kremers, Dmitry N. Chigrin, Bergische Univ. Wuppertal (Germany); Na Liu, Max-Planck Institut für Intelligente Systeme (Germany)

Locally probing chemical reactions or catalytic processes on surfaces under realistic reaction conditions has remained one of the main challenges in materials science and heterogeneous catalysis. Where conventional surface interrogation techniques usually require high-vacuum conditions or ensemble average measurements, plasmonic nanoparticles excel in extreme light focusing and can produce highly-confined electromagnetic fields in subwavelength volumes without the need for complex near-field microscopes. Here, we demonstrate an all-optical probing technique based on plasmonic smart dust for monitoring local chemical reactions in real time. The silica shell-isolated gold nanoparticles which form the smart dust can work as strong light concentrators and optically report subtle environmental changes at their pinning sites on the probed surface during reaction processes. As a model system, we investigate the hydrogen dissociation and subsequent uptake trajectory in palladium with both “dust-on-film” and “film-on-dust” platforms. Using time-resolved single particle measurements, we demonstrate that our technique can in-situ encode chemical reaction information as optical signals for a variety of surface morphologies. The presented technique offers a unique scheme for real-time, label-free, and high-resolution probing of local reaction kinetics in a plethora of important chemical reactions on surfaces, paving the way towards the development of inexpensive and high-output reaction sensors for real-world applications.

8809-5, Session 2

Split-ball resonator

Arseniy I. Kuznetsov, A*STAR - Data Storage Institute (Singapore); Andrey E. Miroshnichenko, The Australian National Univ. (Australia); Yiguo Chen, A*STAR - Data Storage Institute (Singapore); Vignesh Viswanathan, National Univ. of Singapore (Singapore); Yuan Hsing Fu, A*STAR - Data Storage Institute (Singapore); Daniel Pickard, National Univ. of Singapore (Singapore); Boris S. Luk’yanchuk, A*STAR - Data Storage Institute (Singapore)

One of the main challenges in the field of plasmonics and metamaterials is to engineer nanostructures with strong magnetic and electric dipole resonances at visible frequencies. Getting these two resonant responses together in the same frequency range can lead to unique material properties associated with near-zero or even negative effective refractive index. Until now there were only a few experimental demonstrations of resonant magnetic response of metallic nanostructures in the red spectral region. However, strong losses inherent to plasmonic structures in the visible spectral range significantly limit possibilities to shift the magnetic resonance to shorter wavelengths. In this paper, we introduce a new concept and experimentally demonstrate a strong magnetic dipole resonance tuneable throughout the whole visible spectral range using standard plasmonic metals such as gold and silver. The key aspect is nanometer cuts fabricated inside almost perfectly spherical plasmonic nanoparticles. Such 3D spherical design allows for shifting magnetic dipole resonance down to electric dipole resonance wavelength in the visible spectral range. This results in Fano-type interference of electric and magnetic resonant modes inside the single particle. Experimentally this novel design has been realized using laser-induced transfer method to produce a perfect sphere and helium ion beam milling (HIM) to introduce a tiny cut with nanometer resolution. Due to high quality of the sphere surface controlled by strong surface tension forces during the laser transfer process and straight side walls of the cut made by HIM magnetic resonance can clearly be observed at 625 nm in gold nanoparticles. Using silver nanoparticles instead of gold can shift magnetic resonance down to blue wavelengths making it tuneable through the whole visible spectral range.

8809-6, Session 2

Femtosecond laser induced surface melting and nanojoining for plasmonic circuits

Anming Hu, Univ. of Waterloo (Canada); Guoliang Deng, Sichuan Univ. (China); Sebastien D. Courvoisier, Harvard School of Engineering and Applied Sciences (United States); Orad Reshef, Christopher C. Evans, Eric Mazur, Harvard Univ. (United States); Norman Y. Zhou, Univ. of Waterloo (Canada)

Femtosecond laser induced nonthermal processing is an emerging nanofabrication technique for delicate plasmonic devices. In this work we present a detailed investigation on the interaction between ultra-short pulses and silver nanomaterials, both experimentally and theoretically. We systematically study the laser-silver interaction at a laser fluent from 1 J/m2 to 1 MJ/m2. The optimal processing window for welding occurs at fluences of 200–450 J/m2. We investigate the size and shape effect on the interaction using finite-element time-domain (FDTD) simulation. FDTD simulation shows that a femtosecond laser pulse can induce surface melting at a few hundred J/cm2 due to the near field enhancement. The femtosecond laser-induced melting thus allows precise welding of silver nanoparticials with subnanosized gaps and silver nanowires for “T” and “X” shape circuits. These welded plasmonic circuits are successfully applied for surface enhanced Raman probes with ultrasensitive resolution, routining light propagation and cell transfection.

8809-7, Session 3

Enhanced light-matter interactions in plasmonic nanoparticle arrays *(Invited Paper)*

Teri W. Odom, Northwestern Univ. (United States)

Metal nanostructures can concentrate optical fields into highly confined, nanoscale volumes, which is important for plasmonic nanolasers, white-light generation, and enhanced non-linear optical effects. The talk will describe how arrays of strongly coupled nanoparticles and three-dimensional bowtie nanoantennas provide new routes not only to achieve these extraordinary properties but also to scale them for wide-spread applications. First, we will describe a new type of subradiant plasmon with a narrow (~5 nm) resonant linewidth that can be easily tuned by changing the height of large (> 100 nm) gold NPs arranged in a 2D array. At resonance, strong coupling between out-of-plane NP dipolar moments suppresses radiative decay, trapping light in the plane of the array and strongly localizing optical fields on each NP. Second, we will focus on NP dimers—3D bowties—that can function as optical nanoantennas. The extremely high electric field enhancements within the gap originate from the near-field interactions between the NPs. These localized fields can provide feedback for a new type of plasmonic laser based on 3D bowtie nanoparticle arrays.

8809-8, Session 3

Plasmonic antennas hybridized with dielectric waveguides

Felipe Bernal Arango, A. Femius Koenderink, FOM Institute for Atomic and Molecular Physics (Netherlands)

All the exciting properties of plasmonic nano-antennas can be used in even more versatile ways, if one can interrogate the antennas efficiently in integrated-photonic-circuits. We will present comprehensive experimental and theoretical evidence that single plasmon particles as well as plasmon Yagi-Uda antennas can be integrated with silicon nitride waveguide circuitry for efficient addressing of antennas through waveguides, as well as for creating unidirectional waveguide-coupled nanosources. In order to usefully apply the combination of plasmonic antennas and integrated dielectric waveguides it is imperative to quantify how strongly the antenna scatters waveguide modes, and conversely how the waveguide affects the antenna resonance frequency and scattering efficiency. We have realized a supercontinuum laser waveguide end-fire set up integrated with confocal and Fourier microscopy to on the one hand quantify the scattering of antennas addressed through single mode waveguides, and conversely to quantify the efficiency with which antennas can couple light into the waveguide mode. On basis of our measurements of how single objects scatter when placed on waveguides, we have successfully designed and realized waveguide integrated Yagi-Uda plasmon array antennas. We demonstrate wavelength controlled waveguide-addressable hot-spots, waveguide addressable beaming, as well as the converse, i.e., efficient unidirectional incoupling of far field radiation into the waveguide. We predict that this system allows single photon sources with beta-factors above 80%, which can be further improved by material optimization. These measurements together with simulations demonstrate that this system is ideal as a platform for plasmon quantum optics schemes as well as for fluorescence lab-on-chip applications.

8809-9, Session 3

Nanoplasmonic Fano resonances: choosing the best regime

Benjamin Gallinet, Ctr. Suisse d’Electronique et de Microtechnique SA (Switzerland)

Plasmonic modes with long radiative lifetimes combine strong nanoscale light confinement with a narrow spectral line width carrying the signature of Fano resonances, making them very promising for nanophotonic applications such as sensing, lasing, and switching. Their coupling to incident radiation, also known as radiance, determines their optical properties and optimal use in applications. An analytical model for Fano-resonant systems including non-radiative losses is introduced. It is theoretically and experimentally demonstrated that the radiance of a plasmonic mode can be classified into three different regimes. In the weak coupling regime, the line shape exhibits remarkable sensitivity to the dielectric environment. It is shown that geometrical displacements and deformations at the Ångström scale can be detected optically by measuring the radiance. In the intermediate regime, the electromagnetic energy stored in the mode is maximal, with large electric field enhancements that can be exploited in surface enhanced spectroscopy applications. In the strong coupling regime, the interaction can result in hybridized modes with tunable energies. Finally, the usage of Fano-resonant systems as biochemical sensors is discussed. It is shown that reducing Ohmic losses is the key to decreasing the limit of detection. A figure of merit including the sensitivity, spectral resolution and contrast of the Fano resonance is derived from the analytical model. A general understanding of Fano–resonant plasmonic systems emerges from this study, which should ultimately lead to optimized applications in switching and optical communications, biological and chemical sensing based on this phenomenon.

8809-10, Session 4

Passive and active tuning of optically resonant nanostructures *(Invited Paper)*

Mark Brongersma, Geballe Lab. for Advanced Materials (GLAM) (United States)

Optically resonant plasmonic and high index dielectric nanostructures form the basis of nanophotonic devices and circuits. There is a long history of spectrally tuning their optical resonances by changing the size, shape, and dielectric environment of these nanostructures. In this presentation, I will discuss ways in which these resonances can be tuned passively by electrical doping and anneal treatments as well as actively by electrical gating.

8809-11, Session 4

Nanoscale chemical imaging of plasmonic hot-spots and dark modes using photo-thermal induced resonance technique

Basudev Lahiri, Glen E. Holland, Vladimir A. Aksyuk, Andrea Centrone, National Institute of Standards and Technology (United States)

Nanomaterials are new material that has special properties owing to their nanoscale morphological features. In order to optimize the performance of nanomaterials for their potential application in number of fields such as energy harvesting, therapeutics, electronics, biology etc. it is of paramount importance that their structure-property relationship is defined clearly.

Although, the present high resolution imaging techniques (SEM, TEM etc.) provides detailed structural information at nanoscale level, the information on chemical composition of nanomaterials are obtained over a very large scale [typically at 3-10μm scale for FTIR], thereby providing an average information over large number of heterogeneous nano-objects. The Photo-Thermal Induced Resonance (PTIR) technique circumvents these limitations by combining the high lateral resolution of Atomic Force Microscopy and the high chemical specificity of IR Spectroscopy. Using PTIR technique, one can simultaneously obtain topological, chemical (IR), thermal and mechanical properties of a sample at a nanoscale level far smaller than the diffraction limit of infrared.

PTIR has been used so far for nanoscale characterization of bacteria, polymers, living cells1,2, but so far there has been no work done on utilising PTIR technique over plasmonic structures. In this work, PTIR technique is used to image bright and dark plasmonic resonances of gold Asymmetric Split Ring Resonators (A-SRRs) with nanoscale resolution. Additionally, The PTIR technique is used to map the local infrared absorption enhancement at the nanoscale, revealing absorption hot spots with local enhancement factors up to 50 times at 100 nm lateral resolution, several times better than the diffraction limit of IR light.

8809-12, Session 4

Effect of asymmetrical nanostructures on detecting the optical rotational properties of large biofilament structures

Yanjun Liu, S. Wu, A*STAR Institute of Materials Research and Engineering (Singapore); D. Popp, Institute of Molecular and Cell Biology (Singapore); Eunice S. P. Leong, A*STAR Institute of Materials Research and Engineering (Singapore); Y. L. Hor, W. K. Phua, A*STAR Institute of High Performance Computing (Singapore); K. L. Mok, Institute of Molecular and Cell Biology (Singapore); Jinghua Teng, A*STAR Institute of Materials Research and Engineering (Singapore); R. Robinson, Institute of Molecular and Cell Biology (Singapore); E. P. Li, Eng Huat Khoo, A*STAR Institute of High Performance Computing (Singapore)

In this abstract, the effects of tapered asymmetrical gammadion on the field enhancement and sensitivity detection of biomolecular structures is presented. The asymmetrical structure is made up of gold material on a glass structure. The designs are then fabricated using e-beam lithography. The chirality of the array is first determined by measuring the circular dichroism (CD) spectrum using a polarimeter. Three modes, arising from Bloch periodic theory and surface resonance mode are observed. Then each asymmetrical gammadion structure is tapered at the arms. Tapering fraction, which define the ratio of tapered end to the untapered end is used for defining the new structure designs. The CD spectra are obtained for tapered and untapered structures under different solutions. The spectra show that the three CD modes changes in degree amplitude and wavelength, especially for smaller tapering fractions for different solution. In addition, it is also observed that the field enhancement factor is significantly higher for the structures with tapering fraction less than 0.2. Subsequently, biomolecules, which has Alpha-helical and beta-sheet structures, are added. The biomolecules, with different chain lengths and chemical combination, produce larger wavelength shift compared to the untapered structures. This is due to the high field enhancement, concentrated around the taper end. This further encourages more interaction between the biomolecules and enhanced light field. The average wavelength shift due to molecular interaction is 17 nm, 13 nm and 12 nm for the tapered gammadion with tapering fraction of 0.1, 0.5 and 1 for the Bloch mode.

8809-13, Session 4

Addressing random metal-dielectric films by far-field control

Pierre Bondareff, Giorgio Volpe, Rémi Carminati, Sylvain Gigan, Ecole Supérieure de Physique et de Chimie Industrielles (France); Samuel Gresillon, Univ. Pierre et Marie Curie (France)

Addressing the nanoscale is obtained by dynamic control onto smaller and smaller objects. Efficient control of carefully designed nanoscale devices has been achieved in the past years, but fabrication and accessibility of the modes adressed from the far-field still represent open challenges. It has been shown recently on random dielectric media that disorder can be turned into an advantage to control light propagation. Combining metal and dielectric in a random system would allow to couple plasmon modes and to control their propagation from the far-field. Random metal-dielectric films which are particularly easy to fabricate and show interesting intrinsic behavior (intense subwavelentgh near-field features, broadband optical response) could therefore be used to achieve such far-field dynamical control of the optical near-field of a nanosystem. We propose a new experimental scheme where plasmonics modes are controlled by wavefront shaping of the incident beam with a spatial light modulator directly imaged on a random metal-dielectric film. This allow us to extract information about the extension of the modes, a key parameter for the far-field control of such films. Experimental results on the control of the propagation of surface plasmons polaritons on the surface will be presented. In particular, we will show that the filling fraction influences the efficiency of the coupling between far-field excitation and the plasmonic modes. This influence is what has been previously demonstrated in the near-field and paves the way towards far-field control of hot-spots.

Plasmonic interaction of 3D erected split-ring resonators *(Invited Paper)*

Wei Ting Chen, Chun Yen Liao, Yao-Wei Huang, Pin Chieh Wu, Shulin Sun, National Taiwan Univ. (Taiwan); Kuang-Yu Yang, Academia Sinica (Taiwan); Lei Zhou, Fudan Univ. (China); Guang-Yu Guo, National Taiwan Univ. (Taiwan) and National Chengchi

Univ. (Taiwan); Vassili A. Fedotov, Univ. of Southampton (United Kingdom); Nikolay I. Zheludev, Univ. of Southampton (United Kingdom) and Nanyang Technological Univ. (Singapore); Din Ping Tsai, National Taiwan Univ. (Taiwan) and Academia Sinica (Taiwan)

Here, we designed and fabricated 3D SRR arrays by using double exposure e-beam lithography technique for investigating the plasmonic interaction in the case of 3D metamolecules. We have studied the plasmonic resonance of a single erected SRR structure. Subsequently, based on our prior work, we studied the plasmonic interactions in the cases of two, three and four 3D SRRs within a unit cell, and found magnetic plasmon-enhanced energy splitting, magnetic plasmon induced transparency (PIT) and toroidal dipole response, respectively. In the case of a metamolecule consisted by two 3D SRRs, the energy splitting of the metamolecule is enhanced because of magnetic dipolar interaction. The plasmon induced transparency (PIT) phenomenon that can be analogized of the electromagnetically induced transparency (EIT) are experimentally demonstrated in the metamolecule consisted by three 3D SRRs. In such 3D plasmonic metamaterial system, the PIT phenomenon was dominated by a magnetic dipole state coupled to a magnetic quadrupole state rather than the electric responses. Moreover, the toroidal resonances, the fundamental electromagnetic excitations that cannot be represented in terms of the standard multipole, are studied in the case of a metamolecule consisted by four 3D SRRs. We found that both the toroidal and magnetic resonances can be generated by the magnetic dipolar interaction between each SRRs. The toroidal dipolar response with lowered lasing threshold can be used to approach the lasing spaser owing to the fine field confinement. These researches have promising applications in the field of plasmonics, such as integrated 3D plasmonic metamaterials, plasmonic biosensor and lasing spaser.

8809-15, Session 5

Plasmonic sources and detectors for extreme interconnects *(Keynote Presentation)*

Meir Orenstein, Technion-Israel Institute of Technology (Israel)

Future intrachip optical interconnects will require ultrasmall reliable simple and fast light sources as well as nano-small detectors the later with substantial large voltage swing for a small number of absorbed quanta and very small internal noise. Plasmonic fits extremely well into this application - enhancing spontaneous light emission and light detection of these nanoelements, as well as mitigating effectively the coupling of the information carrying quanta from/to these nano-semiconductor structures. In addition to the enhancement of quantum efficiencies, plasmonic scheme enhances the response speed of the transmitter and receiver making plasmonics viable for this fast interconnect application

8809-16, Session 5

Enhancing charge separation in semiconductors through plasmon induced resonant energy transfer

Scott K. Cushing, Jiangtian Li, Alan D. Bristow, Nianqiang Wu, West Virginia Univ. (United States)

The solar energy conversion efficiency of semiconductors is limited by weak charge separation and partial spectral coverage. Localized surface plasmon resonance (LSPR) allows the energy of incident light to be localized to a sub-wavelength volume by the collective oscillation of surface electrons in metal nanostructures. It is well known that LSPR can enhance light trapping through multiple scattering processes and photoconversion efficiency by the transfer of the hot plasmonic carriers to the semiconductor. Our recent studies have discovered that LSPR can also increase the charge separation in a semiconductor by Plasmon-Induced Resonant Energy Transfer (PIRET). PIRET increases the charge separation above and below a semiconductor's band gap, even if an insulating barrier separates the metal and semiconductor. Although the coupling is known to proceed through a nonradiative mechanism, the details remain unclear.

We have combined transient absorption measurements with core shell nanoparticles to investigate the PIRET mechanism. The thickness of the SiO2 interlayer in the Au@SiO2@Cu2O nanoparticles is varied to determine the distance dependence of the nonradiative coupling. The LSPR is varied across the visible region by changing the size of the Ag core in the Ag@SiO2@Cu2O nanocubes, allowing the dependence of the energy transfer on the spectral overlap between the Cu2O and LSPR to be determined. The induced carrier density measured by transient absorption measurements are directly linked to action spectrum photocatalysis measurements, mapping out the PIRET mechanism. The results can be used to optimize PIRET for full spectrum photoconversion enhancement in semiconductors.

8809-17, Session 5

Room temperature lasing in gallium nitride-based nanorods structure

Yu Cheng Hsu, Kuok-Pan Sou, Shih-Pang Chang, National Chiao Tung Univ. (Taiwan); Min-Hsiung Shih, Academia Sinica (Taiwan); Hao-Chung Kuo, Chun-Yen Chang, National Chiao Tung Univ. (Taiwan)

In this work, we have demonstrated that the metal-cladded GaN NRs laser can be operated at room temperature. By use of the metal-cladded layer to form a cavity, the well-confined resonant mode was observed within the GaN NR that was theoretical realized by implemented finite element method to simulation. The simulation result including the lasing behavior compared with different GaN nanorod morphology and lasing mode in the metal-cladded GaN NRs laser, finally, discuss the metal layer benefit in this NR structure. In the experiment, the wavelength of lasing action was observed around 365 nm that have low threshold power density of 5.2 mJ/cm2 with high quality factor approximately 1500. We also demonstrate the large area GaN NRs stick on GaN template which adopted nanoimprnit lithography and KOH based solution etching technique to defined the GaN NR arrays and control the NRs dimension. Besides, to understand lasing action in metal-cladded nitride-based NR with shape concern as the cavity that have potential to realize the long wavelength GaN-based nanolaser.

8809-18, Session 5

Electric spaser in the extreme quantum limit *(Invited Paper)*

Mark I. Stockman, Georgia State Univ. (United States) and Ludwig-Maximilians-Univ. München (Germany) and Max-Planck-Institut für Quantenoptik (Germany); Dabing Li, Changchun Institute of Optics, Fine Mechanics and Physics (China)

We consider theoretically the spaser excited electrically via a nanowire with ballistic quantum conductance. We show that in the extreme quantum regime, i.e., for a single conductance-quantum nanowire, the spaser with the core made of common plasmonic metals, such as silver and gold, is fundamentally possible. For ballistic nanowires with multiple-quanta or non-quantized conductance, the performance of the spaser is enhanced in comparison with the extreme quantum limit. The electrically-pumped spaser is promising as an optical source, nanoamplifier, and digital logic device for optoelectronic information processing with speed ~100 GHz to ~10 THz.

8809-19, Session 6

Tunable polarization-controlled directional launching of surface plasmon-polaritons with polarization-invariant conversion efficiency *(Invited Paper)*

Federico Capasso, Harvard School of Engineering and Applied Sciences (United States)

The efficient generation of surface plasmon polaritons (SPPs) from light has traditionally faced challenges in the polarization sensitivity of the coupling efficiency and in the control of the directionality of SPPs. We have designed and demonstrated plasmonic couplers that direct SPPs depending on the polarization of the incident light. They are based on polarization sensitive aperture optical antennas, arranged in fishbone shaped columns defined in a gold film. In contrast to conventional plasmonic couplers, the total SPP conversion efficiency of the device is independent of polarization and the information on the polarization of the incident light is encoded in the state of the SPP field. Bidirectional as well as unidirectional launching of SPPs in opposite directions are demonstrated by near-field optical imaging, using linearly polarized and circularly polarized light of opposite handedness, respectively This coupling concept is further applied to circular metallic structures that that generate either radially convergent or divergent SSP depending on the handedness of the circularly polarized light , illustrating how such couplers can be extended to a broad range of designs and applications.

8809-20, Session 6

Long-wavelength infrared extraordinary transmission through Ga-doped ZnO films with 2D hole arrays

Justin W. Cleary, Air Force Research Lab. (United States); Junpeng Guo, The Univ. of Alabama in Huntsville (United States); Joshua R. Hendrickson, Air Force Research Lab. (United States); Nima Nader Esfahani, Solid State Scientific Corp. (United States); Kevin D. Leedy, Air Force Research Lab. (United States); David C. Look, Wyle Labs. (United States)

Extraordinary optical transmission (EOT), or transmission greater than that predicted by conventional optics theory, through highly conductive ZnO films with sub-wavelength hole arrays is investigated in the long-wavelength infrared regime. EOT is facilitated by the excitation of surface plasmons and can be tuned utilizing the physical structure sizes; i. e. film thickness, period, hole diameter, and hole shape. Ga-doped ZnO films grown via pulsed laser deposition (PLD) are characterized by infrared ellipsometry and Hall measurements. PLD Ga-doped ZnO has been shown to have fluctuations in optical and electrical parameters based on fabrication techniques, providing a complimentary tuning means. The sub-wavelength 2D hole arrays are fabricated in the Ga-doped ZnO films via standard e-beam lithography and etching processes, with the optical transmission then being measured with a microscope coupled FTIR system. EOT through the structures is observed and compared with finite difference time-domain simulations. This highly conductive ZnO EOT structure may prove useful in novel integrated components such as tunable biosensors or surface plasmon coupling mechanisms.

8809-21, Session 6

Chirality in the interaction between plasmons, light, and vortex electron beams

Ana Asenjo-Garcia, Javier García de Abajo, Consejo Superior de Investigaciones Científicas (Spain)

We have studied the interaction of plasmonic chiral matter with both circularly polarized light and vortex electron beams. For light, we compare the calculations based upon multiple scattering theory with recent observations of circular dichroism (CD) in nanoparticles assembled using DNA origami [1]. We analyze the effect of varying distance between the particles and particle sizes as well as the influence of the material in the CD signals showing that it is possible to optimize the position of the particles to enhance the CD signal or to reverse its sign just with minor displacements.

For electrons, we predict strong dichroism in the electron energy-loss spectroscopy (EELS) signal by using electron vortex beams [2,3]. These vortex beams carry orbital angular momentum that can be exchanged in the interaction with chiral plasmons: when an electron looses energy by interacting with a chiral sample and it passes through a fork mask, different beams are diffracted (each with different orbital angular momentum), and the energy lost by the components with opposite units of angular momentum will be different. Incidentally, this method benefits from high spatial resolution of electron microscopes and might be really useful for magnetic dichroism imaging.

8809-22, Session 6

On plasmon-polariton propagation along metallic nano-chain

Witold A. Jacak, Wroclaw Univ. of Technology (Poland)

The collective wave type plasmon-polariton self-modes in the metallic (Au, Ag) nano-chain were determined and analyzed with respect to the nano-sphere size and chain-separation parameters. At some regions for parameters the undamped modes were identified when the interaction had been assumed as the near-field-zone dipole coupling. These modes were found on the rim of the stability of the linear theory, which indicates artifact of the model of near-field coupling. Inclusion of the medium- and far-field zone contributions to dipole interaction removes, however, instability and allows for fully analytical demonstration of exact quenching of irradiation losses of plasmon-polaritons in the chain to the level of only ohmic attenuation. The plasmon-polariton dispersion and the group velocity of plasmon-polariton wave packets were examined with respect to nano-sphere and chain parameters and mode polarization. Previous numerical results related to long range plasmon-polariton propagation including logarithmic divergence in transversal polarization plasmon-polariton dispersion due to far-field dipole coupling in the chain, are transparently interpreted within the analytical approach. The presented analysis verifies usefulness of widely applied simplifications in numerical investigation of plasmon-polariton propagation in discrete metallic nano-structures.

8809-23, Session 6

Plasmonic band theory *(Invited Paper)*

Shanhui Fan, Aaswath P. Raman, Wonseok Shin, Stanford Univ. (United States)

We show that by explicitly introducing the electronic degree of freedom, the understanding of modal properties in plasmonic structures can be significantly simplified. In particular, such formalism allows a rigorous proof of an upper bound of modal loss rate in plasmonic structures that depends only on materials, but not the detailed geometry.

8809-24, Session 7

Graphene nanoplasmonics *(Keynote Presentation)*

Harry A. Atwater Jr., Victor Brar, Michelle Sherrott, California Institute of Technology (United States); Min S. Jang, Seoul National Univ. (Korea, Republic of)

Single-layer graphene has been shown to have intriguing prospects as a plasmonic material, with modes having plasmon wavelengths ~20 times smaller than free space (λspp ~ λ0/20) have been observed in the 2-6 THz range, and active graphene plasmonic devices operating in that regime have been explored. However there is great interest in understanding the properties of graphene plasmons across the infrared spectrum, especially at energies exceeding the graphene optical phonon energy. We use infrared microscopy to observe the modes of tunable plasmonic graphene nanoresonator arrays as small as 15nm. We map the wave vector-dependent dispersion relations for graphene plasmons at mid-infrared energies from measurements of resonant frequency changes with nanoresonator width. By tuning resonator width and charge density, we probe graphene plasmons with λspp ≤ λ0/100 , and plasmon resonances as high as 310 meV (2500cm-1) for 15nm nanoresonators. Electromagnetic calculations suggest that the confined plasmonic modes have a local density of optical states more than 106 larger than free space, and thus could strongly increase light matter interactions at infrared energies.

8809-25, Session 7

Plasmon hybridization in graphene metamaterials

Atsushi Ishikawa, RIKEN (Japan); Takuo Tanaka, RIKEN (Japan) and Hokkaido Univ. (Japan)

Plasmonic properties of structured graphene and their coupling phenomena are investigated at terahertz (THz) frequencies. Two-dimensional (2D) plasmons in graphene have recently attracted much interest due to their unique plasmonic properties, such as strong field confinement, relatively long life times and dramatic tunability by electrostatic gating. Graphene plasmonics has been naturally explored in a 2D system, but stacking graphene structures into the third dimension is assumed to gain more functionality for the versatile plasmonic applications. In such complexes, plasmon coupling among neighboring graphene structures becomes more prominent and important, thus their underlying near-field interactions has to be addressed. Here, we study a stacked pair of graphene ribbons, which is the most fundamental coupled model system to describe the plasmon hybridization. We fabricated and characterized a pair of graphene ribbon on a heavily-doped Si substrate with nanometer-thick SiO2 gap layer between. The interaction between the graphene plasmons and their induced mirror images in the substrate forms a coupled system, mimicking a stacked pair of graphene ribbons, thereby dramatically modifies the mode profiles and resultant spectral responses. The polarization-dependent and gate-voltage-controllable magnetic plasmon resonances arising from the plasmon hybridization are demonstrated at THz frequencies. Excellent agreement between the experiment and numerical results reveals the important resonant behavior of structured graphene and their hybridized systems.

Enhanced gold film-coupled graphene-based plasmonic nanosensor

Thomas Maurer, Julien Proust, Jérémie Béal, Silvère Schuermans, Rana Nicolas, Univ. de Technologie Troyes (France); Edy Wijaya, Jean-Pierre Vilcot, Institut d'Electronique, de Microélectronique et de Nanotechnologie (France); Jérôme Plain, Univ. de Technologie Troyes (France); Rabah Boukherroub, Institut de Recherche Interdisciplinaire (France); Pierre-Michel Adam, Univ. de Technologie Troyes (France); Gaëtan Lévêque, Abdellatif Akjouj, Bahram Djafari-Rouhani, Univ. des Sciences et Technologies de Lille (France); Sabine Szunerits, Institut de Recherche Interdisciplinaire (France); Rana Nicolas, Univ. de Technologie Troyes (France) and Lebanese Univ. (Lebanon) and American Univ. of Beirut (Lebanon); Michel Kazan, American Univ. of Beirut (Lebanon); Ziad Herro, Lebanese Univ. (Lebanon)

Motivated by previous work showing that the LSPR behavior of metallic nanostructures on the top of a thin metal thin film is exquisitely sensitive to the spacer distance of the film-nanoparticles [1], we seek to investigate in the present work the influence of a few-layered graphene spacer film. As mentioned in most introductions of reports about graphene, the great deal of efforts around graphene comes from its "unique" electronic properties. However, as underlined by A. K. Geim, graphene cannot be reduced only to its "unique electronic properties" and it should be reminded that it is the only one-atom-thick materials [2]. Moreover, graphene has been theoretically considered as an alternative coating for gold based SPR [3].

Here, we take advantage of graphene's one-atom thickness in order to use it as the thinnest possible spacer between a gold film and gold nanoparticles. We investigate graphene-based SPR interface decorated with an ordered array of gold nanostructures. A commercial thermal release tape, which enables the mechanical transfer of a surface of 1 mm2 graphene sheet originally grown by chemical vapor deposition (CVD) on nickel-coated silicon substrate onto classical SPR interface (glass/5 nm Ti/ 50 nm Au). The graphene-modified SPR interface was in the following decorated with an ordered array of gold nanoparticles via electron beam lithography (EBL). On top of a chromium adhesion layer (d= 3 nm), gold nanoparticles of 50 nm in height, with a centre-to-centre distance of 300 nm and varying particle diameter (80 nm, 110 nm and 150 nm) were formed by EBL.

We have shown [4] that the deposition of a few-layers of graphene between a gold thin film of 50 nm and an ordered array of gold nanoparticles displays two clear resonances: the planar LSPR mode of the gold nanostructures at λ2 ≈ 770 nm and in addition a low wavelength LSPR mode at λ 1 ≈ 510 nm. This low wavelength mode is excited by the high energy branch of the gold film surface plasmon polaritrons, which is itself excited by the gold nanoparticle gratings. The importance in this low wavelength LSPR mode is linked to its low FMHW of 50 nm, which results in a Figure of Merit (FoM) of 2.8 at wavelength of 510 nm.

This FoM ranks this interface among the highly sensitive LSPR sensors with plasmon band in the visible at 500 nm. Indeed, most of the interfaces with high FoM (4-16.5) take advantage of the fact that higher sensitivities are achieved with plasmon bands in the near-infrared of the spectrum (850-1200 nm) [5,6]. Finally, this study provides a further understanding of systems based on arrays of resonant metallic nanoparticles coupled to metallic films. From a practical point of view, it opens the way to the engineering in a controlled and predictable way the spectral properties of metallic nanoparticles-based systems to reinforce their applicability especially in for sensing applications.

Propagation and excitation of graphene plasmons

Xiaolong Zhu, Wei Yan, Claus Jeppesen, Peter U. Jepsen, DTU

Fotonik (Denmark); Ole Hansen, Technical Univ. of Denmark (Denmark); N. Asger Mortensen, Sanshui Xiao, DTU Fotonik (Denmark) and Technical Univ. of Denmark (Denmark)

Graphene has attracted considerable attention due to its unique electronic and optical properties. In this paper, we theoretically investigate the propagation of graphene plasmons in nanoribbon waveguides and experimentally observe the excitation of the graphene plasmons in a continuous graphene monolayer. Firstly, we investigate the performance of bends and splitters in graphene nanoribbon waveguides, and show that bends and splitters do not induce any additional loss provided that the nanoribbon width is sub-wavelength. We use transmission line theory to qualitatively interpret the behavior observed in our simulation. Then we theoretically investigate the nanofocusing of graphene plasmons in a tapered graphene waveguide and find out that the field near the tip is strongly enhanced and that graphene plasmons propagating toward the tip of the tapered graphene waveguide are slowed down. Lastly we experimentally demonstrate the excitation of graphene plasmons in a continuous graphene monolayer resting on a two-dimensional subwavelength silicon grating (SWSG). The silicon grating is realized by a nanosphere lithography technique (a widely used technique for fabricating low-cost wafer-scale samples) with a self-assembled nanosphere array as a template. A chemical-vapour-deposition-grown monolayer graphene on copper is then transferred onto the SWSG after chemically etching away the copper. Guided graphene plasmons excited in the graphene monolayer on the diffractive grating are observed in transmission spectrum measured at midinfrared frequencies. Numerical simulations and analytical resonance band properties are implemented to further support the experimental results.

8809-28, Session 7

Electro-optic modulator based on a metal-ferroelectric nanocomposite

Etai Rosenkrantz, Shlomi Arnon, Ben-Gurion Univ. of the Negev (Israel)

We present an innovative method for modulating light using a ferroelectric thin-film embedded with metal nanoparticles. Due to the electro-optic effect in ferroelectric PZT, changes in refractive index can be controlled by an external electric field. Consequently, the local surface plasmon resonance of embedded noble metal nanoparticles changes with the media's refractive index. As a result, their optical extinction cross-section is shifted and light passing through the film could be controlled. In other words, an external electric field could modulate light. Using Mie theory for spherical particles, we were able to find the metallic nanoparticle's diameter that generates the maximum optical contrast, at a given wavelength. In addition, to establish an accurate model, we considered the impact on plasmon resonance resulting from deformation of the nanoparticles. The deformation is caused by the piezoelectric property of the ferroelectric host material. We assumed 20 nm diameter Au or Ag nanoparticles embedded in a 1 µm thick PZT film. Simulations showed that these particles can reach an optical contrast of up to 12 dB, in the visible spectrum. In addition, deformation of particles had negligible impact on the shift in resonance frequency compared to the change in PZT refractive index. In this study we have shown that a nanocomposite comprising of nanoparticles embedded PZT thin film can perform as an optical modulator. This modulator will be able to achieve a high contrast with low power consumption.

8809-29, Session 7

Ultrafast all-optical magnetization reversal in GdFeCo films around plasmonic nanostructures

Vladimir Kochergin, MicroXact, Inc. (United States); Sergiy Cherepov, Robert N. Schwartz, Univ. of California, Los Angeles (United States); Lauren A. Neely, Kevin Flanagan, MicroXact, Inc. (United States); Eugene V. Kochergin, Donetsk National Univ. (Ukraine); Kang L. Wang, Univ. of California, Los Angeles (United States)

It has recently been experimentally demonstrated that reproducible and controllable all-optical magnetization reversal in GdFeCo films can be achieved with a single ultrafast (from 40fs to 3ps) femtosecond laser pulse. While the microscopic origin of the effect is still unclear, the effect is believed to be caused by a combination of light-induced quasi-static magnetic field, with dynamic thermal effects due to laser heating.
This finding reveals great potential for ultrafast data storage through magnetic switching without the aid of an external magnetic field. It was further recently predicted that utilization of plasmonic nanostructures may provide the way to achieve fast all-optical magnetization switching with smaller/cheaper laser sources with longer pulse durations. We will present the simulations of temporal dynamics of magnetization reversal around plasmonic nanostructures with the combination of Landau Lifshitz Bloch and finite element modeling. Our modeling results predict that plasmonic nanostructures can significantly alter all-optical magnetization switching process and may help achieve a number of technologically important effects that cannot be achieved otherwise. Results of experimental studies of optical magnetization reversal in GdFeCo films around plasmonic nanostructures are also provided, verifying theoretical predictions.

Quantum optics with nanowires *(Invited Paper)*

Valery Zwiller, Reinier W. Heeres, Technische Univ. Delft (Netherlands)

We perform a Hong-Ou-Mandel experiment with indistinguishable plasmon pairs in an integrated quantum plasmonics experiment where superconducting single plasmon detectors are used for on-chip detection at the single plasmon level. We will discuss future possible implementations based on our all-on-chip approach where emission, propagation, interaction and detection can all be performed efficiently at the single photon level.

8809-31, Session 8

Entangling quantum emitters coupled to epsilon-near-zero structures in plasmonic waveguides near frequency cutoff

Ruzan Sokhoyan, Harry A. Atwater Jr., California Institute of Technology (United States)

Future quantum computing and communication systems are likely to exploit coherently coupled quantum emitters. In free space, dipole-dipole interactions between quantum emitters drastically diminish when the inter-emitter spacing is comparable to half a resonant wavelength. Coupling quantum emitters to plasmonic structures could dramatically increase their interaction range, due to the small mode volume characteristic to plasmonic fields. Within the framework of quantum electrodynamics, we articulate here how coupling quantum dipole emitters to a plasmonic waveguide could enable observation of quantum cooperative effects, focusing on the emitter entanglement and collective decay. We consider a single-mode plasmonic rectangular waveguide with a dielectric core and metal cladding which is known to mimic behavior of an epsilon-near-zero metamaterial at the frequency cutoff [1]. Assuming different resonant frequencies of the quantum emitters we investigate how the inter-emitter interactions are varied when approaching the cutoff frequency of the fundamental plasmonic mode supported by the waveguide. At the frequency cutoff of the considered geometry, one observes the enhancement of the local density of photonic states that results in the augmented emitter-field interactions. We calculate Purcell factor, collective decay and coupling parameters as a function of the

spatial position and resonant frequencies of the emitters. We investigate entanglement generation at the spontaneous transition of the emitters by calculating concurrence as a function of time. Finally, we analyze how the described effects change when non-identical emitters are involved.

8809-32, Session 8

Graphene spaser

Vadym Apalkov, Mark I. Stockman, Georgia State Univ. (United States)

We predict that a graphene monolayer coupled to a multi-quantum well (quantum cascade) system can form a graphene spaser. This creates a coherent quantum generator of surface plasmons in graphene. The active element of the graphene spaser is a multi-quantum well system with a design similar to that of the gain medium of a quantum cascade laser. With realistic parameters of the multi-quantum well system, the spasing in the graphene monolayer can be achieved at a finite doping of graphene and at a surface plasmon frequency close to a typical frequency of intersubband transitions in multi-quantum well system.

8809-33, Session 8

Quantum plasmonics: electron transfer processes *(Invited Paper)*

Peter Nordlander, Rice Univ. (United States)

Plasmon energies can be tuned across the spectrum by simply changing the geometrical shape of a nanostructure. Plasmons can efficiently capture incident light and focus it to nanometer sized hotspots which can enhance electronic and vibrational excitations in nearby structures.[1] For narrow plasmonic junctions, quantum mechanical effects can play an important role: the large field induced in the junction can facilitate electron tunneling and charge transfer[2] and also lead no nonlinear optical response.[3] Another important but still relatively unexplored effect is production of hot energetic electrons which can transfer into nearby structures and induce a variety of processes. This process is a quantum mechanical effect: the decay of plasmon quanta into electron-hole pairs. I will discuss how plasmon induced hot electrons can be used in various applications: such as to induce chemical reactions in molecules physisorbed on a nanoparticle surface;[4] to inject electrons directly into the conduction band of a nearby substrate;[5] and to induce local doping of a nearby graphene sheet.[6]

From individual to strongly coupled metallic nanocavities *(Invited Paper)*

Yehiam Prior, Adi Salomon, Weizmann Institute of Science (Israel); Radoslaw Kolkowski, Joseph Zyss, Ecole Normale Supérieure de Cachan (France)

Localized plasmonic modes of metallic nanoparticles may hybridize like atomic orbitals forming a molecule. However, the rapid decay of the plasmonic fields outside the metal severely limits the range of these interactions to tens of nanometers. Herein, we demonstrate very strong coupling of nanocavities in metal films, sustained by propagating surface plasmons with a range on the scale of hundreds of nanometers for the properly selected metal/wavelength combination. Such strong coupling drastically changes the symmetry of the charge distribution around the nanocavities making it amenable to probing by the highly symmetry sensitive nonlinear optical response of the medium. We show that when strongly coupled, equilateral triangular nanocavities lose their individual three-fold symmetry to adopt the lower two-fold symmetry of the coupled system (see Figure). The coupled system then responds like a single dipolar entity, and the SHG emission can be either enhanced or suppressed depending on the incoming beam polarization. While this phenomenon holds for nanocavities, it is very different for nanoparticles which do not couple at the same distances, a situation which seems not to obey Babinet's principle

8809-35, Session 9

Theory of plasmonic waves on a chain of metallic nanoparticles in a liquid crystalline host

Nicholas A. Pike, David G. Stroud, The Ohio State Univ. (United States)

We calculate the change in the dispersion relations of plasmonic waves along a chain of metallic nanoparticles when the host is a nematic or a cholesteric liquid crystal (NLC or CLC).

Since an NLC is uniaxially anisotropic, the standard quasistatic method for calculating the dispersion relations of plasmonic waves is modified in two ways: (i) the anisotropic host splits

the triply-degenerate single-particle dipolar plasmonic modes into a non-degenerate and a doubly degenerate mode; (ii) the dipole-dipole interaction between excitations on different

particles is modified by the host anisotropy. Including these modifications, we calculate the resulting dispersion relations for a metallic chain in an NLC host, with principal axis (director) parallel or perpendicular to the chain. Both the longitudinal (L) and transverse (T) dispersion relations are significantly changed. Furthermore, when the director is perpendicular to the chain, the doubly degenerate T branch is split into two non-degenerate linearly polarized branches. We treat a CLC with twist axis parallel to the chain as an NLC with director axis rotating around the chain axis with a characteristic pitch angle. In this case, the two T branches are again split, but are no longer linearly polarized. To illustrate these results, we calculate the L and T dispersion relations for both NLC and CLC and a Drude metal. The present work suggests that these plasmonic dispersion relations can be controlled using NLC or a CLC host and applying suitable external fields.

Resonance energy transfer in plasmonic systems *(Invited Paper)*

Tigran V. Shahbazyan, Jackson State Univ. (United States)

We discuss energy transfer between fluorophores such as dye molecules or semiconductor quantum dots placed nearby plasmonic structures. We develop a theory for energy transfer between quantum dots placed near a doped monolayer graphene and show that longitudinal plasmons can mediate highly efficient energy transfer at distances far exceeding the Forster radius. A simple analytical expression for energy transfer efficiency is derived that incorporates all the essential processes involved. Numerical calculations of the transfer efficiency performed for a pair of PbSe quantum dots separated by up to 1000 nm from each other indicate that plasmon-assisted long-range energy transfer can be

enhanced by up to a factor of 104 relative to the Forster's transfer in vacuum. We also discuss energy transfer from an ensemble of molecules deposited on top of a core-shell metal nanoparticle to an acceptor linked to its surface. We show that when thickness of dielectric shell is not very small, the energy transfer is dominated by cooperative effects. Our calculations show a significant increase of per donor transfer efficiency due to acceptor coupling to subradiant modes.

8809-37, Session 10

3D nanoantennas *(Invited Paper)*

Kobus Kuipers, FOM Institute for Atomic and Molecular Physics (Netherlands)

The unique optical properties of metals at optical frequencies enable a huge control of nanoscale light fields. Work in the past few years has shown how antenna concepts can be borrowed from the microwave regime and downscaled to the optical regime. This requires the fabrication of metallo-dielectric nanostructures. Here, I will present a new method to fabricate 3D nanoantenna structures, like ground-plane antennas. The resulting structures are so-called core-shell structures allowing a significant tailoring of their properties by varying the thickness of the shell. The 3D method allows the fabrication of nanoscale helices that exhibit optical dichroism.

8809-38, Session 10

Double quantum light emission from gold nanowires and interacting gold nanospheres

Mourad Abid, King Saud Univ. (Saudi Arabia); Mohamed Abid, King Saud Univ. (Saudi Arabia); Sophie Brasselet, Institut Fresnel (France)

Over the last two decades, metallic nanomaterials such as gold, silver and copper have attracted much more attention due to their unique electronic and optical properties compared to the "bulk" system [1]. These properties are strongly dependent on the characteristics of the metallic nanomaterials like the size, shape, environment and nature of the materials [2]. Noble metal nanomaterials present a strong absorption in the visible region coined as the collective oscillation of the conduction electrons and named surface plasmon polariton. While the linear optical processes in small metallic nanomaterials are well understood, few investigations have been carried out to understand the nonlinear optical processes involved in metallic nanomaterials [3]. In nonlinear optics, two photons of frequency are converted into one photon of frequency and arises from the quadratic susceptibility of the material. This process is consequently forbidden, under the dielectric dipole approximation in media with inversion symmetry and makes the nonlinear optical techniques, good candidates for probing interfaces and surfaces where the centrosymmetry is broken [4].

In this study, we investigated the angular resolved second harmonic emission of gold nanowires and interacting gold nanospheres. The study led to the identification of nonlocal dipole and local quadrupole emission in spherical nanomaterials depending on the size, the shape of the nanomaterial. By changing the polarization orientation in anisotropic metallic nanomaterials like nanowires or aggregates, it has been possible to select and control the mode of emission. Finally, we demonstrate the possibility to fashion the cartography of the local electric fields.

Tailoring the magnetoplasmonic response of ferromagnetic nanoparticles through symmetry breaking

Kristof Lodewijks, Irina Zubritskaya, Chalmers Univ. of Technology (Sweden); Randy K. Dumas, Johan Akerman, Univ. of Gothenburg (Sweden); Alexandre Dmitriev, Chalmers Univ. of Technology (Sweden)

The interaction between magnetic materials and plasmon resonances has been extensively studied in the field of magnetoplasmonics. It was recently shown that ferromagnetic nickel nanoparticles support localized surface plasmon resonances that can be exploited to modify the magneto-optical behavior at will [1]. As such, the magnetization behavior that is measured in spectroscopic Magneto-Optical Kerr Effect (MOKE) measurements can change both in sign and magnitude depending on the excitation wavelength and its relative position with respect to the localized surface plasmon resonance (LSPR) frequency. The large phase change between both spectral sides of the LSPR and the intrinsic phase shift that the magnetization of the ferromagnetic material induces allows tuning of the magnetic response by means of the plasmon resonance. Here we show that symmetry breaking adds one more degree of freedom by modifying both the magnetic and optical behavior of the nanoparticles. We studied the magnetization behavior of round and elliptical nickel nanoparticles in longitudinal spectral MOKE, measuring along the different symmetry axes of the system. Magnetically, the system becomes bi-anisotropic as the particles have an easy- and a hard-axis, while two pronounced plasmon resonances can co-exist in the particles along both symmetry axes. We show that depending on the incident polarization, the wavelength of excitation and the spectral position of both plasmon resonances, we can tweak the sign, amplitude and coercivity of the magnetization behavior of the nanoparticles. Future applications include magnetic memories and (bio-) chemical sensing.

Modeling plasmonic superlattice crystals *(Invited Paper)*

Michael B. Ross, Daniel Park, Martin G. Blaber, George C. Schatz, Northwestern Univ. (United States)

This talk summarizes several interrelated projects concerned with the optical properties of silver and gold nanoparticle superlattice crystals. Motivation for this work has come from recent work in Chad Mirkin's group[1] in which a large variety of superlattice crystal structures have been synthesized using DNA linkers. Optical measurements are only starting to be done, so the present work is aimed using theory to show what optical properties are possible for these structures. The calculations are mostly based on effective medium approximation calculations with Mie theory, FDTD and DDA used for the superlattice crystal. However we have also performed careful studies of the accuracy of the effective medium approximations through comparisons with generalized Mie theory and DDA calculations with explicit particles.

Our calculations for several micron size gold superlattice crystals show that these materials can show both plasmonic resonance behavior and whispering gallery mode resonances, with the former dominating at <600 nm and the latter at >700 nm, with a transition region in between. This leads to plasmon enhanced lensing optical properties at certain wavelengths and for certain volume fractions unusual backscattering properties.

For silver superlattice crystals we find a range of structures and wavelengths for which the real part of the dielectric function is negative, leading to metallic behavior even when the volume fraction is <10%. And even when the dielectric function is positive, there are unusual resonance shifts for rod-like crystal shapes such that longitudinal resonances can be blue of transverse resonances. Finally, for superlattices made from anisotropic particles, there are parameters which allow both negative permeability in addition to negative permittivity.

Hybrid optical antenna with high directivity gain

Alireza Bonakdar, Hooman Mohseni, Northwestern Univ. (United States)

Enhancing the coupling of diffraction limited propagating optical mode with the localized sub diffraction near field of electronic dipole has great impact on applications such as quantum metrology, optical quantum information, single molecule florescence spectroscopy and ultra sensitive photo detection. Optical metallic antenna as a far field to near field convertor enhances optical processes such as absorption and spontaneous emission. The main figure of merit to evaluate the role of antenna in delivery of optical energy to a quantum absorber and extracting it from a quantum emitter is the directivity gain. In spite of enhancing near field, existing metallic antennas such as Bowtie have resonant dimensions too small to collect far field power efficiently and deliver it directly toward the load which results in poor directivity gain. Unfortunately, increasing the metallic antenna size cannot be a solution due to elevation of ohmic loss. Here, we propose a hybrid antenna, which has a high directivity and very low loss, leading to a large antenna gain. In order to get benefit from optical absorption enhancement due to light confinement and avoid poor optical power collection, we combine dielectric and metallo-dielectric antennas. Dielectric antenna is designed to efficiently collect optical power from large area and illuminates the focused light toward metallo-dielectric antenna. On the other hand, metallo-dielectric antenna delivers the collected light to the detection site while enhancing the electric field by resonant cavity effect. With the same principle, we also fabricated and demonstrated a hybrid antenna on the facet of a fiber.

8809-42, Session 11

Nanostructures: from physics to bio and nanomedicine *(Keynote Presentation)*

Enzo Di Fabrizio, King Abdullah Univ. of Science and Technology (Saudi Arabia)

In the last few years, there has been a burst in the study and conceiving of new devices for the generation and manipulation of electromagnetic field at the nanoscale, where radiation-matter interaction is strongly enhanced. Several fabrication methods are now available for material preparation and nanostructuring, but only few of them can ensure the stringent design control needed for the effective and reproducible device behaviour.

We report, herein, novel processes of micro and nanofabrication techniques for several applications in different research fields, from material science to bioscience.

During the lecture it will be presented selected topics from the research activity at PSE and BESE divisions at KAUST. In particular it will be highlighted the results on single molecule detection, novel cell manipulation methods and early Cancer detection through novel methods based on miniaturization.

8809-43, Session 11

Direct measurement of bow-tie nanoantennas metal loss

Iman Hassani Nia, Omer G. Memis, Hooman Mohseni, Northwestern Univ. (United States)

The loss in optical antennas can affect their performance for their practical use in many branches of science such as biological and solar cell applications. However the big question is that how much loss is due to the joule heating in the metals. This would affect the efficiency of solar cells and is very important for single photon detection. This is also an important question for applications where high heat generation in nanoantennas is desirable, for example, payload release for cancer treatment. Recently several groups have demonstrated such temperature measurements using Raman spectroscopy and fluorescence polarization anisotropy. The latter method is more reliable with a temperature accuracy of ~0.1° C, but requires deposition of fluorescent molecules on the antenna surface. Here we present a method based on integrated micro-thermocouple and thermo-reflectance that allows temperature accuracy of about 0.02° C, as well as spatial resolution of ~500 nm. Moreover, this method does not require the addition of new materials to the nanoantenna. In this talk we present the measured heat dissipation from nanoantennas and compare them with 3D simulation results.

8809-44, Session 11

Extracting and focusing of surface plasmon polaritons inside finite asymmetric metal/insulator/metal structure at apex of optical fiber by subwavelength holes

Yasushi Oshikane, Osaka Univ. (Japan); Kensuke Murai, National Institute of Advanced Industrial Science and Technology (Japan); Motohiro Nakano, Takaya Higashi, Osaka Univ. (Japan)

We have been studied a finite asymmetric metal-insulator-metal (MIM) structure on glass plate for near-future visible light communication (VLC) system with white LED illuminations in the living space (DOI: 10.1117/12.929201). The metal layers are vacuum-evaporated thin silver (Ag) films (around 50 nm and 200 nm, respectively), and the insulator layer (around 150 nm) is composed of magnesium fluoride (MgF_2). A characteristic narrow band filtering of the MIM structure at visible region might cause a confinement of intense surface plasmon polaritions (SPPs) at specific monochromatic frequency inside a subwavelength insulator layer of the MIM structure. Central wavelength and depth of such absorption dip in flat spectral reflectance curve is controlled by changing thicknesses of both insulator and thinner metal layers. On the other hand, we have proposed a twin-hole pass-through waveguide for SPPs in thick Ag film (DOI: 10.1117/12.863587). At that time, the twin-hole converted a incoming plane light wave into a pair of channel plasmon polaritons (CPPs), and united them at rear surface of the Ag film. This research is having an eye to extract, guide, and focus the SPPs through a thicker metal layer of the MIM with FIBed subwavelength pass-through holes. The expected outcome is a creation of noble, monochromatic, and tunable fiber probe for scanning near-field optical microscopes (SNOMs) with intense white light sources. Basic experimental and FEM simulation results will be presented.

8809-45, Session 11

Nano-focusing of surface plasmons in metallic nano-structures: new developments and results *(Invited Paper)*

Dmitri K. Gramotnev, Nanophotonics Pty Ltd. (Australia)

The development of new optical technologies for probing, imaging and optical manipulation of nanoscale amounts of substances and single molecules is a major goal of modern nanophotonics. One of the ways for achieving this goal is based on nanofocusing of light, i.e., effective concentration and delivery of light energy to nanostructures into regions as small as a few nanometers. This paper will present and analyze the recent achievements in plasmon nanofocusing in metallic nanostructures. Structural optimization is also discussed, including the comparative analysis of the considered configurations and their applications. Special focus will be on the configurations with three-dimensional nanofocusing including three-dimensionally tapered structures and two-dimensionally tapered structures with diffraction-limited plasmon pre-focusing. These include tapered metal rods of different geometries, spherical dielectric tips covered in thin tapered metal film, dimples lenses formed in insulator-metal-insulator (IMI), metal-insulator-metal (MIM) and metal-insulator-insulator (MII) structures, etc. The benefits of efficient and low-loss diffraction-limited plasmon pre-focusing are combined with the subsequent plasmon nanofocusing to achieve the most efficient energy transfer to the nanoscale and minimize dissipative losses. The analysis will include the adiabatic and paraxial approximations, and will also involve rigorous numerical simulations. Applications for a new generation of nano-optical sensors, near-field imaging techniques with the resolution as good as a few nanometers, and near-field superresolution spectroscopy will also be considered.

8809-46, Session 11

Nonresonant broadband funneling of light via ultrasubwavelength channels

Ganapathi S. Subramania, Sandia National Labs. (United States); Stavroula Foteinopoulou, Univ. of Exeter (United Kingdom); Igal Brener, Sandia National Labs. (United States) and Ctr. for Integrated Nanotechnologies (United States)

Efficient control of light-matter interaction at deeply subwavelength scales is key to many photonics applications such as detectors, sensors and novel light sources. Enhancing and funneling light efficiently through nanoscale channels can dramatically improve the performance of such devices by making them compact and more efficient. Currently, this is accomplished by utilizing the extraordinary optical transmission phenomenon wherein structural surface plasmon resonances are excited in perforated nanostructured metal films. As a result the phenomenon is inherently narrowband with low transmission. Here, we introduce a new paradigm structure consisting of a double-grooved metallic nanostructure platform that can outperform extraordinary optical transmission structures while operating nonresonantly across broadband (Phys. Rev. Lett. 107, 163902(2011)). Our platform consists of a continuous periodic metallic nanostructure composed of an array of connected large (~100-200nm) and small (~ 15-20nm) rectangular slits. The key feature of our platform is that the optical power can be channeled through an area as small as ~ (lambda/500)2 associated with optical field enhancement and high transmission while operating across a broad wavelength band in the mid-infrared (~ 2- 20 um). We will discuss the nonresonant mechanism underlying this phenomenon based on a simple quasistatic picture that shows excellent agreement with our numerical simulations. We will also show experimental implementations of this platform and discuss pertinent results.

Sandia National Laboratories is a multi-program laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000.

8809-47, Session 12

Ultrafast slow light *(Invited Paper)*

Markus B. Raschke, Univ. of Colorado at Boulder (United States)

Surface plasmon polariton nanofocusing on scanning probe tips enables the spatiotemporal control of optical fields on nanometer length and femtosecond time scales. The resulting high field localization allows for background-free nanospectroscopy and the quantum coherent control of single emitter. One unique consequence of adiabtic plasmonic nanofocusing is the underlying divergence of the effective index of refraction over a broad bandwidth. This allows to overcome the limitations to narrow spectral ranges of the traditional methods for slow light generation. We measure the decrease in group velocity of broadband surface plasmon polariton propagation using femtosecond time-domain interferometry. We achieve a group velocity decrease to 0.2 c at the apex for a broadband 10 fs pulse. This for one provides direct experimental confirmation of the proposed mechanism of adiabatic nanofocusing. We furthermore demonstrate the potential how the precise control and engineering of the tapered plasmonic device geometry shall enable new broadband SPP-based slow light applications.

Laser induced electron emission from field emitter arrays with plasmonic gate electrodes

Mustonen Anna, Paul Beaud, Paul Scherrer Institut (Switzerland); Thomas Feurer, Univ. Bern (Switzerland); Soichiro Tsujino, Paul Scherrer Institut (Switzerland)

Recently laser induced electron emission from metallic nanotip arrays has been investigated for a purpose of generating high charge ultrafast electron pulses [1, 2]. In particular, short electron bunches with up to 30 million electrons were successfully generated by near-infrared laser pulses with 50 fs pulse duration, showing feasibility of high bunch charge generation by laser induced field emission for application in accelerators such as, for example, SwissFEL free electron laser facility. The experiments also showed the importance of the laser incident angle and polarization for efficient electron generation. The laser induced charge was more efficiently generated when the laser electric field was enhanced at tip apex, the effect known as formation of "hot spot" at the sharp end of a metallic wedge. Therefore, we propose to further optimize light coupling to field emitter nanotips by integrating gate electrodes that support excitation of surface plasmon polaritons at wavelengths of interest [3]. The study indicates that the submicron arrays with the plasmonic gate electrodes can increase electron yield by 30 times and simplify experimental setup by allowing efficient excitation at normal incidence. By using an advantage of SPP generated on gate surface, optical excitation of the emitter tips is also possible for double gate field emitter arrays, where the second gate is used for electron beam collimation.

Ultrafast field-driven photoemission spectroscopy and control at metallic nanotips

Georg Herink, Lara Wimmer, Daniel R. Solli, Max Gulde, Sergey V. Yalunin, Katharina Echternkamp, Claus Ropers, Univ. Göttingen (Germany)

In this contribution, we present experimental and theoretical results on strong-field photoemission from single metallic nanotips excited by ultrashort laser pulses over a broad spectral range spanning from the visible to the far-infrared. Employing the quadratic wavelength-scaling of the ponderomotive energy, we reach deeply into the strong-field regime with electron acceleration up to several hundreds of electron volts without inducing structural damage. We find electron dynamics that emerge from the combination of optical field enhancement and nanolocalization. Specifically, for long wavelengths, an acceleration regime is identified where electrons escape the confined field within a fraction of the optical half-cycle, resulting in a field-driven acceleration and wavelength independent electron dynamics. This condition is achieved when the electron quiver amplitude exceeds the spatial decay length of the optical near-field – effectively causing a quenching of oscillatory electron motion. In this acceleration regime and for strong-fields, the photoemission yield and final kinetic energies are strongly dependent on the momentary electric field, which enables ultrafast switching of the photocurrent. In further experiments, we employ multicolor fields for efficient ultrafast photoemission gating and spectral streaking spectroscopy. Numerical simulations reveal the underlying photoemission dynamics and highlight the role of the nanostructure geometry and external parameters.

8809-50, Session 12

Carrier-envelope phase effects on strong-field emitted electrons from gold nanotips

(Invited Paper)

Christoph Lienau, Petra Gross, Bjoern Piglosiewicz, Doo-Jae Park, Slawa Schmidt, Jan Vogelsang, Carl von Ossietzky Univ. Oldenburg (Germany)

We report on the first experimental observation of pronounced carrier-envelope phase (CEP) effects on strong-field photoemission of electrons from nanometric gold tips. We believe that this is an important step towards the steering and control of the motion of electrons around metallic nanoparticles on nanometer length and attosecond time scales.

Sharp metallic nanotips irradiated with few-cycle laser pulses are sources of highly confined electron wavepackets of short temporal duration and high spatial directivity [1]. This is the case especially in the strong-field regime, where electron emission by tunneling becomes dominant over multi-photon and above-threshold ionization. For sufficiently long laser wavelengths and short pulses, electrons are accelerated to escape the near field within one half-cycle of the laser oscillation. In this case, the motion of the field-emitted electrons should be sensitive to the phase of the driving light field. We have experimentally studied the CEP effect by illuminating sharp gold tips with near-infrared light generated by a CEP-stable noncollinear optical parametric oscillator and recording the kinetic energy spectra of the emitted electrons.

Enhanced light-matter interaction and spatial coherence in complex plasmonic systems

(Invited Paper)

Rémi Carminati, Ecole Supérieure de Physique et de Chimie Industrielles (France)

Disordered gold films exhibit original optical responses in the near infrared [1,2]. We explore the near-field plasmonic response of disordered gold films, coupling experiments [3] and theory [4]. We demonstrate the ability of these films to produce substantial changes in the spontaneous emission dynamics of nanosources of light [3]. We address basic issues, as the spatial confinement of plasmon modes close to the percolation threshold [3], the coexistence of radiative and nonradiative (dark) modes [5], and spatial coherence [6]. These films combine ease of fabrication and substantial enhancement of light-matter interaction, and are interesting platforms for fundamental and applied studies in nanophotonics.

Near-field mediated plexcitonic coupling and giant rabi splitting in individual metallic dimers

Andrea E. Schlather, Nicolas Large, Alexander S. Urban, Peter Nordlander, Naomi J. Halas, Rice Univ. (United States)

In nanostructured materials, energetically-matched plasmons and excitons can undergo strong dipole-dipole interactions that greatly alter their optical properties. We report the formation of hybrid metallic dimer-J-aggregate nanostructures that exhibit coherent coupling between the localized surface plasmons (LSP) of the metallic dimer and excitons from molecular J-aggregates. By varying the diameters of the nanodisks, we can systematically tune the dimer plasmon energy across the exciton transition energy of the J-aggregate. Hyperspectral dark field spectroscopy allows us to directly measure the plexcitonic interactions in individual hybrid nanostructures. Plexcitonic coupling in these nanostructures manifests as Rabi splitting, which has been observed both experimentally and through rigorous theoretical calculations. In the strong coupling regime, the resonant scattering peak from the dipolar dimer plasmon splits into two Lorenzian peaks of different energies, which are separated by a dip at the J-aggregate exciton energy. When the plexcitonic peak energies are plotted on a dispersion curve, the Rabi splitting energy can be extracted. In this study, we show that Rabi splitting energies as high as 400 meV have been experimentally obtained for a single hybrid plexcitonic dimer. We report the highest values for plexcitonic coupling in a single nanostructure to date. In addition, the nature of the plexcitonic coupling and its dependence upon dimer geometry (i.e. disk diameter, gap distance) and field enhancement gradients inside the dimer gap have been thoroughly investigated through polarization-dependent measurements.

8809-53, Session 13

Geometric dependence of the line width of localized surface plasmon resonances

Ke Zhao, Peter Nordlander, Rice Univ. (United States)

We study the geometric dependence of damping of nanoparticles [1]. We find that for a fixed number of electrons and plasmon frequency, spherical nanoshells possesses a broader line width than ellipsoidal nanorods for excitation along the long axis. By incorporating retardation effects into a harmonic oscillator model for the plasmon resonance, we show that the geometries of nanoparticles strongly affect their plasmon linewidths through dynamic depolarization. The effect can be interpreted as a renormalization of the mass of the electrons, and subsequently, the total energy of the oscillating electron liquid. The scattering spectrum derived from our model agrees very well with the FDTD simulation, which supports our model. Since plasmon damping determines many important features and applications of LSPR, such as the Q-factor of the plasmonics devices, our study can be an important guidance for the design of nanoplasmonic systems.

8809-54, Session 13

Theoretical sensitivity limit of the localized surface plasmon resonance (LSPR) to the dielectric environment

Alexei Deinega, Univ. of Toronto (Canada); Maria Bogdanova, Kintech Lab. (Russian Federation); Yurii E. Lozovik, Institute of Spectroscopy (Russian Federation); Sergiy Zalyubovskiy, Radislav A. Potyrailo, GE Global Research (United States)

We discuss maximal sensitivity limit achievable by localized surface plasmon resonance (LSPR) supported by metal nanoparticles.

We start with perturbation theory and show how derived results can be simplified under additional assumptions. These assumptions include case of negligible metal dispersion in the vicinity of resonance, case of lossless metal, and quasistatic limit. At the last case sensitivity is directly proportional to wavelength and depends on the fraction of the electromagnetic energy confined within the sensing volume (fill factor) which is less then unity. Therefore one should not expect to find optimized nanoparticle geometry with dramatic increase in sensitivity at a given wavelength. The particle shape should be chosen to have LSPR wavelength as far to the infrared, and fill factor should be optimized via the geometry of the particle.

We show that sensitivity of the LSPR is competitive with traditional surface plasmon resonance (SPR) for thin (less than 10nm) analyte layers. At the same time LSPR performs better in terms of signal to noise ratio.

All theoretical results are supported by finite-difference time-domain (FDTD) calculations for gold nanoparticles of different geometries (rings, split rings, paired rings and sandwiches). We calculate sensitivity by a shift of the peak in scattering spectra and estimate it by perturbation theory as well. We obtain good agreement between results obtained using both ways.

8809-55, Session 14

Probing plasmon resonances and local optical fields of silver nanoaggregates by electron energy-loss and one- and two-photon excited surface-enhanced Raman spectroscopy *(Invited Paper)*

Katrin Kneipp, Shima Kadkhodazadeh, Jakob B. Wagner, Harald Kneipp, Technical Univ. of Denmark (Denmark)

Enhanced local fields of plasmonic nanostructures are currently revolutionizing optical technologies. Comprehensive characterization of local fields is of key importance in further development of plasmon supported methods and devices.

Exciting capabilities for probing plasmonic structures and their local fields at high spatial resolution more than two orders of magnitude better than in diffraction limited optical experiments are opened up by using electron beams [1]. Complementary, high energy resolution in probing of local fields in hot spots can be achieved by optical methods using one and two-photon excitation along with tunable excitation lasers.

Our studies reveal the relation between local optical fields and electron energy-loss and show that in the near infrared range, which support SERS at high enhancement level, areas of highest local optical fields correlate with those of lowest electron energy-loss.

One- and two-photon excited SERS experiments at the single molecule level using tunable excitation wavelengths provide information about local fields in hot spots and their dependence on photon energy. Our studies verify experimentally the predicted increase of local optical fields in the hot spots with increasing wave lengths.

The reported experiments enable experimental validation of numerous computations of optical fields performed for plasmonic nanostructure. Also for complex nanostructures, which are not easily approachable by computation, they allow to characterize local optical fields and to identify optimum excitation wavelengths for plasmonic supported spectroscopy.

8809-56, Session 14

SERS measurement study on the interface of nanostructured plasmonic Ag gratings and thin C60 layer

Akram Amooali Khosroabadi, College of Optical Sciences, The Univ. of Arizona (United States); Dallas L. Matz, The Univ. of Arizona (United States); Palash Gangopadhyay, College of Optical Sciences, The Univ. of Arizona (United States); Jeanne E. Pemberton, The Univ. of Arizona (United States); Robert A. Norwood, College of Optical Sciences, The Univ. of Arizona (United States)

Nanostructured electrodes and interfaces can enhance light absorption in organic solar cells due to efficient light harvesting. Ultrathin films of an active layer (P3HT:PCBM) deposited on nanostructured grating electrodes show more absorption as a result of increased light trapping inside the structure. Plasmonic nanostructured electrodes with various geometries and dimensions have been fabricated on printed Polyacrylonitrile (PAN) pillars and characterized. Preliminary surface enhanced Raman scattering (SERS) measurements show significant signal enhancement (over two orders of magnitude) on nanostructured samples when compared to planar Ag substrates due to local electromagnetic field enhancement. Also conversion of PAN to graphitic carbon is evidenced in SERS spectra. The surface area was determined using underpotential deposition (UPD) of thallium and agrees with results calculated using SEM images. The FDTD simulated electric field distribution inside the samples confirms the experimental results. The magnitude of the electric field increases up to 60 times, showing SERS signal enhancement of three to four orders of magnitude depending on the dimensions of the pillars and gratings. Study of the interaction between a top organic layer (C60) and the Ag electrode will help us to understand the nanoscale charge transfer rate that is critical to optimizing organic solar cell performance.

8809-57, Session 14

Cascaded plasmon resonances multi-material nanoparticle trimers for extreme field enhancement

Seyfollah Toroghi, Chatdanai Lumdee, Pieter G. Kik, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

Cascaded optical field enhancement in coupled nanostructures has attracted significant attention due to field enhancement factors that dramatically exceed those observed in isolated nanostructures. This additional field enhancement is expected to enable improved performance in plasmon related applications such as surface enhanced Raman spectroscopy, photoluminescence and nonlinear refraction and absorption. It has previously been shown that cascaded field enhancement exists in coupled nanospheres with identical composition; however this effect has not yet been studied in systems containing multiple materials. In this study, we numerically investigate the polarization-dependent optical response of multi-material trimer nanostructures composed of Au nanoparticles surrounded by two Ag nanoparticles. The silver dimer creates the strong optical near field required to drive gold nanoparticle in the cascaded field enhancement scheme. Results reveal different cascading regimes depending on particle size difference. For small size differences, clear mode splitting is observed, and relatively small field enhancement values are obtained. In the limit of large size difference between the Ag and Au nanoparticles, multiplicative cascaded field enhancement is demonstrated to occur, leading to a field enhancement factor of 20, 10 times larger than that observed in isolated Au nanoparticles. The presented structure appears compatible with chemical synthesis and assembly methods, suggesting that cascaded multi-material trimers could form the basis of biochemical sensors that require large electric field enhancement.

Core-satellite plasmonic nanostructures for SERS-based molecular sensing

Yuanhui Zheng, Melbourne Ctr. for Nanofabrication (Australia); Udo Bach, Monash Univ. (Australia) and Commonwealth Scientific and Industrial Research Organisation (Australia) and Melbourne Ctr. for Nanofabrication (Australia)

Research in the field of plasmonic sensing represents a hot topic nowadays due to rising demands of single molecule detection. Recently there has been a tremendous interest in surface enhanced Raman scattering (SERS) based molecular sensing using plasmonic nanostructures. An ideal SERS substrate should be extremely sensitive, highly reproducible and cheap. This requires that the plasmonic nanostructure can induce a high SERS enhancement, generate a reproducible SERS signals and can be fabricated at low cost. Many SERS-active nanostructures have been widely studied. However, these structures usually suffer from low signal enhancement, poor reproducibility or high fabrication lost. In our work, we report a low-cost, highly sensitive and reproducible near-infrared SERS sensor based on self-assembled core-satellite nanostructures. The core-satellite nanostructures were fabricated through a novel hierarchical self-assembly strategy that involves electrostatic and DNA-directed self-assembly processes. These nanostructures show strong and highly reproducible SERS activity superior to that of a commercial Klarite® SERS substrate and an ability of detecting target analytes, e.g. benzenethiol, at concentrations down to 1 nM.

8809-59, Session 14

Self-assembled fabrication of SERS-active substrates made of plasmonic nanoparticles

Nicholas Sharac, Salvatore Campione, Sarah M. Adams, Himanshu Sharma, Michelle Khine, Filippo Capolino, Regina Ragan, Univ. of California, Irvine (United States)

Coupled noble metal nanoparticles with nanometer scale inter-particle spacing induce strong local electromagnetic field enhancements at the plasmon resonance that find promising applications in bio-sensing devices, particularly surface enhanced Raman spectroscopy (SERS). Bottom-up lithographic fabrication methods have increasingly been explored for their ease of use and low costs. We have developed two unique self-assembly methods to achieve substrates with potential for SERS. We have fabricated nanocluster assemblies of 10 nm and 20 nm gold nanoparticles with spacing as close as 1 nm. Chemically modified gold nanoparticles are attached to a PS-b-PMMA thin film surface, showing preferential attachment to the modified PMMA domains. Electrophoretic deposition drives the assembly of nanoparticles, and ensures close spacing. We have also patterned periodic arrays of gold nanotriangles with initial tip-to-tip spacing below 100 nm. The triangles are made using nanosphere lithography and gold vapor deposition on a polyolefin thermoplastic. The substrate shrinks when heated, reducing inter-particle spacing down to 20 nm. Shrinking reduces tip-to-tip spacing, and has shown to tune the plasmon resonance of the arrays and should lead to higher SERS enhancements. Numerical simulations of localization of fields and plasmonic resonance locations of the two fabricated structures are performed alongside SERS measurements. For example, we have shown in the nanosphere clusters that the maximum SERS enhancement, computed as the fourth power of the local electric field enhancement between spheres, is dramatically affected by the inter-particle distance, reaching in principle values as large as 10^10 for 1 nm gaps.

8809-60, Session 14

TEM study of nanofinger structures for surface enhanced Raman scattering

Kate J. Norris, Univ. of California, Santa Cruz (United States) and NECTAR (United States); Steven J. Barcelo, Alexander M. Bratkovsky, Hewlett-Packard Labs. (United States); Junce Zhang, David M. Fryauf, Univ. of California, Santa Cruz (United States) and NECTAR (United States); Gary A. Gibson, Zhang-Lin Zhou, Shih-Yuan Wang, Zhiyong Li, Hewlett-Packard Labs. (United States); Nobuhiko P. Kobayashi, Univ. of California, Santa Cruz (United States) and NECTAR (United States)

Numerous applications of Surface Enhanced Raman Scattering (SERS) to chemical sensing exist, from food safety and water quality to anti-counterfeiting. It is well known that trapping a molecule in a plasmonic 'hotspot' with enhanced local field on a SERS-active substrate can very strongly enhance its Raman signal. However the structural characterization of the hotspots at nanometer scale that contributes to the significant signal enhancement is still illusive. We will discuss a Transmission Electron Microscopy (TEM) investigation of this novel high performance SERS-active substrates. These substrates consist of gold caps on deformable polymer nanopillars. The nanopillars are formed through nanoimprint lithography in large area pentamer patterns that proved to be the most efficient in our Raman studies. The gold caps are deposited on the nanopillars via e-beam evaporation. Capillary forces pull these structures together when placed in trans-1,2-bis(4-pyridyl)-ethylene (BPE) solution in ethanol, trapping the BPE molecules between the gold caps. Raman spectroscopy shows significant signal enhancement for the trapped molecules. This substrate design has yielded >1010 enhancement for the molecules trapped in the gaps. Both plan view and cross-sectional TEM were used to study the impact of the spacing between gold particles. We will discuss the results in this paper and provide the insights towards structural optimization.

Using TCO nanstructures as the building blocks of nanophotonics in infrared

Shiqiang Li, Robert P. Chang, Northwestern Univ. (United States); Leonidas E Ocola, Center for Nanoscale Materials, Argonne National Laboratory (United States)

Near to mid infrared region is an important spectral region of great scientific and technological interest.. Plasmonics and nanophotonics applications to this regime is relatively recent and mainly focused on the traditional materials like silver and gold, however,there are some intrinsic limitations for them to be applied to infrared spectral region. As alternatives, degenerated semiconductors show superior performance. In this report, we demonstrate how to design and fabricate transparent conducting oxide single crystalline nanorod arrays for plasmonics and nanophotonics. By using an integrated top-down and bottom-up approach, we show that these nanorods can be grown at defined positions and with uniform height and diameter. The electric properties are superior owing to high crystallinity. It also offers unique properties such as tunability of carrier concentration and can be modeled easily by simple free carrier formulation. We pick a few examples to show that how we can design an lattice to observe various useful optical phenomena as the counterparts to those of silver and gold in the visible.

Self-growing of plasmonic optofluidic waveguides

Hui Liu, Yajian Zheng, Shining Zhu, Nanjing Univ. (China)

Numerous liquid channel networks naturally occur in biological systems, such as vessel networks in animals and pipeline networks in plants. These connected channel networks exchange substances, energy, and information between tissues and organs and are important factors in sustaining life. On the other hand, optofluidic chips have attracted considerable attention in different fields. By combining liquid and light, optofluidic chips possess numerous potential applications. The substantial number of fluidic topology networks in biological systems provides a basis for the construction of a bio-inspired optofluidic topology network to realize novel, complex, and advanced applications. In this work, we report a new self-assembly method for the establishment of a plasmonic optofluidic network. Through this process, various topology structural networks that mimic biological liquid channel systems are obtained. Light propagation in the network is directly observed, and a complicated optical circuit can be realized in this network. Based on this technique, other interesting biological functions can be simulated in self-assembled optofluidic networks. Thus, these self-growing plasmonic optofluidic networks exhibit great potential for bionics and bioengineering applications.

Effect of metal arrangement on localized surface plasmon polaritons in bimetallic nanoparticles

Anton Kuzma, International Laser Ctr. (Slovakia) and Slovenska Technicka Univ. (Slovakia); Martin Weis, Slovenska Technicka Univ. (Slovakia); Jozef Chovan, International Laser Ctr. (Slovakia); František Uherek, International Laser Ctr. (Slovakia) and Slovenska Technicka Univ. (Slovakia)

Bimetallic plasmonic nanoparticles recently attracted attention due to promising applications in photonics, sensors, or biophysics. Among others heterogeneous arrangements the core-shell nanoparticles have been envisioned as most suitable for applications. Hence, the technique for determination of the nanoparticle structure must be precise and sensitive enough. There exist methods for composition estimation of nanoparticle colloids, but optical methods are most popular ones as fast and low-cost techniques. Various experimental methods have been suggested for fabrication of bimetallic colloid systems, such as chemical synthesis or laser ablation. In this contribution we evaluate the optical properties of Au-Ag nanoparticle colloid system prepared by laser ablation in water. Observed shift of the plasmonic wavelengths has been interpreted as presence of core-shell nanoparticle structure. The detail analysis of plasmonic properties for several metal arrangements has been done using the finite-difference time-domain (FDTD) method. The nanoparticles have been modeled as (i) core-shell nanospheres, (ii) bimetallic particles consisting of two parts (Au and Ag), or (iii) colloid consisting of pure Au and Ag nanoparticles. Results of numerical simulations show that all three investigated nanoparticle metal arrangement systems exhibit shift of the plasmonic wavelength with increase of the Ag/Au volume ratio in a similar way as recorded in the experiment. It points out that it is not possible to distinguish the metal arrangements in nanoparticles by the optical methods only and the conclusions from optical properties can be misleading. Thus optical methods can certainly prove only that bimetallic nanoparticles consist of alloy or phase separated metals.

Observation of switching between SA and RSA in silver/gold-polyaniline nanocomposite films

Anand P. Balan, Jayalekshmi Sankaran, Cochin Univ. of Science & Technology (India)

In the present work, attempts have been made to embed Silver (Ag) / Gold (Au) - nanoparticles into polyaniline (PANI) matrix using an easy wet chemical route. It is expected that the resulting nanocomposite will show the interesting third order nonlinear optical characteristics of Ag/Au-nanoparicles modified by the advantageous properties of the conducting polymer PANI. Structural characterisation of Ag/Au-PANI nanocomposite samples was done using X-ray diffraction and Raman studies. UV-visible absorption spectra show the presence of surface plasmon resonance (SPR) peaks centred at 410 nm and 520 nm for Ag-PANI and Au-PANI nanocomposite films respectively, which is a signature of nano dimensionality of the composite samples. Third order nonlinear behaviour of the nanocomposite films was analysed using Z Scan technique employing the second harmonic output (532 nm) of a Q-switched Nd:YAG laser (Minilite, Continuum). It is seen that Ag/Au-PANI nanocomposite film samples show simultaneous presence of saturable absorption (SA) and reversible saturable absorptions (RSA) behaviour at 50/75/100 µJ laser excitations. This switching between SA and RSA has been reported in many metal nanocomposite systems. However similar behavior in nanocomposite film samples has not been pursued much. The highlight of the present work is the observation of the switching between SA and RSA in Ag/Au polyaniline nanocomposite films. The switching behavior can be ascribed to the interplay between ground state plasmon band bleaching and excited state absorption. Two photon assisted absorption has been identified as the prime factor contributing towards the observed RSA in these nanocomposite films.

Retrieval of the electrodynamic polarizability tensor for the design of magneto-electric optical nano-antennas

Felipe Bernal Arango, A. Femius Koenderink, FOM Institute for Atomic and Molecular Physics (Netherlands)

Smart designs of novel magnetoelectric metamaterials can only be achieved by a thorough understanding of the response of its building blocks. The response of a single plasmonic or magnetoelectric antenna like e.g. the archetypical splitring resonator can be understood in the framework of magnetoelectric point scattering theory. Here, the characteristic quantity of the scatterer is its polarizability tensor. In this talk we present a scheme based on the surface integral equation method (SIE) (Kern & Martin J. Opt. Soc. Am. A 26, 732 (2009)), to retrieve the electrodynamic polarizability tensor of nanostructures, ranging from dielectric and magneto electric scatterers to plasmonic nanoantennas. We compare two retrieval procedures, firstly a vector spherical harmonic projection (VSH) of the scattered field, used in our recent paper “Ubiquity of Optical Activity in Planar Metamaterial Scatterers” (PRL (108), 22, 2012), and secondly a method based on the integration of the electric and magnetic effective currents obtained from SIE which allows for this retrieval to work close to interfaces and other structures. We show that the VSH is valid always while the effective current method only works for small scatterers. We demonstrate the power of this method by showing the very first ab-initio design of an optical magneto electric antenna based on a splitring antenna array that is capable of converting the emission of a single emitter in directional emission with either right or left handed elliptically polarized light. This antenna may find applicability in spin angular momentum encoding of quantum information.

Plasmonic interaction in 3D multiparticle structures

Dong-Wook Kim, Ahrum Sohn, Ewha Womans Univ. (Korea, Republic of); Dukhyun Choi, Kyung Hee Univ. (Korea, Republic of)

There have been growing research interest in 3D plasmonic nanostructures, which has additional degrees of freedom to tailor the optical properties. The optical spectra can be modulated by changing

the inter-particle separation and the arrangement symmetry in two independent directions/planes. Thus, multiple plasmonic coupling in the nanostructures gives rise to new hybridized plasmon mode formation. Fabrication of 3D nanostructure fabrication usually requires low-throughput and high-cost top-down processes. In this study, we propose bottom-up fabrication procedures for a 3D multiparticle plasmonic system, using an anodic aluminum oxide template. The process can provide large-area samples at an affordable cost.

The 3D plasmonic multiparticle system consists of hexagonal array of 30-nm-sized Au nanoparticles with a 60-nm-sized Au particle underneath the center of each array. The optical reflectance spectra exhibit peculiar dips in visible range, which is well reproduced by finite-difference time-domain (FDTD) simulations (Lumerical FDTD Solutions). The calculated field distribution clearly reveals the plasmonic interaction between the constituent nanoparticles and resulting hybridization of the localized modes. The simulations also suggest that the key factors to determine the unique optical features. In the experiments, the interaction between the large- and small-sized nanoparticles can be controlled by varying the template thickness. Such plasmonic coupling significantly influences the resonant mode energy and spatial distribution of the electromagnetic field.

Strategies for self-organization of Au nanoparticles assisted by copolymer templates

Thomas Maurer, Alexandre Plaud, Aurélien Sarrazin, Jérémie Béal, Julien Proust, Univ. de Technologie Troyes (France); Samuel Lamarre, Univ. Laval (Canada); Pierre-Michel Adam, Jérôme Plain, Univ. de Technologie Troyes (France); Anna-Marie R. Ritcey, Univ. Laval (Canada); Rana Nicolas, Univ. de Technologie Troyes (France) and Lebanese Univ. (Lebanon) and American Univ. of Beirut (Lebanon); Michel Kazan, American Univ. of Beirut (Lebanon); Ziad Herro, Lebanese Univ. (Lebanon)

For the past fifteen years, the investigations of the Localized Surface Plasmon Resonance (LSPR) for plasmonic nanoparticles (NPs) has opened new perspectives for optical nanosensors. The application possibilities are all the more numerous as the fundamental studies go to the direction of single molecule sensing. What is at stake today is the development of such large scale and low cost devices.

The scientific aim is here to propose and review different strategies for organizing gold nanoparticles via the use of Polystyrene-Polymethylmethacrylate (PS-PMMA) copolymer templates. We developed both top-down and fully bottom-up processes:

1) etching of copolymer templates and use of the induced holes as nucleation sites after gold film annealing.

2) Incorporation of functionalized Au NPs in copolymer solution and organization in PS domains either by thermal annealing or Langmuir-Blodgett method

3) Incorporation of Au salts in PS-PMMA copolymer solution and in-situ synthesis and organization of Au NPs in PS domains.

These processes are original routes to organize Au NPs onto substrates. Surprisingly, the extinction optical measurements showed an expected main LSPR peak at about 550nm (for 10nm Au NPs) but also a second or even a third peak at longer wavelengths (respectively ~700nm and ~800nm). Discrete Dipole Approximation (DDA) simulations confirmed the experimental results and tend to argue that the 2nd and/or 3rd peak would come from coupling between very close Au NPs. Possible applications will be discussed.

This presentation opens new routes for large-scale fabrication and organization of Au NPs onto substrates. It could pave the way for developing new kind of sensors.

Tunable sensitivity and wide dynamic range phase detection of multichannel grating-coupled SPR sensor

Wen-Kai Kuo, Chi-Xian Chen, Peng-Zhi Lin, National Formosa Univ. (Taiwan)

We report a multichannel grating-coupled surface plamson resonance (GCSPR) sensor by utilizing a proposed phase-shift interferometer (PSI) for tuning sensitivity and wide dynamic phase detection. The grating structure of the sensor device was fabricated by nano-imprinting technique and a thin meal film was thermally evaporated onto the grating surface. In our system, a cylindrical lens with focal length of 60 mm to form a V-shaped convergent beam with incident angles ranging from 12 degree to 16 degree. Two liquid-crystal modulators (LCM) able to produce over one wavelength retardation were used to produce five-step phase shift in the PSI system. A low-cost web-camera with 130 Mega pixels was used to capture these phase shift images of the multichannel GCSPR sensor and then the five-step phase-shift reconstruction algorithm can obtain spatial phase-shift information. The phase detection sensitivity can be tuned by rotating a polarizer in front of the web-camera. Experimental result shows that detection range larger than 0.01 RIU and detection sensitivity tuning approximately from 10E-5 to 10E-7 RIU can be obtained in our system. In conclusion, this tunable sensitivity and wide range phase detection functions can provide a more flexible SPR sensor detection method. Moreover, the grating coupled and multichannel scheme can provide low-cost and high throughput detection.

Surface plasmon amplification in finite-width gold stripline based on Nd:YVO4 gain crystal

Thanh Phong Vo, Alireza Maleki, Judith M. Dawes, Macquarie Univ. (Australia)

We have succeeded to amplify the surface plasmon polaritons (SPP) signal on finite-width gold stripline using Nd:YVO4 crystal (1.1% doping) as gain medium. The setup is built to allow a precise control of probing spot (λ=1064nm) on 3µm-width gold striplines using high magnification and ultra-long working distance objective (50X/0.55 NA) with CCD camera. The stripline is made by focused ion beam technique from 30nm-thick gold film which being coated on 1mm-thick Nd:YVO4 crystal using ion assisted deposition technique. The p-polarized laser at wavelength 808nm (0.2W/cm2) is employed to pump crystal gain. TM-polarized probing laser couples to SPP modes by adjusting the incident angle through prism and reflected light is directed to photodetectors.

The reflectivity versus incident angle R(θ) is measured in two cases: on planar gold film and on 3um-width gold stripline. The minimum value of R indicates the resonant angle where the incident energy is transferred to SPP (21.6 degree in film and 24.1 degree in stripline). By dividing the value of normalized reflectivity at resonant angles with and without pumping laser, the relative enhancement signal is about 55% on film and 12.5% on stripline. However the most important result is the narrowed width W of reflectivity curves with and without pumping laser obviously indicating the SPP amplification since W is linked to losses and inversely proportional to the SPP propagation length. The value of gain can be estimated by fitting Fresnel reflection equation with experimental data R(θ), this finally yields the imaginary value of gain medium ≈ -0.015, corresponding to compensation of 44% of internal SPP losses.

Localized surface plasmon resonance sensor based photonic crystal fibers with nano-composite material

Congjing Hao, Ying Lu, Liangcheng Duan, Baoqun Wu, Jianquan Yao, Tianjin Univ. (China)

Localized surface plasmon resonance-based optical chemical sensors and biosensors are the appropriate, cheap, simplified and rapid alternative to more sophisticated detection techniques. In this paper, we propose a localized surface plasmon resonance refractive index sensor based on photonic crystal fiber filled with nano-composit materials (metal-dielectric-metal) and liquid analyte. In such sensor, by introducing the model stack of inner-silver (18nm) fused silica (220nm) silver (18nm) to the air holes of the photonic crystal fiber cladding, the interactions between the liquid analyte and the nanomaterials can change the evanescent field distribution in the air holes of optical crystal fiber cladding to generate the localized surface plasmon resonance phenomenon, and measuring the change of absorption spectrum or transmission spectrum can obtain the change of refractive index of the analyte. We have got the optical field distribution of the fundamental mode, dispersion relations of plasmonic mode and core guided mode, and the relationship between wavelength and attenuation constant of the fundamental mode by by finite element method, respectively. Meanwhile, we find that more than one resonance peaks in a larger wavelength range can be achieved, which make the proposed sensor possible to precisely tune the resonance wavelength to generate multiple peak shifts. This is useful in the application of multiple wavelength sensors.

Low-threshold photoinduced transformations and enhanced absorption and fluorescence of hybrid materials comprising silver nanoparticles and polymethine dyes

Tigran A. Vartanyan, Nikita A. Toropov, Anton A. Starovoytov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

Granular metal films were obtained via thermal evaporation of silver on transparent supports in a vacuum chamber at 10^{-7} mbar. Subsequent annealing for different times leads to formation of films with pronounced plasmon bands tunable over the visible. Several polymethine dyes were dissolved in alcohol and spin-coated over the supported granular silver films as well as on the bare quartz and sapphire substrates for comparison. The samples were characterized by optical spectroscopy and scanning electron microscopy.

To avoid uncontrollable damage of silver granular films in the course of the spin-coating process the samples were soaked in pure alcohol overnight. The silver granular films obtained in this way were stable enough to sustain multiple cycles of dye coating and subsequent washing in a solvent without noticeable changes of their properties checked by optical spectroscopy.

Transformations of polymethine dye molecules were studied under the action of cw and pulsed laser irradiation. The threshold of laser induced transformations of dye molecules in hybrid films was found to be much lower than that for the bear dielectric substrate. Optical density increases by 0.005 under the action of Nd:YAG laser second harmonic pulses at the fluence of 7 mJ cm^{-2}. Most interesting, in the case of a hybrid film, laser induced transformations lead to the increased absorption in the J-aggregate band while the dye layers on a bare substrate experience, albeit three times smaller, decrease of absorption. Besides photoinduced transformations, a complex interaction between plasmon and dye absorption and fluorescence bands were observed and interpreted.

Angular and polarization properties of cross-holes nanostructured metallic filters

Romain Girard-Desprolet, STMicroelectronics (France) and CEA-LETI (France); Salim Boutami, CEA-LETI (France); Sandrine Lhostis, STMicroelectronics (France); Guy Vitrant, IMEP-LAHC (France)

Nanostructured metallic filters have been widely investigated since Ebbesen highlighted the role of plasmons resonances in extraordinary optical transmission for sub-wavelength structures [1]. This gave rise to a growing interest in pattern metallic layers for filtering, polarizing and display applications. Different types of structures have been studied, such as Metal-Insulator-Metal arrays, metallic patches arrays and holes arrays in a metallic layer, where the filtered wavelength is governed by the nanostructures characteristic dimensions. Regarding holes arrays, various basic shapes have been tested, especially squares, circles, triangles.

Most of the hole designs show a particular sensitivity to polarization and to azimuth angle when the incidence angle is increased. Their spectral response is thus severely dependent of impinging light properties, causing color shifts and losses of transmission. For image sensors, such errors would lead to drastic disparities in pixels sensitivity over a matrix and to distortion in color rendering.

In literature we find some examples of cross-shaped holes with low influence of polarization at normal incidence [2]. In this work we address a complete review on cross-shaped holes designs and materials composition and we identify specific ranges of cross dimensions, shape factors and period array to get conditions of spectral response stability in terms of polarization and azimuth angle, which has never been shown so far. We have determined particular structures that would allow the realization of image sensors and displays with extremely low color errors whatever the orientation and the polarization of the incident light.

Modelling of ellipsoidal nanowires: control and application

Elliott Claven, Queensland Univ. of Technology (Australia)

Akimov et al explains that the distance a plasmon can travel is further if it is supported by a thicker circular nanowire, while thinner nanowires are expected to be able to increase QD coupling. Ellipsoidal nanowires may be a good compromise due to their ability to have both thin and thick dimensions. Furthermore it has been shown that the plasmon resonances along the main axis of an ellipsoidal particle is governed by the relative aspect ratio of the ellipsoid.

Using COMSOL Multiphysics we found the fundamental plasmon mode supported by an ellipsoidal nanowire and then studied this mode for various geometrical parameters, materials and illumination wavelengths. Accordingly it was found that ellipsoidal nanowires exhibit a minimum for the wavenumber and a maximum for the propagation distance at roughly the same dimensions. Highlighting that there is an aspect ratio for which there is poor coupling but low loss.

We plan to fabricate ellipsoidal nanowires using lithography. This will be done by first cleaning an ITO-glass slide and covering this slide with polymethyl methacrylate (PMMA) using a spin-coater. The next step will be to mill ellipses into the PMMA by use of a Focused Ion Beam (FIB), followed by a covering of gold/silver using a thermal evaporator and then using a lift-off process to remove the PMMA for testing of the nanowires. We hope that the results of our investigations will lead to new active and passive plasmonic devices.

Resonant enhancement of Spin Hall effect mediated by scattering from plasmonic nanostructures: a polarimetric investigation

Shampy Mansha, Amit Kumar, Jalpa Soni, Indian Institute of Science Education and Research Kolkata (India); Subhasis D. Gupta, Univ. of Hyderabad (India); Ayan Banerjee, Nirmalya Ghosh, Indian Institute of Science Education and Research Kolkata (India)

A novel approach based on conventional polarimetry formalisms like Jones and Stokes-Mueller algebra combined with the scattering theory has been developed to analyze / interpret the spin orbit interaction (SOI) of light mediated by scattering from plasmon resonant metal nanostructures. The individual SOI effects have been analyzed / quantified via scattering Mueller matrix derived polarimetry parameters, namely, diattenuation d and retardance δ parameters. These results show that each of the SOI effects can be tuned, enhanced / optimized in plasmonic nanostructures via the diattenuation and retardance parameters achieved by choosing suitable system parameters (wavelength, size and shape of nanoparticles). We also demonstrate that the interference of two neighboring modes in plasmonic nanostructures (orthogonal electric dipolar modes in rods or electric dipolar and quadrupolar modes in spheres) can be used to effectively enhance the contributing SOI effects. The SOI is also observed to be associated with Spin Hall effect. We have also derived explicit expressions for Spin Hall Shift parameters in terms of the scattering matrix elements. The developed theory has been explored to study the role of plasmon resonances (dipolar and quadrupolar resonances in nanorods and nanospheres) in metal nanostructures and whispering gallery modes in dielectric microspheres. The results indicate that the Spin Hall Shift can also be significantly enhanced exploiting these resonance effects. The details of the theoretical formalisms for studying SOI and Spin Hall effect and the results of investigations on metal nanostructures and dielectric microspheres will be presented.

8809-95, Session PWed

Hybrid ARROW-B plasmonic waveguide coupler

I. Shruti, Venus Dillu, Ravindra K. Sinha, Delhi Technological Univ. (India)

In recent years, there has been a tremendous growth on the study of surface plasmon polariton (SPP), as one of many enthralling fields of nanophotonics which probes how electromagnetic fields can be confined below subwavelength dimensions. The SPPs which propagate along metal dielectric interface can be guided through metallic nanostructure and has a vivid future for plasmonic integrated circuits (PICs). However, plasmonic nanostructures, usually suffer from metal induced attenuation which makes it impractical to send signals across entire PICs solely, through plasmonic waveguides. Therefore, integration of plasmonic waveguides with conventional low loss dielectric waveguides has become increasingly important for designing better devices.

In this paper, we have proposed a hybrid antiresonant reflecting waveguide, type B (ARROW-B) plasmonic coupler, which consists of a hybrid ARROW-B plasmonic waveguide exhibiting subwavelength confinement and a dielectric waveguide. The two dimensional modal electric field distribution and the propagation characteristics of the bound and radiation modes is evaluated and studied using finite-element-method (FEM) at =1.55 micron. The coupling characteristics for TM mode versus structure parameters and wavelength have been shown. Further, the coupling length and high extinction ratio has been calculated for the proposed structure. The directional coupler can also be used to efficiently excite the hybrid plasmonic mode with the conventional dielectric mode. This directional coupler can be potentially useful for signal routing and as a power splitter/combiner etc. between plasmonic waveguides and dielectric waveguides in future plasmonic integrated circuits.

Enhancing thermal emission from patterned Pt microstructures using periodic structuring or nanoparticles

Gabriel Vasile, Univ. of Iceland (Iceland) and National Institute of Research-Development for Cryogenics and Isotopic Technologies (Romania); Mustafa Arikan, Snorri Ingvarsson, Univ. of Iceland (Iceland)

We investigate the thermal radiation in the infrared regime of microfabricated Platinum (Pt) heaters, i.e. resistively heated wires, either with Gold (Au) nanoparticles deposited on the surface or with periodic structuring of the surface. The purpose of the work is to enhance the emissivity of the Pt heaters by modifying their surface properties. Polarization resolved thermal radiation was measured at different temperatures. Measurements show that the intensity of the thermal radiation increases by several times when nanoparticles are deposited on the microheater surface or the microheater surface is periodic structured, compared with an identical size heater but without any modifications of the surface.

8809-97, Session PWed

Simulation of arrays of metal nano-particles using a monochromatic recursive convolution finite-difference time-domain method

Saswatee Banerjee, Sumitomo Chemical Co., Ltd. (Japan)

The arrays of metal nano-particles can support localized surface plasmon resonance (LSPR) modes, making them suitable for coloring applications. The LSPR peaks of such arrays can be tuned by changing the structural parameters, such as, shape, size, of each particle and the interparticle distance. In this paper we study the dependence of LSPR properties of arrays on the structural parameters.

The extinction spectra of a spherical particle can be computed analytically using Mie theory. No analytical computation method is available for particle arrays. Numerical methods, e.g., discrete dipole approximation, finite-difference time-domain (FDTD) method are used [1, 2]. Here, we compute the extinction spectra of linear arrays of nano-particles using a monochromatic version of recursive convolution (RC) FDTD method [3]. We developed this method to be able to use the handbook values of permittivity of the material of the particles at each wavelength.

The simulations indicate that the position and size of the peaks of the extinction spectra are determined by the interparticle distance between any two particles and the number of particles in the array. In case of linear arrays of infinite, silver nano-cylinders, the LSPR peak can be shifted toward the longer wavelengths (red-shift) by reducing the interparticle distance. The red-shift increases as the interparticle distance becomes smaller. The peaks of extinction spectra become larger as the number of particles in the array increases.

Fourier modal method for the analysis of LSP arrays interacting with dielectric waveguides

Ricardo Tellez Limon, Mickael Fevrier, Rafael Salas-Montiel, Sylvain Blaize, Univ. de Technologie Troyes (France)

Based in the Localized Surface Plasmons (LSP), in recent years have been designed many nano-scale optical devices, being also developed several computational algorithms for their study and characterization.

Among these methods lies the Fourier Modal Method (FMM), also named RCWA, which is a rigorous method that solves the Maxwell equations in the frequency domain. It is based on the description in Fourier series of the structure, the permittivity and the electromagnetic field. With this formulation is possible to find the proper modes of a periodic structure and its dispersion curves as an eigenvalue problem, and also is possible to modulate the propagated light along the structure as an evolutionary state.

The FMM method allowed us to study the light interaction of a periodic array of metallic nanoparticles with a dielectric waveguide, generating near-field intensity maps of the electromagnetic field components, as well as the determination of the optical power transmitted, reflected and absorbed by the structure.

As this method allows us to characterize the LSP resonances, is possible to use it in the design of integrated plasmonic devices for sensing applications.

Metallic nanostructures for controlled optical properties of surfaces

Boyang Zhang, Junpeng Guo, The Univ. of Alabama in Huntsville (United States); Nima Nader, U.S. Air Force Research Lab. (United States); Walter R. Buchwald, Richard Soref, Univ. of Massachusetts Boston (United States); Hou-Tong Chen, Los Alamos National Lab. (United States); Joshua R. Hendrickson, Air Force Research Lab. (United States)

Deterministic control of the optical properties of materials in the mid-infrared spectrum is experimentally demonstrated using periodic arrays of gold structures. By multiplexing together different sized gold squares within the unit cell of a device, we are able to demonstrate near perfect absorption of light. Using gold square sizes of 865nm and 815nm, wideband absorption, well exceeding the bandwidth that is possible when using single sized squares, is achieved. In addition, these plasmonic resonance based structures can be arranged in such a way as to generate multi-spectral band absorption, such as dual and triple spectral band absorbers. Experimental results agree very well with simulations obtained using a finite difference time domain (FDTD) technique. Electrical field profiles indicate that the primary cause of absorption is due to image induced quadrupole modes between the structured gold surface and an underlying thick gold layer.

Using a germanium substrate, we also show that structured gold surfaces can be used as thin anti-reflection coatings. Tuning of the surface reflection coefficient and phase is possible by adjusting the size of gold structures that are fabricated on a magnesium fluoride dielectric layer, allowing the total reflection to go to zero. With this tuning ability, it is no longer necessary to satisfy the condition for quarter-wavelength anti-reflection coatings. This enables metamaterial anti-reflection coatings with total thickness less than the quarter wavelength.

UVA mediated synthesis of gold nanoparticles in pharmaceutical-grade heparin sodium solutions

Pilar Rodriguez-Torres, Luis A. Díaz-Torres, Martin Olmos-Lopez, Ctr. de Investigaciones en Óptica, A.C. (Mexico); Pedro Salas-Castillo, Clara Gutierrez, Univ. Nacional Autónoma de México (Mexico)

A photochemical-based method in which UVA light (λ=366 nm) is used for synthesizing gold nanoparticles by irradiating gold (III) chloride hydrate (HAuCl4) in the presence of pharmaceutical-grade heparin sodium (PGHEP) as a reducing and stabilizing agent in aqueous solution is presented. Different HAuCl4 to PGHEP concentration ratios were exposed to UVA for up to seven hours. The as-synthesized nanoparticles were characterized by UV-VIS and Raman spectroscopy, transmission electron microscopy (TEM), and pH measurements. The synthesized AuNPs present spherical as well as anisotropic shapes, such as oval, triangular, hexagonal sheets, rods, and some other faceted forms, with dimensions ranging from 20 nm to 300 nm. All obtained products show good temporal stability in solution. Surface plasmons differ when varying HAuCl4 to PGHEP concentration ratio. The obtained samples exhibit two absorption peaks, one in the region between 500-600 nm, and another one in the near-IR between 900-1200 nm; both peaks shift to longer wavelengths and increase their absorption intensity as the HAuCl4 to PGHEP concentration ratios increase. TEM images show the change in nanoparticles yield as well as the shape and sizes change depending on HAuCl4 to PGHEP concentration ratio variation. pH measurements suggest that acidic media promote anisotropic nanoparticle formation. Raman spectroscopy was used to find out which heparin sodium main groups attached to the nanoparticles surface, and in what amount. In summary, it is found that when modifying the reactants concentrations and keeping the UV exposition time as the only fixed parameter, different nanoparticles with distinctive characteristics can be attained.

Narrow-waist metal bar infrared optical antennas

Junpeng Guo, Hong Guo, Zeyu Pan, Boyang Zhang, The Univ. of Alabama in Huntsville (United States); Joshua D. Caldwel, Blake S. Simpkins, U.S. Naval Research Lab. (United States)

Optical half-wave antennas comprising metal bars with a constricted waist are investigated in the mid-wave infrared regime with experiments and numerical simulations. A narrow-waist metal bar antenna is an optical antenna with a reduced width in the middle of bar compared with a rectangular bar. Narrow-waist gold metal bar optical antenna arrays with various reduced waist widths and periods are designed, fabricated, and tested. The experimental results agree well with numerical simulations. It is found that surface plasmon resonance and the resonant near fields on the resonance can be significantly enhanced by reducing the waist width of metal bar antenna. Additionally, the reduction of the waist width causes a red-shit of the surface plasmon resonance and an increased in the photon absorption cross-section in the metal bars. The findings in the work provide an additional degree of freedom for making IR optical antennas to meet various applications.

Plasmonic Ag nanoparticles and nanostructures on thin substrates for enhanced energy harvesting

Richard M. Osgood, Stephen Giardini, U.S. Army Natick Soldier Research, Development and Engineering Ctr. (United States); Kenneth Diest, MIT Lincoln Lab. (United States); Steven E. Kooi, MIT Institute for Soldier Nanotechnologies (United States); Gustavo E. Fernandes, Brown Univ. (United States); Prakash Periasamy, Colorado School of Mines (United States); Lian Li, Univ. of Massachusetts Lowell (United States); Peter J. Stenhouse, Michael Ghebrebrhan, U.S. Army Natick Soldier Research, Development and Engineering Ctr. (United States); Jayant Kumar, Univ. of Massachusetts Lowell (United States); Christopher Gear, MIT Lincoln Lab. (United States); Jimmy Xu, Brown Univ. (United States); Ryan P. O'Hayre, Colorado School of Mines (United States)

Nanoparticles and nanostructures with plasmonic resonances are currently being employed to enhance the efficiency of solar cells [1]. Ag stripe arrays have been shown theoretically to enhance the short-circuit current of thin silicon layers [2]. Monolayers of Ag nanoparticles with diameter d < 300 nm have shown strong plasmonic resonances when coated in thin polymer layers with thicknesses < d [3,4]. We study experimentally the enhancement of short-circuit current and solar spectrum-averaged efficiency solar cells with thin (< 750 nm) silicon layer, when combined with a monolayer of plasmonic (Ag, Al) nanoparticles having different average inter-particle spacings. Using both simulation and optoelectronic measurements, we also research the use of Ag stripes to enhance the efficiency of thin silicon films. These Ag stripes are combined with 200 nm and 60 nm wide "teeth", which act as nanoantennas, and form vertical rectifying nanostructures on Nb/NbOx substrates. We employ spectrophotometry and high-power, focused continuous wave lasers to experimentally measure the efficiency enhancement of Ag nanoparticle- and stripe-coated thin silicon, organic photovoltaic, and Nb/NbOx films. We measure power conversion efficiency, and interpret it in terms of plasmonically-enhanced enhanced absorption, photogeneration, rectification, hot carrier effects, etc.

Rotated grating coupled surface plasmon resonance on wavelength-scaled shallow rectangular gratings

Aniko Szalai, Univ. of Szeged (Hungary); Gábor Szekeres, Univ. of Szeged (Hungary) and Univ. of Szeged (Hungary); Maria Csete, Univ. of Szeged (Hungary)

Theoretical investigation of rotated grating coupling phenomenon was performed on a multilayer comprising 416-nm-periodic plasmon-wavelength-scaled shallow rectangular polymer grating on bimetal film made of gold and silver layers. During the multilayer illumination by 532 nm wavelength p-polarized light the polar and azimuthal angles were varied in a parametric sweep performed by COMSOL software package. In case of modulation amplitude larger than a minimal value, splitting was observed on the dual-angle dependent reflectance in two regions: i) close to 0° azimuthal angle corresponding to incidence plane parallel to the periodic pattern (P-orientation); and ii) around ~33° azimuthal angle (C-orientation), in agreement with our previous experimental studies. The near-field study revealed that in P-orientation the E-field is enhanced at the glass side with p/2 periodicity at the first minimum appearing at 49° polar angle, and comprises maxima below both the valleys and stripes; while E-field enhancement is observable both at the glass and polymer side with p-periodicity at the second minimum developing at 55° tilting, comprising maxima intermittently below the valleys or above the stripes. In C-orientation coupled plasmonic modes are observable, involving modes propagating along the valleys at the secondary maxima appearing at ~33° azimuthal and ~48° polar angles, while modes confined along the polymer stripes are observable at the primary minima, which are coupled most strongly at the ~33° azimuthal and ~56° polar angles. The secondary peak observable in C-orientation is proposed for biosensing applications, since the supported modes are confined along the valleys, where biomolecules prefer to attach.

Super-weak scattering of nanopatterns in multilayer hyperbolic metamaterials

Hao Shen, Univ. of California, San Diego (United States) and Institute of Physics (China); Dylan Lu, Zhaowei Liu, Univ. of California, San Diego (United States)

Optical scattering is a ubiquitous phenomenon in a medium with refractive index contrast. Localized plasmonic resonances in metallic nano-particles or nano-holes leading to strong plasmonic scattering have been widely explored and utilized for sensing, detection and imaging. This general concept, however, will be overthrown in engineered metallic multilayer metamaterials. In this work, we present that engraved nanopatterns of any shapes in multilayer hyperbolic metamaterials (MHMs) become invisible in a certain band of frequencies. The invisibility is caused by so-called super-weak scattering of nanopatterns, when the permittivity of the consisting MHMs along a certain direction that interacts with the incident electrical field matches with the surrounding medium. This abnormal phenomenon is demonstrated experimentally by the optical scattering and transmission characterization of nanopatterns with various geometries in Au-Si MHMs. Such super-weak scattering is invariant to pattern size, shapes and incident wave angles, which also agrees with full-wave electromagnetic simulation results. By varying the metal filling ratio in MHMs, the working wavelength of super-weak scattering can be tuned to any colors at visible light frequencies. This kind of invisibility in MHMs may lead to potential applications in optical encryption.

Fabrication of wafer scale metallic nanorings and nanotubes via argon sputter redeposition for plasmonics

Zachary J. Favors, Aaron S. George, Cengiz S. Ozkan, Mihrimah Ozkan, Univ. of California, Riverside (United States)

Fabrication of metallic nanostructures defined in highly ordered arrays has been achieved using lengthy electron beam lithography (EBL) steps and may be limited to metals used as well as final dimensions. We propose an alternate inexpensive and fast method void of EBL that allows for use of a number of noble and magnetic metals and tuning of metallic nanorings and nanotubes down to 50 nm. Using Argon sputter redeposition, we are able to fabricate highly tunable, wafer-scale metallic nanorings and nanotubes defined via anodic aluminum oxide (AAO) templates. The AAO templates can be grown on a variety of polished semiconducting substrates using evaporated high purity aluminum and a two step anodization process. After evaporation of a thin film of metal onto the template, inductively coupled plasma (ICP) etching using Argon is performed to physically blast the deposited metal nanoparticles within the pores of the AAO outward into ring and tube structures. The dipole surface plasmonic resonances contained within the nanotubes and nanorings are investigated with respect to structure dimensions and metal. By simply adjusting anodization, evaporation, and etching parameters we are able to highly tune the final geometry, structure, and composition of the metallic nanotubes and nanorings to diameters as low as 50 nm at the wafer scale.

Quantum-plasmonic interaction: emission enhancement of Er 3+ - Tm 3+ co-doped tellurite glass via tuning nanobowtie

Otavio B. Silva, Victor A. Garcia Rivera, Fernando W. A. Sobreira, Fabio A. Ferri, Univ. de São Paulo (Brazil); Yannick Ledemi, Younès Messaddeq, Ctr. d'optique, photonique et laser (Canada); Euclydes Marega Jr., Univ. de São Paulo (Brazil)

Metallic nanobowtie is well known as a suitable structure for development of antennas that can be integrated on wide number of devices, especially in optical communications. Such feature is achieved due the presence of surface plasmon polariton (SPP) that provides a great charge density on nearby region from its tips. Considerable studies

have described theoretical and experimentally the influence of gap between tips on radiation emission, once this parameter may improve the local field, as such length decrease. In optical regime, the emission enhancement is due the quantum-plasmonic interaction create from tips region (localized local field) and the transitions levels (Er3+ and Tm3+ ions). However, metallic nanobowtie with absence of gap still deserve attention, because in addition to present similar properties from regular case as previously mentioned, can also interacts with different systems, like gain materials, that can be embedded thermically into the substrate. One of remarkable class of such material is rare earth ions, not only by the enhancement on measured intensity, but also its easiness to implement it on glasses, which constitute the main type of substrate adopted on plasmonic structures. In this work we performed the analysis of effects due implementation of erbium (Er3+) and thulium (Tm3+) rare earth ions into BK7 glass over a pattern of nanobowtie on absence of gap between its tips, fabricated by focused ion beam (FIB) technique from silver (Ag) and gold (Au) films. The bowties are vertically excited by an argon laser (Ar) which wavelength is 488 nm. Furthermore, computational simulations based on finite element method (FEM), were performed to verify the dependence of nanobowtie's geometry over the electric field along its symmetry axis.

Plasmon enhanced single-photon detection

Gábor Szekeres, Áron Sipos, Maria Csete, Univ. of Szeged (Hungary)

Novel infrared superconducting nanowire single-photon detectors (SNSPD) were designed, which comprise a meandered pattern of niobium-nitride (NbN) stripes and different integrated plasmonic structures on silicon substrate. To enhance detection efficiency in case of 1550 nm wavelength p-polarized light illumination, integrated patterns with P-pitch (~792.5 nm) commensurate with the plasmon-wavelength at silica-gold interface were designed, while to enhance absorptance, integrated patterns with p=P/3 periodicity (~264 nm) were also investigated. In OC-SNSPDs integrated with ~quarter-photonic-wavelength nano-optical cavity closed by a gold reflector, the highest absorptance (27/63 % in P/p-pitch designs) was attained at perpendicular incidence onto NbN patterns in P-orientation, corresponding to incidence plane parallel to the stripes, due to the E-field antinode at the NbN-silica interface. In NCAI-SNSPDs, where each NbN stripe is located at the entrance of a quarter-plasmon-wavelength MIM nano-cavity, enhanced absorptance (34/85.1 % in P/p-pitch designs) is attainable at perpendicular incidence in S-orientation, when the incidence plane is perpendicular to the integrated pattern, due to collective resonances on the nano-cavity array. The longer vertical gold segments with P-pitch in NCDAI-SNSPDs, which can be embedded into the silica substrate via two-step lithography, enable to reach large absorptances at small polar angles in S-orientation, due to grating-coupling phenomenon. The highest absorptance among P-pitch designs (75 %) is attainable in NCDAI-SNSPD, and the maximal absorptance (92.7 %) in p-pitch NCDAI-SNSPD is also larger than in the counterpart NCDAI-SNSPD. P-pitch NCDAI-SNSPDs supporting coupled surface waves with potential to ensure synchronous E-field enhancement below the NbN stripes are proposed for detection efficiency maximization.

Fabrication of nanoparticles for generation of force and torque at nanoscale

Gediminas Gervinskas, Gediminas Seniutinas, Swinburne Univ. of Technology (Australia) and Melbourne Ctr. for Nanofabrication (Australia); Lorenzo Rosa, Swinburne Univ. of Technology (Australia); Etienne Brasselet, Univ. Bordeaux 1 (France); Saulius Juodkazis, Swinburne Univ. of Technology (Australia) and Melbourne Ctr. for Nanofabrication (Australia)

Inscription of nano-grooves on thin metal films and arrays of nanoparticles is used to create patterns which scatter and absorb light with different cross sections for left and right circularly polarized light. Dielectric nanoscale hybridation of the metallic nanostructures is also realized. An optical extinction was measured from a single particle as well as from tens of nanoparticles. We use our fabrication approach introduced earlier to inscribe and center chiral groove patterns on arrays of nanoparticles without positioning errors. Numerical simulations were carried out to estimate light enhancement, force and torque generated by the nanoparticles both under plane wave and bounded light fields carrying orbital angular momentum.

Focused ion milling with sub-15 nm resolution in 50-nm-thick gold nanoparticles and film coatings can produce high fidelity patterns over write fields with cross sections up to 100 by 100 micrometers. Such high fidelity nano-writing allows to characterize optical properties of single particles as well as their ensembles. One can envisage direct write of plasmonic circuitry elements such as split ring resonators. Another promising approach to create nanoparticles which have features extending out of the film plane by tens-of-nanometers is demonstrated by combination of electron beam lithography and dry etching where sacrificial resist film is removed gradually as gold is dry-etched in the openings. After dry etching, vertical protrusions are formed near the edges of the grooves defined by electron beam lithography. Optical properties of such hybridized polymer-gold nano-wells and grooves were characterized experimentally and numerically simulated.

Infrared near-perfect emitter based on complementary bowtie aperture array

Nan Zhou, Yan Li, Xianfan Xu, Purdue Univ. (United States)

Complementary bowtie aperture (CBA) has been shown to efficiently confine and enhance the magnetic field in the optical frequency range. In this work, we demonstrate a near-perfect absorber in the infrared region based on CBA array combined with a metal ground plane. According to the Kirchhoff's law of thermal radiation, the CBA array is also a perfect emitter at the resonant wavelength, at a given temperature. Different from metamaterial-based perfect absorbers where the simultaneous electric and magnetic resonances are achieved in electric resonator and metal layer, the near perfect absorption/emission of our structure originates from the strong coupling of plasmons supported by the CBA array and the ground plane. The structure is modeled numerically and characterized experimentally by spectroscopic reflection measurement. Parametric study illustrates the flexibility of manipulating absorption and emission with our structure in the near, mid and far infrared regime.

Nano plasmon array for detection of light propagation in waveguide

Seulki Kim, Chan-Min Kang, Jinsik Kim, Jungho Park, Korea Univ. (Korea, Republic of)

Surface plasmons (SP), propagating at metal/dielectric interface, have been studied in various fields such as bio and chemical sensors. Nowadays, the other applications of SP were highlighted for facilitating the all integrated optical circuit in nano space.

We introduce the design and fabrication of a periodic array of gold nanostructure for detection of light which is propagated in a SiON waveguide. The gold nanostructures are designed using COMSOL Multiphysics tools and fabricated by electron beam lithography and lift-off processes. The array is composed of 5 nano rods. The nanorod has 50 nm height, 100 nm width and 15 um length.

The enhancement of light at nano array was detected. Below the specific distance between nano array and waveguide, the nano array can detect the evanescent tail of light. The results demonstrate nanorod array can verify the fact that the incident light propagates in a waveguide or not

when optical components are densely integrated. The various geometries of nanorods array could be applied in fluorescence enhancement, high-harmonic generation and free space coupler.

Optical near field imaging of localized surface plasmons modes in metallic nanostructures integrated on dielectric waveguides

Josslyn Beltran, Ctr. de Investigación Científica y de Educación Superior de Ensenada (Mexico); Natalia Dubrovina, Institut d'Électronique Fondamentale (France); Rafael Salas-Montiel, Univ. de Technologie Troyes (France); Heriberto Marquez-Becerra, Ctr. de Investigación Científica y de Educación Superior de Ensenada (Mexico); Mickael Fevrier, Sylvan Blaize, Univ. de Technologie Troyes (France); André de Lustrac, Institut d'Électronique Fondamentale (France); Anatole Lupu, Univ. de Technologie Troyes (France) and Institut d'Electronique Fondamentale (France); GIlles Lérondel, Univ. de Technologie Troyes (France)

The study of surface plasmon-polaritons interactions in metallic nanostructures has been a topic of interest during last years due to their use in various areas such as the photonics, chemistry and biology. Example of use is found in biosensors for the efficient detection of biological analyte and in nanophotonic elements for on-chip photonics.

Here, we study the interactions properties of localized surface plasmons in a hybrid waveguiding structure made of bi-dimensional array of gold nanowires vertically integrated on silicon-on-insulator waveguides across the near infrared spectrum. With the use of near-field scanning optical microscopy (NSOM) in perturbation mode, we qualitatively obtained the spectral response of such hybrid structure through intensity near field maps of the light propagation. Amplitude and phase properties of the electric field are also obtained with the use of a heterodyne scattering NSOM. It is confirmed, from the NSOM images, the efficient excitation of the cut wires resonance in a guided wave configuration when the fundamental TE mode of the silicon waveguide is set as the input field. These experimental results demonstrate that metallic nanostructures integrated on silicon are suitable for the development of localized surface plasmon integrated devices.

Epitaxial growth of DNA-assembled plasmonic nanoparticle superlattices

Sondra Hellstrom, California Institute of Technology (United States); Youngeun Kim, Northwestern Univ. (United States); Jim Fakonas, California Institute of Technology (United States); Andrew J. Senesi, Robert Macfarlane, Northwestern Univ. (United States); Seyoon Kim, California Institute of Technology (United States); Chad A. Mirkin, Northwestern Univ. (United States); Harry A. Atwater Jr., California Institute of Technology (United States)

Recently, it has been demonstrated that plasmonic nanoparticles can be assembled into a wide variety of crystalline arrays using DNA functionalization and hybridization.[1] These DNA-nanoparticle (DNA-NP) superlattices have typical grain sizes of a few hundred nanometers up to one micron, with poorly controllable edges, sizes and orientations, and this limits optoelectronic characterization and device integration. Borrowing from techniques of conventional crystal growth, we are growing DNA-NP lattices epitaxially. Using electron-beam lithography, we pattern gold on silicon in the form of the first layer of a DNA-NP crystal in any major crystal plane and with lateral dimensions over many microns. By functionalizing this substrate with DNA and treating it with complementary DNA-coated nanoparticles, we can produce a 3D structure which was seeded initially in two. By observing the layer-by-layer growth, we are able to better understand the crystallization process itself. We can also exert fine control over the size and orientation of DNA-NP assemblies, and we anticipate extending the range of particle sizes and geometries which are capable of forming crystal lattices. This will enable more sophisticated optical measurements and extend the range of properties which these materials can exhibit.

Spectroscopic ellipsometry study of plasmon resonances of copper in uniaxial mixed oxide medium

Zahra Ghadyani, Morten Kildemo, Lars Martin S. Aas, Norwegian Univ. of Science and Technology (Norway)

We have used spectroscopic ellipsometry to study plasmon resonances of Cu nanoparticles hosted in uniaxial mixed oxide medium. The samples are prepared by low energy ion sputtering of the mixed oxide film. The plasmonic resonances observed in spectroscopic ellipsometry data confirm presence of copper nanoparticles. The ellipsometric data is fitted using a uniaxial dielectric function model containing Lorenzian oscillators to account for plasmon resonances. The spectral position of plasmon resonances are determined by adjusting the parameters of dielectric function. The size and shape of copper nanoparticles as well as properties of the surrounding medium are derived from spectral position of plasmon resonances. This study can be particularly useful in real time in situe investigation of the fabrication process.

Low-loss nanophotonic waveguide simulation based on metal heterostructure surface plasmon polaritons

Yasin Farzami, Mahdi Davoodi, Malek-Ashtar Univ. of Technology (Iran, Islamic Republic of)

In this research, the low-loss nanophotonic waveguide is simulated using 2D FDTD method. We assume that waveguide structure consists of rectangular-shaped metal heterostructure nanoparticles with dimensions of 65nm x 50nm and a surface-to-surface spacing of 50nm between adjacent particles. The nanoparticles made of Al-Ag metal heterostructue constructed with a rectangular Ag guide. The particles are surrounded by vacuum. The dielectric constant of metals is modeled using a Drude model. We use a cw source in order to excite SPPs. Time and space steps are determined based on Courant's stability condition. In our simulation, PML boundary condition is specified at four computational boundaries. Simulation results show that by converting light into the SPPs, this waveguide transfers the light energy at λ=780.2nm with propagation loss as low as 1.68dB/μm

Glass-metal nanocomposite submicron structures

Mihail I. Petrov, Univ. of Eastern Finland (Finland); Ivan S. Sinev, Anton K. Samusev, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Yuri P. Svirko, Univ. of Eastern Finland (Finland); Andrey A. Lipovskii, Saint Petersburg Academic Univ. (Russian Federation)

Glass metal nanocomposites that is glasses embedded with metal nanoparticles (GMN) and GMN-based plasmonics and photonics

structures are studied. These materials exhibit unique optical properties governed by surface plasmon resonance (SPR) in individual metal nanoparticles resulting in local optical field enhancement, high nonlinear effects, etc. The GMN can be nanostructured with a simple and cost-effective electric field imprinting technique based on electric field assisted dissolution of nanoparticles. This means local destruction of the nanoparticles inside the glass matrix by locally applied external DC voltage. Our near field optical microscopy studies showed that GMN can be patterned with spatial resolution down to 100-150 nm. This opens a route for simple production of 2D photonics and plasmonics structures. We show that optical properties of these structures are mainly governed by the SPR. Particularly, they exhibit properties either of dielectric or metallic structures depending on the spectral range. Changing GMN parameters one can tailor characteristics of the GMN based structures that provides additional degree of freedom in their optical properties engineering. The case of 1D periodic structure and its optical response is discussed in details including the transition from amplitude to phase diffraction regime and resonant excitation of propagating modes, including recently observed in GMN surface polariton modes. The properties of GMN based optical structures make them prospective for linear and nonlinear plasmonics and photonics.

8809-61, Session 15

Silicon, plasmonics, and in between *(Keynote Presentation)*

Uriel Levy, Ilya Goykhman, Boris Desiatov, Noa Mazursky, Avner Yanai, Liron Stern, Meir Grajower, Joseph Shappir, The Hebrew Univ. of Jerusalem (Israel)

In this talk we demonstrate the role of metal optics in enhancing the performances of active silicon devices. As an example, we will show how Schotkky diode devices can be used for the detection of sub-bandgap electromagnetic radiation with improved efficiency. Both guided wave and free space configuration are demonstrated. Additional metal optics platforms for enhancing light-matter interactions will be discussed as well.

8809-62, Session 15

Engineering multimodal localized surface plasmon resonances in silicon nanowires

Li-Wei Chou, Michael A. Filler, Georgia Institute of Technology (United States)

Semiconductors, as a result of their widely tunable carrier density (10^19 - 10^21 cm-3), are emerging as promising plasmonic materials for applications in the infrared. Silicon, in particular, is inexpensive relative to the noble metals and benefits from a robust suite of processing tools due to its extensive use in the semiconductor industry. To this end, we recently reported that phosphorus-doped Si nanowires can support mid-infrared localized surface plasmon resonances (LSPRs) with quality factors comparable to those of the noble metals [1]. Herein, we demonstrate that axial control of dopant profile in individual nanowires permits complex, user-programmable, multimodal spectral responses. Highly aligned Si nanowire arrays are synthesized via the vapor-liquid-solid (VLS) technique with a combination of Si- and P-containing precursors. In-situ infrared absorption spectroscopy measurements reveal intense absorption bands (5 – 10 micrometer) with dopant concentration and shape-dependent spectral shifts consistent with longitudinal LSPRs. Discrete dipole approximation calculations confirm that the observed spectral response results from resonant absorption and free carrier concentrations on the order of 10^19 cm-3. We also observe near-field coupling between neighboring plasmonic domains, which varies as a function of intrinsic spacer length and can be described with hybridization theory. Our results highlight the utility of VLS synthesis for surface plasmon engineering in semiconductors, create new opportunities to study basic surface plasmon physics, and pave the way for applications including bond selective catalysis, ultra-sensitive molecular detection, and thermal energy harvesting.

Tunable and thermally stable plasmonic sensing platform: gold nanoparticles on Al2O3 coated Au films

Chatdanai Lumdee, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States); Binfeng Yun, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States) and Southeast Univ. (China); Pieter G. Kik, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

Substrate-based tuning of plasmon resonances on gold nanoparticles (NP) is a versatile method of achieving plasmon resonances at a desired wavelength, and offers reliable nanogap sizes and large field enhancement factors. The reproducibility and relative simplicity of these structures makes them interesting candidates for frequency-optimized sensing substrates. Prior studies showed that plasmon resonance tuning throughout the visible range and into the near-infrared is feasible. However thus far the structures have either been relatively fragile or feature relatively small tuning range. In this work, we study the optical scattering spectra of isolated 60 nm diameter gold nanoparticles on aluminum oxide (Al2O3) coated gold films with various oxide thicknesses. The structure is shown to simultaneously provide a large tuning range and high thermal stability. Dark-field scattering images of these particles reveal red ring-shaped scattering patterns. The corresponding scattering spectra show peaks at wavelengths from 690 nm to 610 nm as the Al2O3 thickness increases from 0 to 3.56 nm, as well as a weak scattering signal around 530 nm. The relative strength and polarization of these two main features is reproduced in numerical simulations, and is demonstrated to be affected by radiation from image charges in the substrate. The thermal stability of the frequency tuned substrates is investigated by high power (100 W/mm2) illumination at 633nm. While Au NP deposited directly on Au show clear spectral changes upon illumination, the addition of an Al2O3 spacer layer leads to scattering spectra that remain stable even after high power illumination.

8809-64, Session 15

Novel thin film materials for plasmonic applications

Sara Zuccon, Marco Nardello, Vanessa Polito, Alain Jody Corso, Maria-Guglielmina Pelizzo, Paola Zuppella, IFN-CNR LUXOR Lab. (Italy)

The performances of an Inverted Surface Plasmon Resonance (ISPR) biosensor based on novel materials have been studied theoretically and experimentally. The principle of ISPR is based on a maximum of reflectivity at the coupling angle instead of the common used minimum of reflectivity, this solution has not been extensively explored yet.

The sensor response has been firstly simulated by the use of a dedicated Matlab routine. Different structures involving different materials have been considered and compared, in order to find the optimized solution.

The metals have been deposited on a flat substrate made of optical glass. Different noble metals of optimized thickness have been then deposited on top of it. The substrates have been finally coupled with a prism to test the ISPR response.

The metallic layers have been deposited at our lab by Electron Beam Evaporation. The process have been optimized for each material considered.

On top of the metallic nanostructure a thin layer of Graphene (from 1 to 10 SLG) have been eventually considered both theoretically and experimentally. We tried different solutions for the deposition of this layer starting both from Graphene Oxide and Graphene (i.e. spin-coating, drop-casting, solvent-induced precipitation and the scotch-tape approach).

The metals and the graphene layers have been characterized optically at the UV-vis spectrometer and morphologically at the profilometer and AFM.

The response of the sensors has been tested at our laboratory on a dedicated optical-bench set-up based on the Kretchmann configuration with angular modulation.

The theoretical and experimental data are reported.

8809-65, Session 15

Fano resonance in silver nanoparticles in SOI structure: design of plasmonic nano switch

Venus Dillu, I. Shruti, Ravindra K. Sinha, Delhi Technological Univ. (India)

Fano resonance is a resonant scattering phenomenon resulting in asymmetric line shape. It arises when quantum interference takes place between two scattering amplitudes: one due to scattering within a continuum of states (background process) and second due to excitation of discrete state (the resonant process). Fano type resonance is observed mainly in plasmonics nanostructures, metamaterials, diffraction grating and hole/particle arrayed structures. This resonance profile has prospective applications in sensing, lasing, switching etc. In this paper we investigate potential of plasmonic nano switch as a result of Fano-resonance observed in periodically arrayed silver (Ag) nanoparticles embedded over silicon (Si) on insulator (SOI) substrate, by using 3-D finite difference time domain method. Structural parameters of the embedded silver nanoparticles were optimized giving rise to plasmon modes in the device. We find that as the device is scanned for a range of wavelength varying from visible to near infra-red, the transmission spectra exhibits Fano-line shape asymmetry for input wavelength regime near 1.3 - 1.55micron, whereas normal resonating peak is observed in the visible region. The optical properties of the switch reveal, enhancement in transmission due to strong plasmonic Fano resonance between the background and resonant processes. Sharp Fano-resonance, specific to interacting quantum systems, is exhibited by the proposed embedded hybrid design of silver nanorods into Si, which meets the condition required for high contrast switches and hence can be exploited as per anticipated results. Fano resonance in this nanorod-substrate system can also be used for designing nanoantennae, lasers, sensors, SERS etc.

8809-66, Session 15

High-nonlinearities in Si-based nanoplasmonic guides *(Invited Paper)*

Abdulhakem Y. Elezzabi, Shawn S. Sederberg, Univ. of Alberta (Canada)

In this investigation, we consider silicon-based plasmonic devices as a platform for high-non-linear field effects. 80 nm wide Silicon-based plasmonic devices are fabricated on silicon-on-insulator (SOI) substrates using processing techniques that are largely CMOS compatible, allowing them to be integrated with electronic and silicon photonic devices. Here, we will demonstrate passive 3D routing and ultrafast active switching in a silicon-based plasmonic device platform. In order to visualize the timescale of the nonlinear optical effects in the waveguides, we employ a pump-probe cross-phase modulation setup incorporating 100 fs, 1550nm laser pulses. We demonstrate high nonlinearities on these structures at pump powers of less than 1 mW and switching time scale of ~ 3ps.

8809-67, Session 16

Enhancement of nonlinear properties of metal nanostructures by passive elements *(Invited Paper)*

Martti Kauranen, Robert Czaplicki, Hannu Husu, Roope Siikanen, Jouni Mäkitalo, Tampere Univ. of Technology (Finland); Joonas Lehtolahti, Janne Laukkanen, Markku Kuittinen, Univ. of Eastern Finland (Finland)

The optical properties of metal nanoparticles depend on their plasmon resonances. The resonances give rise to strong local fields near the particles, which can enhance nonlinear interactions. However, surface defects can also support their own localized plasmonic modes and thereby lead to highly local nonlinear responses.

We have earlier shown that localized defect modes can lead to effective quadrupole effects in second-harmonic generation (SHG) from arrays of metal nanoparticles. Significant improvements in sample quality, however, have allowed the dipole limit to be reached. This opens the possibility of designing nonlinear metamaterials with truly engineered properties, which we have demonstrated by varying the detailed ordering of nanoparticles in an array.

In this paper, we present a summary of our most recent results regarding the enhancement of nonlinear properties by passive elements, which have no nonlinear response as such. More specifically, we combine noncentrosymmetric SHG-active particles with passive elements that consist of centrosymmetric nanobars. The passive elements are shown to modify the local-field distribution at the fundamental frequency, thereby enhancing SHG. The enhancement is shown to arise from lattice interactions between the two types of particles, opening new opportunities for optimizing the nonlinear properties of plasmonic nanostructures.

8809-68, Session 16

Nonlinear extreme ultraviolet light generation in plasmonic nanostructures

Murat Sivis, Claus Ropers, Univ. Göttingen (Germany)

Plasmonic nanostructures offer the possibility to control and enhance optical fields, and they play a major role for the integration of strong-field physics with nano-optics. Emerging applications involve the study of nonlinear phenomena in confined nanometric volumes, including above-threshold and strong-field photoemission, carrier-envelope-phase dependencies and electron acceleration effects in inhomogeneous light fields. Particular interest was drawn to reports of nanostructure-enhanced high harmonic generation, which may provide unique access to coherent extreme ultraviolet (EUV) radiation and attosecond pulses in compact implementations.

In this contribution, we revisit the fundamental mechanisms of the excitation and radiation processes in atomic gases interacting with optical near-fields. Specifically, we present experimental results on highly nonlinear EUV generation in plasmonic bow-tie nanoantennas and tapered hollow waveguides using ultrashort, low-energy laser pulses. We find that the detectable radiation in our experiments on bow-ties exclusively stems from incoherent fluorescence induced by multiphoton absorption and strong-field ionization. We demonstrate that the small interaction volume in nanostructures generally favors the predominance of incoherent over coherent processes, and that local intensities in the optical near-field can be gauged by a novel means that utilizes relative transition strengths. Thus, despite sufficient local intensities for ionization, no contribution from coherent high harmonic generation is observed. Furthermore, also for plasmonic waveguide structures, stable EUV emission from fluorescent transitions in various gases is presented. In addition to the aforementioned excitation mechanisms, we find strong evidence that multistep collisional processes provide an additional excitation channel.

8809-69, Session 16

Plasmoelectric potentials in metal nanostructures

Matthew T. Sheldon, Ana M. Brown, Harry A. Atwater Jr., California Institute of Technology (United States)

The resonant plasmonic properties of metallic nanostructures depend strongly on charge carrier density. While researchers have reported shifts of the resonant absorption frequency of plasmonic nanostructures due to electrostatically induced changes of charge density, the converse — the dependence of charge density and electrostatic potential on optical absorption— has been largely overlooked. Here, we report a theoretical framework and provide experimental evidence for a 'plasmoelectric effect', an optically induced electrochemical potential in plasmonic nanostructures from narrowband absorption. A simple thermodynamic model shows that, unlike the more familiar thermoelectric or photovoltaic effects, the magnitude and sign of the plasmoelectric potential depends on the frequency difference between the plasmon resonance and incident radiation.

We experimentally test our predictions by characterizing the electrical and optical response of colloids of monodisperse Au or Ag nanoparticles spin-cast on ITO films. Scanning Kelvin probe force microscopy (KPFM) determines the surface potential of device structures while varying the frequency of incident radiation near the plasmon resonance. Under 1000 mW cm-2 single-frequency illumination, we measure induced potentials of ± 15 mV from 60 nm Au particles, with a characteristic sign change for illumination blue or red of the particle absorption maximum. Additionally, power and frequency-dependent increases of optical absorption from samples under monochromatic illumination indicate shifts of the plasmon resonance when compared with the spectral response of samples under white light illumination. We observe clear evidence for the size-dependent and frequency-dependent trends consistent with our theoretical framework, providing deeper mechanistic insight and highlighting potential applications for this plasmoelectric effect.

8809-70, Session 17

Toward low-threshold stimulated emission of surface plasmon polaritons *(Invited Paper)*

John K. Kitur, Thejaswi U. Tumkur, Mikhail A. Noginov, Norfolk State Univ. (United States)

Stimulated emission of localized surface plasmons and surface plasmon polaritons (SPPs) paves a path to active plasmonics. Unfortunately, most of stimulating emission processes in plasmonic systems reported up to date have prohibitively high thresholds. At this time, we show that the stimulated emission threshold of SPPs can be reduced by an order of magnitude if the operation range is changed from visible to near-IR and multilayered metal/dielectric metamaterials with hyperbolic dispersion are used instead of simple silver substrates. The study of the relationship between the stimulated emission threshold and the density of photonic states is in progress.

8809-71, Session 17

Cross-section curvature effect in plasmonic ring lasers

Feifei Shi, Xudong Liu, Xin Gong, Zhaoyu Zhang, Peking Univ. Shenzhen Graduate School (China)

Nanolasers have shown their potential in optical communication and information storage, due to their tiny footprint, potential high modulation rate and light spot under diffraction limit. In recent years, many structures use metal as whole or part of the cavity to achieve light confinement at subwavelength scale. In this paper, we propose and compare two novel types of hybrid plasmonic lasers, both with an ultrathin insulator layer sandwiched by a ring shape semiconductor and planar silver layer. The lasers differ in their cross-section curvature on the interface of metal and insulator. Finite difference time domain (FDTD) method is used to calculate and optimize these two ring laser structures. The resonant wavelength is set around 490 nm. The ultrathin thickness of the insulator layer makes photonic modes hybridize with surface plasmon plaritons (SPPs) at Ag-insulator interface, which confines the light field strongly in the ultrathin layer. The SPPs carry high momentum and high effective refractive index to TM mode. Whispering gallery mode is achieved according to strong feedback at the ring boundary by total internal reflection. The ring lasers have relatively high Q factors, approaching 100, at 250 nm radius and mode confinement around ?2/360. The mode volume can be shrunk to 0.1(?/n)3 and 0.01(?/n)3 respectively, which leads to Purcell factors around 70 for square cross-section and 380 for circle cross-section. We discuss the curvature effects on the mode volume and on the quality factor which accounts for the high Purcell factor for the circle cross-section.

8809-72, Session 17

Controlled generation of optical vortex beams from metallic nanostructures

Etienne Brasselet, Univ. Bordeaux 1 (France); Gediminas Gervinskas, Gediminas Seniutinas, Saulius Juodkazis, Swinburne Univ. of Technology (Australia)

Optical vortices refer to light fields with helical phase spatial distribution that leads to well-defined orbital angular momentum states characterized by a topological charge, which can formally take any integer value. Such unlimited discretization of optical information motivates the development of new designs and protocols to manage on the orbital angular momentum of light. In particular, there is a growing interest towards the elaboration of small scale toolbox to produce, detect, sort and manipulate the orbital angular momentum light. Large-scale integration potential indeed promises novel applications that are not accessible to nowadays nanophotonic technologies. Here we propose a novel universal design of material structuration that enables the generation of optical phase singularities with arbitrary topological charges. We experimentally demonstrate our proposition in the visible domain by implementing the proposed strategy to metallic nanostructures. This is done by fabricating appropriate metallic nanocircuitry and ensuing characterization of the generated optical phase singularities. The production of optical vortex beams with topological charge ranging from -6 to +6 is reported. Experimental data is compared to predicted results from our analytical modeling of the topological optical properties of the device. These findings offer a novel strategy towards singular nanophotonics.

8809-73, Session 17

Plasmonic half-waveplate based on gold nanoslit and its application to ultrasmall radial polarization converter

Miho Ishii, Kentaro Iwami, Norihiro Umeda, Tokyo Univ. of Agriculture and Technology (Japan)

? plasmonic nanoslit array as a half waveplate for visible wavelength is studied, and arranged array pattern is applied to a radial polarization converter. A gold nanoslit array which has both 180 degree phase shift and identical transmittance between TE and TM polarizations is designed and fabricated. Design parameters of the slit array are optimized by using finite-difference time-domain calculation. The optimal design parameters are determined for several wavelengths in the visible range from 440 nm to780 nm. For example, A 252-nm width 500-nm-period nanoslit array with the thickness about 350 nm can be applied to a half waveplate for 633-nm wavelength with 50% transmittance. The slit array with this design is fabricated through electron beam lithography and lift-off process, and evaluated by Senarmont method. Furthermore, four-divided slit pattern arrangement is fabricated to make an ultrasmall radial polarization converter. From the observation under polarization microscopy, characteristic transmission pattern of radial polarization is successfully observed. This technique is expected to be applied to microscale radial polarization converter array for MEMS applications.

8809-75, Session 18

Static electric field of a point charge in a two-constituent composite medium *(Invited Paper)*

David J. Bergman, Tel Aviv Univ. (Israel)

An exact calculation of the local electric potential field τ(r) is described for the case of a point electric charge where the microstructure is that of an ε1 spherical inclusion embedded in an otherwise uniform ε2 host. The calculation is based upon an expansion of ϕ(r) in the complete set of eigenstates of the static Maxwell equations for the electric potential in and around an isolated spherical inclusion [1]. In the limit where the sphere radius tends to ∞ this becomes a flat interface structure where a perfect imaging of the point charge is expected when ε1 = _ ε2 [2,3,4]. The exact calculation has some novel implications for the perfect imaging phenomenon.

8809-76, Session 18

Plasmonic angular momentum transfer at scattering-dependent multipole modes

Yoon Kyung Lee, Massachusetts Institute of Technology (United States)

Metallic nanostructures at plasmonic resonance enable enhanced transfer of optical energy, momentum, and angular momentum. For subwavelength nanoparticles, the resonance is highly dependent on the shape as well as the size of the particle. While scientists and engineers desire to control and excite different resonant modes at will, it is well known that some natural modes can never be excited by simple plane waves, while others can easily be. In this talk, a general theoretical analysis is presented to explain this selective excitation of higher-order natural modes of metallic nanopolygons. FDTD simulation results support our theory that the broken rotational symmetry of a nanopolygon enables the selective excitation of discrete higher-order natural modes, governed by a simple grating equation in the angular domain.

The nanoparticle acting as an angular grating converts one angular momentum state of light to another by enhanced transfer of angular momentum. We present the angular momentum transfer rate calculated for the dipole and quadrupole resonance of gold nanoparticles, using circularly polarized plane wave at normal incidence. The scattering-dominant dipole and quadrupole mode operate at different angular momentum modes of the nanoparticle, and also show distinct characteristics in terms of torque transfer. The spatial distribution of the electric field on the plasmonic nanoparticle as well as the intensity distribution of the scattered light field is analyzed in detail. Our analysis serves as the basis for using plasmonic nanoparticles for manipulating photon states for quantum computing, as well as for controlling mechanical torque by light.

8809-77, Session 18

Coupling between Ems waves, molecules, and a nanoparticle

Montacer Dridi, George C. Schatz, Northwestern Univ. (United States)

We report here a theoretical study of the coupling between gain media and a plasmonic nanostructure based on 3D FDTD (finite-difference time-domain) simulations. The motivation for this work is to develop a rigorous and accurate model that account for the quantum properties of the molecule (emission, state densities,..) and the EM properties of the nanoparticle.

To account for the interaction between an EM wave and a molecule, we derive the equation of polarization density P which is the expression of the action of an electric field on a given electronic transition. Maxwell equations are then modified to couple P to the EM fields. A rate equation model for a 4-level system completes this description to give the quantum temporal evolution of the state densities. The numerical scheme that we use to solve those equations is fully explicit, and is based on the standard FDTD Yee grid. Using this approach we are able to describe nonlinear gain absorption and saturation effect. We study then the optic response of a periodic array of metallic nanoparticles embedded in gain media, and we demonstrate a lasing action featuring in a stimulated emission peak in the far-field accompanied by nanoscale energy conversion in the near-field. Moreover, we investigate theoretically the effect of the enhancement of the decay rate,the so-called Purcell factor on the threshold intensity.

8809-78, Session 18

Coherent plasmonic engineering using self-assembled reduced symmetry nanostructures

Sushmita Biswas, Jinsong Duan, Krishnamurthy Mahalingam, Dhriti Nepal, Dean Brown, Lawrence F. Drummy, Ruth Pachter, Richard Vaia, Air Force Research Lab. (United States)

Plasmonic metamaterials have emerged as an area of significant interest since they enable design of tools for ultra sensitive chemical and bio-sensing, single molecule detection, nanolasing, spectroscopy, photovoltaics and photodetection. They offer a convenient platform for the study of different coherent phenomena including plasmonic electromagnetically induced transparency (EIT), Fano resonances, super-radiance and sub-radiance owing to the tunability of the interaction parameters through the geometry and design of the system. Although it is theoretically possible to observe some of these effects in simple plasmonic shapes like spheres, in practice large damping effects make them impractical to use. Symmetry breaking allows stronger coupling between the dark and bright modes in plasmonic systems manifesting these effects. We will demonstrate multiple coherent effects in self-assembled reduced symmetry gold nanorod nanosystems in particular heterodimer and Dolmen configurations enabled by the high quality and low radiative losses due to reduced surface scattering from crystalline units, of the plasmonic structures fabricated by bottom-up chemical approach. Optical characterization performed by single particle dark-field scattering microscopy correlated with scanning electron microscopy revealed multiple dark and bright plasmonic resonances in these reduced symmetry structures. Direct excitation of the resonances with electron energy loss spectroscopy further revealed the gap modes as well as the dark and bright modes in these structures. These self-assembled reduced symmetry structures demonstrate a route to improving the quality of the plasmonic structures and will be of significant interest for future design of nanophotonic devices including single photon sources, nanolasers and displays.

8809-79, Session 18

Design of a bull's eye structure based upon the far-field scattering of a subwavelength aperture

Akira Yamada, Mitsuhiro Terakawa, Keio Univ. (Japan)

The extraordinary optical transmission of light through a bull's eye structure (also referred to as a surface plasmon antenna) has been receiving much attention. A variety of recipes have been suggested for the optimization of the geometrical parameters. However, many of the previous studies show methods of optimization empirically. We present a novel concept on designing a bull's eye structure with enhanced optical transmission of a single-wavelength optical source. By using finite-difference time-domain method, we calculated the electric field intensity of the far-field scattering of a subwavelength aperture on a thin gold film. Based on the peak positions of the concentric electric field intensity on the film surface, we determined the optimal positioning between the central aperture and its nearest groove. A fairly optimal periodicity of the groove structure can be determined from the same concentric electric field intensity distribution. By improving other structural parameters on the basis of the parameters determined above, we have succeeded in designing a bull's eye structure with a transmission factor of 60.9. Transmission of light was normalized to the hole area for calculations. Our method of designing a bull's eye structure for enhanced transmission of a single-wavelength optical source is performed under a novel idea, contributing to applications such as enhancing sensitivity of silicon infrared sensors.

8810-1, Session 1

Measurement of the range and transport properties of optical tractor beams

David B. Ruffner, David G. Grier, New York Univ. (United States)

An optical tractor beam is a travelling beam of light that transports material back to its source. Several schemes to create such a beam have been proposed and a few have been successfully demonstrated experimentally, among these optical conveyors that deterministically transport micrometer-scale objects. In addition to their useful and interesting transport properties, optical conveyors have been predicted to act as optical traps with exceptionally large axial trapping stiffness.

Here, we describe recent measurements of the transport properties and trapping characteristics of optical conveyors projected with the holographic optical trapping technique.

These measurements reveal how these practical tractor beams' capabilities will differ from predictions of idealized models as their range is extended from micrometers to millimeters and beyond.

8810-2, Session 1

Experimental demonstration of optical transport, sorting and self-arrangement using a 'tractor beam'

Oto Brzobohatǵ, Vitezslav Karasek, Martin Siler, Lukas Chvatal, Institute of Scientific Instruments of the ASCR, v.v.i. (Czech Republic); Tomás Cižmár, Univ. of St. Andrews (United Kingdom); Pavel Zemánek, Institute of Scientific Instruments of the ASCR, v.v.i. (Czech Republic)

We experimentally and theoretically demonstrate particles delivery sorting in the geometry of "tractor" beam. Particles direction is controlled by polarization of incident beams. Since the particles motion depends on their size, we also demonstrate optical sorting of colloidal particle suspension (i.e. mixture of micrometer-sized particles of various diameters or compositions) by Gaussian beam of diameter 60-100 micrometers. We observed self-arrangement of microparticles into optically bound structures that significantly changed their behaviour in "tractor"beam.

8810-3, Session 1

(Not) just torquing around

Gabriel C. Spalding, Illinois Wesleyan Univ. (United States); Christine E. M. Demore, Zhengyi Yang, Institute for Medical Science & Technology (United Kingdom); Patrick M. Dahl, Illinois Wesleyan Univ. (United States) and Institute for Medical Science & Technology (United Kingdom); Peter Glynne-Jones, Univ. of Southampton (United Kingdom); Andreas Melzer, Michael P. MacDonald, Sandy Cochran, Institute for Medical Science & Technology (United Kingdom)

Modern studies have reshaped our thinking about the linear and angular momentum carried by light (and other wave/particle bombardments), and about both the mathematical bases and language used for thinking about transfer of momentum by propagating beams. Acoustic analogies can play (and have played) a useful role in clarifying the meaning of some recent predictions, and in raising issues regarding the language in common usage for describing transfer of beam momentum. For a wide range of topological charges, we have simultaneously measured the transfer of (so-called "orbital") angular momentum and the axial "radiation pressure" acting upon an acoustically levitated absorber, resulting in a simple, direct demonstration of theoretical predictions for the ratio of these two effects. We have also examined the influence of locally off-axis "skew" momentum in contexts receiving significant recent attention.

8810-4, Session 1

Negative optical forces at dielectric interfaces for long range particle manipulation

Veerachart Kajorndejnukul, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States); Weiqiang Ding, National Univ. of Singapore (Singapore); Sergey V. Sukhov, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States); Cheng-Wei Qiu, National Univ. of Singapore (Singapore); Aristide C. Dogariu, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

Optical "tractor beams" have attracted much interest recently because of their intriguing capabilities for micromanipulation. A tractor beam can exert a "negative" force (NF) that pulls the scatterer in a direction opposite to the propagation of light, in contrast to the usually "positive" push exerted by radiation pressure. The fundamental requirement for NF to occur is the increase of the momentum of light during the process of light scattering. Approaches known so far require non-paraxial incident beams or some exotic media such as gain media for NF to appear. We demonstrate that stable NFs are possible even when using unstructured paraxial beams without presence of any gain or left-handed media. Our approach is based on universal characteristics of optical forces acting on objects at the interface between different dielectric media. Namely, according to Minkowski's momentum transformation theory, when going from medium with lower to higher refractive index, the momentum of light should increase. To verify the concept of the surface assisted NF, we performed a systematic experiment with surface bound dielectric microscopic objects. We demonstrate distinct directional motion against the beam propagation over distances of approximately 200um. The experiment provides new insights for understanding surface effects in momentum exchange and can also assist in developing and evaluating microscopic theories of optical forces at interfaces. The simple scheme and the robust experimental implementation may find a plethora of applications in developing novel micromanipulation approaches and for studying interfacial phenomena.

8810-5, Session 1

Properties of oscillating refractive optical wings with one reflective surface

Alexandra B. Artusio-Glimpse, Timothy J. Peterson, Grover A. Swartzlander Jr., Rochester Institute of Technology (United States)

In the last few decades, progress in the development of optical micromanipulation technologies has been extensive with the integration of phase modulation elements and other beam shaping devices, yet there is still room to grow in the realm of object shaping. Object shaping is the use of microscopic optical elements with specified geometric designs that allow forces from radiation pressure to be predefined without the need for specialized light sources. Optical wings are refractive cambered rods that experience a transverse lifting force under uniform illumination. When rotated away from normal incidence, a specialized optical wing has an intrinsic restoring torque that returns the wing to a sun-facing (or source-facing) orientation. This discussion will address how such

wings may be designed to sustain efficient thrust while also providing significant restoring torque to the wing. This is accomplished by the inclusion of a reflective surface on the refractive wing. Torsional stiffness and orbital periods will be presented for a set of optical wings. Effects of broadband illumination, drag, and gravity will be considered using numerical results from ray-tracing analyses. These results demonstrate the potential for development of passive sun-tracking devices for applications in microbiology and space flight systems. Object shaping presents a second modality for control in optical micromanipulation, and with further development of optical wings new applications may be afforded that today are not possible. Our goal is to inspire researchers to look to optical wing technology as a potential solution to the specialized problems in their own research.

8810-6, Session 1

Non-conservative scattering forces on small particles

Manuel I. Marques, Juan José Sáenz, Univ. Autónoma de Madrid (Spain)

Light forces on small particles may be described as the sum of the dipole or gradient force and the radiation pressure or scattering force [1,2]. Radiation pressure is traditionally considered proportional to the Poynting vector. However, for inhomogeneous waves, there is an additional contribution to the scattering force that can play an important role in determining the actual forces on nanometer sized particles [3]. This additional contribution has been shown to be proportional to the curl of the spin angular momentum of the light field [4], affecting to dielectric and magneto dielectric particles [5-7].

In some specific cases like, for example, crossed circularly polarized standing waves, the field distribution shows regions in which the electric and magnetic fields are parallel corresponding to a null Poynting vector [8]. Although the average value of the momentum density, proportional to the Poynting vector, is zero in these regions, there are scattering forces acting on small dielectric particles due to light's spin force. We will discuss the differences between crossed linear [9-11] and circularly polarized waves and the intriguing interplay between the momentum and spin densities and the force on magneto-dielectric particles.

8810-7, Session 1

Optical forces controlled by the photons spin

Georgiy V. Tkachenko, Etienne Brasselet, Univ. Bordeaux 1 (France)

Optical radiation forces are the mechanical manifestation of the transfer of the linear momentum of light to matter, which basically occurs when light is reflected, refracted, scattered or absorbed in the course of its propagation. Here we report on the full control of the optical radiation pressure at fixed photon flux and incident angle by controlling the photon spin. The experimental demonstration is achieved by using transparent microspheres with typical size of 10 micrometers that enable a strong coupling between linear and angular degrees of freedom of a light field. As result the spin of photons can be used to fully control optomechanical effects driven by the radiation pressure of light. A careful analysis of the possible contribution of the usual optical scattering force is considered and an experimental arrangement is proposed to cancel its contribution in our experiments. This allows us to present an unambiguous demonstration that is quantitatively validated analytically with a good agreement. Moreover, envisioned applications are discussed and experimental proofs-of-principle are presented. These results should contribute to the development of optofluidics and application potential is expected, for instance for the pharmaceutical industry, angular momentum driven nanoactuation or optical sailing.

8810-8, Session 2

Tweezing at extremes *(Invited Paper)*

Miles J. Padgett, Richard Bowman, Graham M. Gibson, Univ. of Glasgow (United Kingdom); Filippo Saglimbeni, Roberto Di Leonardo, Univ. degli Studi di Roma La Sapienza (Italy)

Diamond anvil cells allow the behavior of materials to be studied at pressures up to hundreds of gigapascals in a small and convenient instrument. However, physical access to the sample is impossible once it is pressurized. We show that optical tweezers can be used to hold and manipulate particles in such a cell, confining micron-sized transparent beads in the focus of a laser beam. Here, we use a modified optical tweezers geometry, allowing us to trap through an objective lens with a higher working distance, overcoming the constraints imposed by the limited angular acceptance of the anvil cell. We demonstrate the effectiveness of the technique by measuring water's viscosity at pressures of up to 1.3 GPa. In contrast to previous viscosity measurements in anvil cells, our technique measures absolute viscosity and does not require scaling to the accepted value at atmospheric pressure. This method could also measure the frequency dependence of viscosity as well as being sensitive to anisotropy in the medium's viscosity.

8810-9, Session 2

Optical fabrication and manipulation of semiconductor nanoparticles in superfluid helium

Yosuke Minowa, Yohei Nawaki, Shinya Okamoto, Masaaki Ashida, Osaka Univ. (Japan)

Non-contact manipulation technique of semiconductor nanoparticles or quantum dots is demanding and challenging, which will expand the possibilities to construct quantum-dot-based devices through bottom-up approach. In particular, the technique available under low temperature condition is crucial, because their quantum nature will disappear as the temperature increases. Optical manipulation is one of the widely accepted techniques to control the motion of microparticles and atoms, which utilizes light pressure or light momentum transfer to change the material's momentum. However, researches on optical manipulation of semiconductor nanoparticles are scarce. The difficulties arise from the relatively small polarizability, which normally tends to decrease with decreasing the particle's size in nanometer regime. Here we report on the transportation of ZnO nanoparticles in superfluid helium with the aid of the light pressure. The nanoparticles were fabricated via laser ablation of ZnO sintered tablets in superfluid helium. Many micro/nanoparticles were dispersed after the ablation. Only the nanoparticles were transported

in-situ with the irradiation of the exciton-resonant light. The excitonic resonance is expected to enhance the light matter interaction at low temperature. The transported nanoparticles showed strong ultraviolet and weak visible luminescence at room temperature. This indicates that the nanoparticles contain fewer defects than the original target tablet. Our successful implementation of the optical manipulation under low temperature condition would open up a new route for precision control of the nanoparticle motion.

8810-10, Session 3

Testing quantum physics in space using optically trapped nanospheres *(Invited Paper)*

Rainer Kaltenbaek, Univ. Wien (Austria)

What is the reason for the striking difference between the microscopic quantum world and the macroscopic classical world? Is it only quantum decoherence or is there an unknown mechanism leading to the decoherence of increasingly massive objects? This question has been investigated in matter-wave experiments with ever larger objects, but these experiments quickly approach the limits of what is still possible on Earth (time of flight, low-vibration environment). At the same time, there has been impressive progress in space technology, and space is becoming a promising alternative for tests of quantum physics with massive objects. For example, high-precision accelerometers and micro-propulsion can provide a micro-gravity environment far better than what is achievable on Earth, and optical technology, like that developed for LISA Pathfinder, paved the way for quantum optomechanical experiments in space. Here, we will present results of recent studies aiming at the realization of a space mission testing the foundations of quantum physics in a parameter regime far beyond that of existing experiments. In particular, we will discuss DECIDE, where a dielectric nanosphere is prepared in a Schrödinger-cat-like state of being in two clearly distinct positions at the same time. This leads to double-slit-type interference with a visibility we can then compare to the predictions of quantum theory. With DECIDE, it will be possible to distinctly test several prominent theoretical models that predict deviations from quantum theory - for example: the Diósi-Pensrose model, the continuous-spontaneous-localization model of Ghirardi, Rimini, Weber and Pearle, and the model of Károlyházy.

8810-11, Session 3

Realisation of a microscopic gyroscope by an optically trapped rotating microparticle in vacuum

Yoshihiko Arita, Michael Mazilu, Kishan Dholakia, Univ. of St. Andrews (United Kingdom)

The interaction between light and matter on very small energy scales has emerged as a powerful playground for the elucidation of many physical principles. In this arena, cavity optomechanics has promised new insights into the interplay between optics and quantum physics for macroscopic objects [e.g. Chang et al, PNAS 107, 1005, 2010]. As such there has been a drive for quantum state preparation using macroscopic objects [e.g. Li et al, Nat. Phys. 7, 527, 2011]. Remarkably, rotating objects at absolute zero temperature can spontaneously emit energy, and thus exerts pressure on a nearby object (dynamic Casimir effect) due to quantum fluctuations [e.g. Manjavacas et al, PRA 82, 063827, 2010]. However, to date, there is a notable absence of appropriate experimental systems to explore such regimes. To address this challenge we demonstrate the simultaneous optical trapping and rotation of a microparticle in vacuum. A birefringent microparticle is rotated by a circularly polarized trapping laser beam at rates exceeding 5MHz. Parametric coupling between the rotational and translational degrees of freedom of the trapped object, offers original perspectives on particle dynamics. We show a direct observation of spin stabilization of the trapped particle along the rotational axis in the absence of any "active" feedback method both in experimental and theoretical studies. We attribute this self-stabilization of the rotating particle akin to a microscopic gyroscope effect. This system presents a powerful route to explore new directions in cavity optomechanics and a step towards measuring rotational frictional forces both adjacent to surfaces and in vacuum.

8810-12, Session 3

Micromanipulation of multiple trapped, rotating particles in vacuum

Sayantan Ghosh, Yoshihiko Arita, Tom Vettenburg, Michael Mazilu, Kishan Dholakia, Univ. of St. Andrews (United Kingdom)

Investigation of challenging fundamental phenomena such as mesoscopic quantum entanglement requires cooling of the mechanical modes of oscillators to their quantum ground motional states. To reach this regime, the coupling between objects and their thermal environments must be minimized which in turn limits decoherence in the system. In this context, optical trapping of microparticles in vacuum is an ideal system for investigating the quantum-classical interface, due to its near-perfect isolation from the thermal environment. Recent advances have made cooling of an optically trapped single microparticle with counter propagating dual beams to millikelvin temperatures using active feedback cooling methods. Herein, we demonstrate a compact holographic optical tweezers system to simultaneously trap and rotate multiple microparticles in vacuum. The unixial crystals of vaterite mircoparticles of 4.4mum in diameter are trapped in vacuum with circularly polarized light at aberration corrected multiple foci, which are generated by a spatial light modulator (SLM). The positions of the individual trapped particles are controlled by dynamic reconfiguration of the SLM masks, which allows a minimum particle seperation of $1mu$m. We can simultaneously record the translational and rotational motion for all trapped objects using a single photo-detector. Rotation rates of up to $lesssim1$MHz (with higher harmonics) accompanied by sidebands are observed in a series of power spectra in a wide range of vacuum pressures. The ability to "trap and track" multiple particles in vacuum could possibly lead to the development of powerful optical methods to explore the quantum-classical interface while also paving the way to study fundamental processes such as rotational vacuum friction.

8810-13, Session 3

Quantitatively measuring the orbital angular momentum density of light

Angela Dudley, CSIR National Laser Ctr. (South Africa); Christian Schulze, Friedrich-Schiller-Univ. Jena (Germany); Igor A. Litvin, CSIR National Laser Ctr. (South Africa); Michael Duparré, Friedrich-Schiller-Univ. Jena (Germany); Andrew Forbes, CSIR National Laser Ctr. (South Africa)

Although many techniques are efficient at measuring optical orbital angular momentum (OAM), they do not allow one to obtain a quantitative measurement for the OAM density across an optical field and instead only measure its global OAM. Numerous publications have demonstrated the transfer of local OAM to trapped particles by illustrating that particles trapped at different radial positions in an optical field rotate at different rotation rates. Measuring these rotation rates to quantitatively extract the OAM density is not only an indirect measurement but also a complicated experiment to execute. In this work we theoretically calculate and experimentally measure the OAM density of light, for both symmetric and non-symmetric optical fields. We outline a simple approach using only a spatial light modulator and a Fourier transforming lens to measure the OAM spectrum of an optical field and we test the approach on superimposed non-diffracting higher-order Bessel beams. We obtain quantitative measurements for the OAM density as a function of the radial position in the optical field for both symmetric and non-symmetric superpositions, illustrating good agreement with the theoretical prediction. The ability to measure the OAM distribution of optical fields has relevance in optical tweezing, and quantum information and processing.

8810-14, Session 3

Feedback enhanced precision in optomechanical sensors

Warwick Bowen, Glen I. Harris, David L. McAuslan, Joachim Knittel, The Univ. of Queensland (Australia); Ulrik L. Andersen, Technical Univ. of Denmark (Denmark)

The problem of estimating an unknown force driving a linear oscillator is revisited. When using linear measurement, feedback is often cited as a mechanism to enhance bandwidth or sensitivity. We show that as long as the oscillator dynamics are known, there exists a real-time estimation strategy that reproduces the same measurement record as any arbitrary feedback protocol[1]. Consequently some form of nonlinearity is required to gain any advantage beyond estimation alone. This result holds true in both quantum and classical systems, and in the general case of non-Gaussian noise. Recently, feedback enhanced incoherent force sensing has been demonstrated [Nat. Nano. 7, 509 (2012)], with the enhancement attributed to a feedback induced modification of the mechanical susceptibility. As a proof-of-principle we experimentally reproduce this result through straightforward filtering[1]. To prove the benefit of feedback when nonlinearities are present we apply feedback induced damping to suppress the mechanical parametric instability of a microtoroid cavity optomechanical system. This enables a 5.4 fold sensitivity improvement, with a final displacement sensitivity of 1.8 attometers-per-root-Hz[2]. This is the first time feedback has been used to enhance sensitivity in cavity optomechanics. By clearly demarcating where feedback offers an advantage, our results both clarify a significant ambiguity in the optomechanics and force sensing communities, and contribute towards ultraprecise force sensing with linear oscillators.

[1] G. I. Harris et al. Minimum requirements for feedback enhanced force sensing. Submitted to Phys. Rev. Lett. (2013).

8810-15, Session 3

Enhancing micromechanical measurement with squeezed light

Warwick Bowen, Univ. of Queensland (Australia); Glen I. Harris, The Univ. of Queensland (Australia); Ulrich B. Busk-Hoff, Technical Univ. of Denmark (Denmark); Jiri Janousek, Vincent R. Daria, The Australian National Univ. (Australia); Joachim Knittel, The Univ. of Queensland (Australia); H. Kerdoncuff, Technical Univ. of Denmark (Denmark); B. Hage, The Australian National Univ. (Australia); Ulrik L. Andersen, Technical Univ. of Denmark (Denmark); H. A. Bachor, The Australian National Univ. (Australia)

The quantum nature of light places a fundamental limit on the sensitivity of optical measurements. In circumstances with constrained optical power, this limit may only be surpassed using non-classical resources. Despite the promise of non-classical resources, to date the sole example of a real application is in interferometric gravity wave detection where the optical power is constrained due to absorptive heating. Much broader and widely discussed applications are possible in the areas of quantum optomechanics, where ultimately a non-classical light field interacts with a non-classical mechanical oscillator, and biological sensing, where low light levels are often required to avoid damaging the specimen. Here we report two distinct experiments which use squeezed light to, for the first time, achieve quantum enhanced sensitivity in biological[1] and cavity optomechanical contexts[2], with 2.7 and 0.7 dB of enhancement achieved, respectively. The biological experiments, particularly, allow quantum enhanced microrheology to be performed on the cytoplasm of a Saccharomyces cerevisiae yeast cell, revealing subdiffusive motion with 64% improved bandwidth over the equivalent classical measurement. This provides a pathway towards microrheology of cell mechanics and the cytoskeleton at high frequencies, where motion amplitudes are beneath the sensitivity of current technology. These results present an important first step towards both surpassing the standard quantum limit of measurements using non-classical light, and applications of quantum light in biology.

8810-16, Session 3

Optomechanics at microwave frequencies: mechanical resonators coupled to microwave cavities and superconducting qubits

Mika A. Sillanpää, Aalto Univ. (Finland)

Micromechanical resonators affected by radiation pressure forces allow to address fundamental questions on quantum properties of mechanical objects, or, to explore quantum limits in measurement and amplification. A new setup for the purpose is an on-chip microwave cavity coupled to a mechanical resonator. We run various experiments in the setup. Under blue sideband irradiation, we demonstrate the possibility of building a mechanical microwave amplifier, with noise properties approaching the quantum regime. On the red sideband side, we show how one can couple mechanical resonators via the cavity bus, while simultaneously cooling the mechanical modes very close to the ground state of motion.

One can add intriguing features to the setup by including a superconducting qubit, a quantum two-level system. Such a hybrid approach will allow for combining the benefits of each subsystem, such as the long lifetime of phonons, together with the machinery learned with superconducting qubits. Our superconducting transmon qubit interacts with a 70 MHz phonon mode in a micromechanical resonator. We operate the qubit in the circuit cavity quantum electrodynamics (circuit QED) architecture, where the qubit is coupled also to a microwave cavity. Hence, the combined setup represents an artificial atom coupled to two different cavities. We measure the phonon Stark shift, as well as the splitting of the qubit spectral line into motional sidebands, which feature transitions between the dressed electromechanical states. In the time domain, we observe coherent conversion of qubit excitation to phonons as sideband Rabi oscillations.

8810-17, Session 3

Title to be announced *(Invited Paper)*

8810-18, Session 4

Effective medium approach to compute optical stress

Jack Ng, Hong Kong Baptist Univ. (Hong Kong, China); Che TIng Chan, Hong Kong Univ. of Science and Technology (Hong Kong, China); Wujiong Sun, Fudan Univ. (China)

Light can exert a force on material objects, which may be computed by a surface integral of the Maxwell stress tensor over a surface that encloses the entire object. However, it is also highly desirable to know the optical stress (e.g. to deform a cell). In principles, the stress can be given by the divergence of the stress tensor. Unfortunately, there are still controversies in what is the appropriate stress tensor inside a medium.

Consider an artificial effective medium, for example, consisting of a periodic or random array of dielectric cylinders with sub-wavelength cylinder size and lattice constant. The stress will be calculated by two

methods. The first method is a rigorous but slow microscopic approach where the stress is defined as the force per unit area, and the force can be computed by Maxwell stress tensor. The second method is a very efficient effective medium approach where the cylinder array is treated as an effectively homogeneous medium and the stress for that effectively homogeneous medium is calculated directly using the divergence of three commonly employed stress tensors. It turns out that only the stress tensor derived from free energy, which takes into account the electrostriction, gives consistently correct results. In other words, MST and its "macroscopic generalization" have failed.

Situations other than dielectric cylinders will also be discussed. More examples with different composition and lattice structures will be considered.

8810-19, Session 4

The kinetic subsystem of light and its role in optical manipulation

Brandon A. Kemp, Arkansas State Univ. (United States)

Optical manipulation has allowed for an increase in understanding across scientific fields including biology, chemistry, and atomic physics. Unfortunately, there is still significant debate as to how the dynamics of optical-matter systems should be modeled. The reason for this is the myriad of formulations for the electromagnetic momentum and force density. While significant advances have been made in recent years to interpret the different formulations of electrodynamics, there remains some confusion. Most formulations include contributions from both matter and field. They may be interpreted as providing the canonical, total, or wave momentum, stress, and force. Examples include the well-known Gordon and Minkowski momenta. Conversely, it is widely accepted that the Abraham momentum of light corresponds to the kinetic subsystem. Changes in the kinetic momentum thus should provide center of mass-energy translations of matter providing a route to deriving equations of motion in optical manipulation experiments. In this paper, the idea of a kinetic formulation of electrodynamics is discussed. Consideration will be given to the three viewpoints which are most commonly argued. First, the kinetic subsystem should be postulated as a fundamental tenant of electrodynamics. Second, the kinetic subsystem of electrodynamics should not be postulated, but rather deduced by experimental and theoretical considerations. Third, a kinetic subsystem of electrodynamics cannot be uniquely defined in matter because the fields inside matter cannot be uniquely measured. Finally, it will be argued that identification of the kinetic subsystem of a particular optical manipulation experiment is not necessary nor preferred in most cases.

8810-20, Session 4

Electromagnetic field and force distribution inside matter

Masud Mansuripur, College of Optical Sciences, The Univ. of Arizona (United States); Armis R. Zakharian, Corning Incorporated (United States)

Using the Finite Difference Time Domain (FDTD) technique, we use numerical solutions of Maxwell's equations to compute the distribution of electromagnetic fields and forces inside material media. The media are generally specified by their dielectric permittivity epsilon(w) and magnetic permeability mu(w), representing small, transparent dielectric/magnetic objects such as micro-beads. Using two formulations of the electromagnetic force density, one due to H.A. Lorentz (1892), the other due to Einstein and Laub (1908), we show that the distribution of force inside a given object can differ substantially between the two formulations. This is remarkable, considering that the total force experienced by the object is always the same, irrespective of whether the Lorentz or the Einstein-Laub formula has been employed, The differences between the two formulations should be accessible to measurement in deformable objects.

8810-21, Session 4

Optical forces on particles embedded in a dispersive medium *(Invited Paper)*

Israel De Leon, Sangeeta Murugkar, Zahirul Alam, Eliot Bolduc, Univ. of Ottawa (Canada); Robert W. Boyd, Univ. of Ottawa (Canada) and Univ. of Rochester (United States); Mohammad Mirhosesini, Mahmudur Siddigui, Omar Magaña-Loaiza, Univ. of Rochester (United States); Jerry W. Kuper, TOPTICA Photonics, Inc. (United States); Peter W. Milonni, Univ. of Rochester (United States); Zhimin Shi, Univ. of South Florida (United States)

Theoretical arguments suggest that the magnitude of the force exerted by a light beam on a dielectric particle may depend on the group index of the particle and on the group index of the medium that surrounds it. Since group indices can vary over a significant range, this observation suggests that significant control of optical forces may be achievable.

In this work we describe the status of our experimental effort aimed at determining the dependence of optical forces on group and refractive indices. We also discuss how laboratory results of this sort can help distinguish between the Abraham and Minkowski models for the momentum of a photon in a material medium.

8810-22, Session 4

Holographic reconstruction of optical forces *(Invited Paper)*

Gregor Thalhammer, Andreas Niederstätter, Stefan Bernet, Monika Ritsch-Marte, Innsbruck Medical Univ. (Austria)

According to Newton's law, collecting the light deflected from a trapped particle with a high-NA condenser lens and imaging the intensity distribution at the back-focal-plane provides direct information on the trapping force. This approach has been used to monitor the (radial and axial) optical force acting on a single trapped particle of arbitrary shape. We show that this approach can become even more powerful when combined with holographic reconstruction of the scattered light field. With phase and intensity information at hand, it is possible to simultaneously measure the force on several particles, and to assign each particle its own local force profile.

8810-23, Session 5

Quasi-Bessel hollow beam as optical guide for micro-particles

Andrei V. Rode, The Australian National Univ. (Australia); Li Li, The Australian National Univ. (Australia) and Sun Yat-Sen Univ. (China); Niko Eckerskorn, The Australian National Univ. (Australia); Richard A. Kirian, Deutsches Elektronen-Synchrotron (Germany); Jochen Kuper, Deutsches Elektronen-Synchrotron (Germany) and Univ. Hamburg (Germany); Daniel P. De Ponte, Deutsches Elektronen-Synchrotron (Germany); Wieslaw Z. Krolikowski, The Australian National Univ. (Australia); Henry N. Chapman, Deutsches Elektronen-Synchrotron (Germany) and Univ. Hamburg (Germany)

Coherent diffractive x-ray imaging of individual biological macromolecules with Free Electron Lasers (FEL) requires a "touch-free" high-precision particle injection method to deliver individual biological molecules or nanoparticles into the micron-sized focus of an x-ray beam, both in vacuum or in a gas environment, and operating collinear with a particle laden gas stream produced by an aerodynamic lens. To address this challenge we developed an optical quasi-Bessel pipeline with a hollow core for guiding particles to a focal spot of FEL of ~3 μm

in diameter. We generated the superposition of the quadratic phase of a lens and an axicon with a 0.5° base angle using a phase-only spatial light modulator (SLM) to form a low-diverging first order Bessel beam. The beam was further re-imaged to form a centimetre-long 'syringe' beam with ~7μm diameter and approximately 2000 length-to-diameter aspect ratio. The divergence of the beam was controlled by changing the effective focal lens in the hologram. The SLM-based optical beam was compared with a similar beam composed using physical optical elements. When used in conjunction with an aerodynamic lens the optical forces assist the migration of particles to the centre of the gas flow. The experimental tests were conducted with 5-μm size graphite spherical particles to evaluate the optical force and to estimate the scaling to sub-micron particle size. We present estimated optical forces exerted on the particles and the stiffness of trapping in the transverse plane, both depending on the particle size, optical reflectance, laser power, and background-gas pressure.

8810-24, Session 5

Manipulation of optically levitated particles

Oscar K. Isaksson, Magnus Karlsteen, Chalmers Univ. of Technology (Sweden); Dag Hanstorp, Göteborgs Univ. (Sweden)

We are able to levitate a single oil drop for up to six hours, inside a glass cell, using a vertically aligned laser beam. The drop is trapped just above the focus formed by a 30mm lens. The drop is then made to oscillate in an AC-field applied over the cell. The amplitude of the movement is large enough to be observed by the bare eye.

Scattered light from the laser beam is imaged on a position sensitive detector. The amplitude of the oscillations depends on the amplitude of the electric field and the q/m ratio of the oil drop. The charge is reduced by exposing the drop to alpha particles. The absorption of an alpha particle causes electrons to be detached from the drop. During exposure we observe distinct reductions in the amplitude of the oscillations, and after some time the oscillations starts to increase in amplitude again. The phase of the oscillations with respect to the driving AC electric field then reverses. This means that all excess electrons have been removed, and the drop is now positively charged.

As the next step, we will investigate the size of the reduction in the steps, with the aim to determine how many electrons that are removed by each alpha particle. The ultimate goal is to observe the sequential removal of single electrons from the drop.

8810-25, Session 5

Optically trapped aerosol dye laser

Alper Kiraz, Alexandr Jonas, Yasin Karadag, Mehdi Aas, Koç Univ. (Turkey); Suman Anand, David McGloin, Univ. of Dundee (United Kingdom)

Airborne particles such as aerosols can be readily localized and studied over long periods of time using optical tweezers. Aerosols can also be used as a microcavity to create lasers if the aerosol contains a gain material. The ability to hold such small lasers opens up new possibilities in sensing and may offer new ways to probe airborne particles, while the control over droplet dynamics that can be achieved suggests that tunable laser sources could be produced. Among different methods for manipulating aerosols, optical trapping stands out due to its flexibility as compared to electrodynamic or acoustic trapping. Manipulation of very small droplets is particularly challenging for the case of acoustic trapping. Optical tweezers are well suited for very small droplets and are readily adaptable to manipulate large numbers of particles. Optical manipulation techniques have been used to trap lasing solid microspheres or lasing droplets emulsified in a host liquid before. Here, we demonstrate lasing from optically trapped liquid aerosols.

We have used a CW infrared laser (1064 nm, 300 mW maximum power) and pulsed green laser (532 nm, 20 ns pulsewidth, 33 kHz repetition rate) for trapping and pumping, respectively. Aerosols were generated using an ultrasonic nebulizer from a 39 % glycerol/water solution doped with 1 mM Rodamine B dye. Nonlinear dependence was observed between the intensity of a whispering gallery mode exhibiting lasing and the pump laser power. Experiments performed with different microdroplet sizes also revealed blue tuning in the average lasing wavelength with decreasing droplet size.

8810-26, Session 6

Light-assisted, templated self-assembly using a photonic-crystal slab *(Invited Paper)*

Eric Jaquay, Luis Javier Martinez Rodriguez, Camilo A. Mejia Prada, Michelle L. Povinelli, The Univ. of Southern California (United States)

The force that light exerts on objects provides tremendous flexibility for trapping and manipulation on the nanoscale. While conventional optical tweezers make use of the optical gradient force arising from a tightly-focused laser beam, recent work has leveraged the strong electromagnetic field gradients near microphotonic devices to manipulate particles. Microphotonic devices such as nanoapertures, plasmonic devices, slot waveguides, microring resonators, and photonic-crystal cavities have all been used for optical trapping. However, such work has largely focused on trapping either single particles or small numbers of particles.

Recently, we have proposed to use optical forces near microphotonic devices for a fundamentally different purpose: to assemble periodic arrays of nanoparticles resembling synthetic, 2D crystals. Our approach, which we call light-assisted, templated self-assembly (LATS), exploits photonic-crystal slabs to create resonantly-enhanced optical forces more than four orders of magnitude larger than radiation pressure. The assembled nanoparticle arrays can be viewed as a form of programmable "optical matter:" by adjusting the wavelength or polarization of the input laser, crystalline structures can be assembled and disassembled in a reconfigurable fashion. Unlike traditional colloidal self-assembly, for which free energy minimization results in hexagonal, close-packed structures, our process is not subject to such constraints. Instead, the use of light to drive the system dramatically alters the underlying potential landscape, allowing for the formation of complex lattices and multiparticle clusters. Here, we provide the first experimental demonstration of the LATS method, assembling a square array of over 100 polystyrene particles in the near field of a silicon photonic-crystal slab.

8810-27, Session 6

High-frequency nano-optomechanics: an exploration at the boundary between photonics, mechanics, and microwaves *(Invited Paper)*

Xiankai Sun, Hong Tang, Yale Univ. (United States)

We will first review recent progress on cavity optomechanics and then talk about our work on integrated nano-optomechanical devices that operate at high frequencies (beyond 1 GHz). Their applications and the directions for future research will also be discussed.

8810-28, Session 6

Single element fiber optic nanomechanical transducers

Donald J. Sirbuly, Ilsun Yoon, Univ. of California, San Diego (United States)

The ability to observe, measure and manipulate individual molecular interactions and mechanical phenomena is central to our understanding of complex chemical pathways and biological processes. Detecting single molecule properties such as conformational changes, intramolecular distances, adhesion forces, or monitoring nanomechanical deformations of cellular components is currently accomplished by using sophisticated techniques such as scan probe technologies and optical/magnetic traps. Although these instruments have excellent resolution it is difficult to scale down the size of the force transducer and feedback mechanism to < 500 nm while maintaining exceptional resolution and multiplexing capability. The development of compact nanomechanical transducers with simple feedback mechanisms could enable a new breed of intracellular probes and technologies for high-throughput nanomechanical analysis. In this talk I will be present some of our recent work on plasmonic nanoparticle coatings embedded in the decaying evanescent field of subwavelength optical waveguides to measure angstrom-level distance changes and sub-piconewton forces. By leveraging the strong plasmon-dielectric coupling effects that occur between the metal nanoparticles and waveguide surface, distances and forces can be extracted with superb sensitivity by simply monitoring the scattering intensity of the nanoparticles or transmission through the fiber. With a fiber geometry, small size, and ability to monitor multiple nanomechanical events with a single optical input, this platform can be directly integrated into microfluidic chips for sensing and high-throughput applications.

8810-29, Session 6

Optical waveguide loop for planar trapping of blood cells and microspheres

Balpreet S. Ahluwalia, Olav G. Hellesø, Univ. of Tromsø (Norway)

An optical waveguide loop with an intentional gap at the center is proposed for planar transport and stable trapping of microspheres/cells. The waveguide acts as a conveyor belt to transport spheres towards the gap. At the gap, the counter-diverging light fields hold the sphere at a fixed position. Depending on the gap separation (2-50 µm) a single or multiple spheres and cells were trapped at the gap. Optical stacking of trapped spheres and cells was also observed experimentally. Numerical simulation based on the finite element method was performed in three dimensions using a computer cluster. The optical force on a single particle was computed for various positions of the particle in the gap. Simulations predicted that a small sphere could be tightly trapped with a precision of ±0.2 µm along the gap exploiting the interference fringes formed in the gap. This was experimentally confirmed on a sphere of 1 µm diameter in 2µm gap separation. Waveguides were made of tantalum pentoxide material and both strip and rib geometries were fabricated. The strip design provides strongly diverging beams (higher trap stiffness) at the gap, whereas rib design allows maneuvering the location of trapped spheres in the gap. The waveguides are only 180 nm thick and thus could be integrated with other functions on the chip, e.g. microfluidics or optical detection, to make an on-chip system for single cell analysis and to study the interaction between cells. The diverging light at the gap can be used to trap and excite Raman scattering.

8810-30, Session 7

Plasmonic nanotweezers based on Au bowtie nanoantenna arrays for manipulation of nano-to-macroscopic objects *(Invited Paper)*

Kimani C. Toussaint Jr., Brian J. Roxworthy, Univ. of Illinois at Urbana-Champaign (United States)

Plasmonic optical traps, or plasmonic "nanotweezers", have emerged as an attractive alternative for optical manipulation because they circumvent the diffraction limit, producing highly confined and enhanced fields that both relax constraints for microparticle manipulation and offer a route for improving nanoparticle trapping. Here, we present an overview of the use of Au bowtie nanoantenna arrays (BNAs) for plasmonic optical trapping. We show that optical absorption by the BNAs creates Rayleigh-Benard convection currents, and that phase-like behavior of trapped particles can be observed. Furthermore, we demonstrate that the adhesion layer material and nanostructure orientation strongly effect trapping behavior. In addition, we discuss the use of a femtosecond-pulsed source in plasmonic nanotweezers and demonstrate that the fs pulses (1) augment the near-field optical forces compared to a comparable, continuous-wave nanotweezers, and (2) increase the diagnostic capabilities of plasmonic nanotweezers by providing access to the nonlinear optical response of trapped species. Finally, we show for the first time that plasmonic nanoantennas are an effective tool for manipulating particles larger than 50 ?m. Using low-numerical aperture illumination (0.25-0.6 NA), we show that manipulation of these "macroscopic" objects is facilitated by increasing the number of illuminated nanostructures participating in the trapping event. Moreover, the increased weight of larger particles makes trapping robust against destabilizing convection forces. These results open up a new pathway for the usage of plasmonic nanotweezers and may have applications for manipulating Eukaryotic cells, studying self-organization/aggregation of cells, and micro-manufacturing.

8810-31, Session 7

Aperture optical trapping of nanoparticles: towards immunoassay and spectroscopy applications

Reuven Gordon, Abhay Kotnala, Ahmed Al-Balushi, Ana Zehtabi-Oskuie, Univ. of Victoria (Canada)

This work will review our recent advances in optical trapping of nanoparticles using the double-nanohole aperture in a metal film. With the double nanohole, we are able to trap nanoparticles in the few nanometer range, including single proteins. We have recently incorporated flow-channel and spectroscopy capabilities into the trapping setup. This has allowed for the monitoring of protein-antibody binding at the single molecule level, and spectroscopic (Raman) identification of the nanoparticle that is trapped. The prospect of this work towards parallel single-protein trapping platforms for immunoassay applications will be presented.

8810-32, Session 7

Measurement of the signal from a single DNA molecule trapped by a nanoplasmonic structure

Jung-Dae Kim, Waleed Muhammad, Yong-Gu Lee, Gwangju Institute of Science and Technology (Korea, Republic of)

Optical tweezers use focused laser to trap microobjects suspended in the medium to the focal point. They are becoming an indispensable tool in microbiology because of its ability to trap tiny biological particles so that single particle analysis is possible. However, it is still very difficult to trap particles such as DNA molecules that are smaller than the diffraction limit. Although trapping of those is possible by increasing the laser power inversely proportional to the cube of the particle diameter, such high power can cause permanent thermal damages. One of the current solutions to this problem is to intensify the local field by the use of the near-field enhancement coming from nanoplasmonic structures illuminated with lasers. Such solution allows one to use low powered laser and still be able to trap them. In this paper, we present the trapping of a single DNA molecule by the use of the strong field enhancement due to a sub-micrometer sized hole drilled on a gold plate by an e-beam milling process and the trapping is verified by the measurement of the scattering signal that comes from the trapped DNA.

8810-33, Session 7

Plasmon-based optical trapping of soft matter nanoparticles

Yasuyuki Tsuboi, Tatsuya Shoji, Hokkaido Univ. (Japan); Hajime Ishihara, Osaka Prefecture Univ. (Japan)

Optical trapping techniques have been extensively investigated as noninvasive and versatile manipulation tools. With a conventional optical tweezer technique using a focused laser beam, micrometer-sized particles involving artificial beads and living cells can be stably trapped and manipulated at a focal point. However, the techniques still have disadvantages for stable trapping toward further smaller nanoparticles. These disadvantages are, that high laser intensity (≥ MW/cm2) is needed to overcome the Brownian motion of nanoparticle, and the spatial resolution in trapping is limited to more than several hundreds of nanometers due to the diffraction limit of incident light.

On the other hand, combination of optical trapping with metallic nanostructure can potentially overcome these disadvantages on the basis of their capability to enhance an electromagnetic field of incident light by a localized surface plasmon (LSP). Plasmonic nanostructures generate much larger trapping forces using relatively lower incident light intensity as compared with that used in conventional optical tweezers.

In the present study, we report such LSP-based optical trapping for organic nanoparticle systems5. In particular, we investigated trapping behavior for soft matter nanoparticles such as an artificial gel and DNA by means of fluorescence microspectroscopy and microscopic real-time video observation. We discovered unique as well as interesting micro-pattern formation in the trapping. We found that photothermal effects simultaneously induced by laser irradiation may play an important role in trapping and micro pattern formation. For desirable optical trapping, it is very important to precisely control these competing three forces.

8810-34, Session 7

Using fluorescence correlation spectroscopy to measure the gradient optical force in an optical tweezers system

André A. de Thomaz, Diogo B. Almeida, Vitor B. Pelegati, Hernandes F. Carvalho, Carlos L. Cesar, Univ. Estadual de Campinas (Brazil)

Gradient optical forces depend on the cubic power of the particle radius, while scattering forces depend on the sixth power of the particle size. Therefore, optical tweezers can only trap particles larger than 40 to 50 nm at room temperature. Below that size Brownian motion fluctuation energy exceeds the trapping potential. Although one cannot trap the particles, the force gradient is still present and could be studied if we managed to measure this force. On the other hand Fluorescence Correlation Spectroscopy [FCS] has been used to observe Brownian motion of single molecules through the excitation focal volume. The autocorrelation curve will change in the presence of a gradient force and could be used to monitor the optical forces even in the no trapping regime. We used an integrated photonic multimodal platform, equipped with both, Optical Tweezers and FCS, to perform a study of the FCS correlation curve of fluorescent beads as a function of trapping force. We observed the correlation spectra as a function of the trapping power and the particle size, in the whole range of no trapping to trapping situations. The Fourier transform of an autocorrelation curve is the power spectrum itself. Interestingly we observed, the typical Fourier Transform power spectra obtained with quadrant detectors of trapped particles for large particles, such as 5 micron diameter beads. We then studied the correlation spectrum for smaller beads, up to the point we could observe the usual diffusion curve for very small particles and low trapping power.

8810-35, Session 7

Enumerating virus-like particles in an optically concentrated suspension by fluorescence correlation spectroscopy

Yi Hu, Ming-Tzo Wei, Xuanhong Cheng, H. Daniel Ou-Yang, Lehigh Univ. (United States)

Fluorescence correlation spectroscopy (FCS) is a sensitive method for enumerating low concentration naoparticles in suspension. However, clinically relevant concentrations are often lower than the FCS detection limit. Feasibility of FCS for enumerating field-enriched nanoparticles involves understanding of the behavior of nanoparticles in the external field. This paper reports an experimental study that combines optical trapping and FCS to examine existing theoretical predictions. Colloidal suspensions of polystyrene nanospheres and HIV-1 virus-like particles are used as model systems. Optical trapping energies and statistical analysis can be used to predict the potential and the limits of FCS for enumerating optically concentrated nanoparticles.

8810-36, Session 7

Volume phase transition of polymer gel induced by plasmonic optical trapping with infrared light radiation

Kosei Ueno, Sho Nozawa, Hiroko Itoh, Wakako Nakano, Hiroaki Misawa, Hokkaido Univ. (Japan)

Closely-spaced gold nanochain structures whose plasmon resonant wavelength is far-infrared region were fabricated by electron beam lithography and lift-off techniques. To induce volume phase transition of polymer gel owing to radiation force working on nanogap, poly(N-isopropylacrylamide)-sodium acrylate (PNIPAM-SA) co-polymer gel was deposited on the closely-spaced gold nanostructures and subsequently femtosecond or continuous wave (CW) laser beam (10 μm (30 THz) or 10.6 μm (28.3 THz)) was irradiated on the gold nanostructured substrate. When the PNIPAM-SA co-polymer gel was placed on closely-spaced gold nanoparticles and subsequently laser beam was irradiated on them, the volume phase transition of polymer gel was clearly observed even with an irradiation power of 0.1 kW/cm2 under the incident polarization parallel to the nanochain structure. On the other hand, we have confirmed that the volume phase transition of polymer gel was not observed under the incident polarization perpendicular to the nanochain structure. Therefore, we conclude that the volume phase transition of polymer gel was induced since the balance of the osmotic pressure in polymer gel collapsed due to intense radiation force at nanogap. In this system, however, there is a possibility that the volume phase transition was induced by the rise in heat on gold nanostructures based on the plasmon excitation. Therefore, we are trying to perform analogous experiments using polyacrylamide gel which does not effect on temperature and possibility for the infrared sensor.

Information and thermodynamics: experimental verification of Landauer's erasure principle *(Invited Paper)*

Antoine Bérut, Artyom Petrosyan, Sergio Ciliberto, Ecole Normale Supérieure de Lyon (France)

Rolf Landauer argued that the erasure of information is a dissipative process. A minimal quantity of heat, proportional to the thermal energy, is necessarily produced when a classical bit of information is deleted. A direct consequence of this logically irreversible transformation is that the entropy of the environment increases unavoidably by a finite amount. We experimentally show the existence of the Landauer bound in a

Return to Contents

generic model of a one-bit memory. Using a system of a single colloidal particle trapped in a modulated double-well potential, we establish that the mean dissipated heat saturates at the Landauer bound in the limit of long erasure cycles. This result demonstrates the intimate link between information theory and thermodynamics. For a memory erasure procedure, which is a logically irreversible operation, a detailed Jarzynski Equality is verified, retrieving the Landauer limit independently of the work done on the system.

8810-38, Session 8

Particle dynamics and thermodynamics in a virtual potential

John Bechhoefer, Momcilo Gavrilov, Yonggun Jun, Simon Fraser Univ. (Canada)

Feedback, or ABEL traps can create arbitrary virtual potentials for exploring the dynamics of small Brownian particles. In a feedback trap, the particle position is measured periodically and, after each measurement, one applies the force that would be produced by the gradient of the “virtual potential” that is imposed at the particle location.

Virtual potentials differ from real ones in that the feedback loop introduces dynamical effects not present in ordinary potentials. These dynamical effects are caused by small time scales associated with the feedback. The time scales include the delay between the measurement of a particle’s position and the feedback response, the feedback response that is applied for a finite update time, and the finite camera exposure from integrating motion.

Here, we present detailed theoretical, simulation, and experimental studies of the dynamics (power spectra, correlation function) and thermodynamics (work, heat) of a particle in a virtual harmonic potential with constant and time-dependent stiffness. We show that deviations from the behavior in a continuous potential are measured by the ratio of these small time scales to the relaxation time scale of the virtual potential. From the understanding we gain, we can explore the thermodynamics of particles in an arbitrary time-dependent potential. A first application of such ideas is to measure the thermodynamic cost of information erasure in double-well potentials.

8810-39, Session 8

Frustration effects and grain boundaries in colloidal particle orderings on optical substrates

Danielle McDermott, University of Notre Dame (United States); Andras Libal, Univ. Babes-Bolyai (Romania); Gia-Wei Chern, Charles M. Reichhardt, Cynthia J. Olson Reichhardt, Los Alamos National Lab. (United States)

We propose that a system of colloidal particles interacting with a honeycomb array of optical traps that each contain three wells can be used to realize a fully packed loop model. One of the phases in this system can be mapped to Baxter’s three-coloring problem, offering an easily accessible physical realization of this problem. As a function of temperature and interaction strength, we find a series of phases, including long range ordered loop or stripe states, stripes with sliding symmetries, random packed loop states, and disordered states in which the loops break apart. For square arrays of traps that each contain two wells, a spin ice state can be realized, and using colloidal particles, we show that it is possible to produce dynamical ice defects by creating multiply occupied or unoccupied traps. Our geometries could be constructed using ion trap arrays, BEC vortices in optical traps, or magnetic vortices in nanostructured superconductors.

8810-40, Session 8

Soft spots and light-force induced rearrangements in colloidal glasses *(Invited Paper)*

Arjun G. Yodh, Ye Xu, Tim Still, Univ. of Pennsylvania (United States); Kevin B. Aptowicz, West Chester Univ. of Pennsylvania (United States); Matt Gratale, Univ. of Pennsylvania (United States)

I will describe recent work which explores the connections between particle dynamics and mechanical response of disordered media. For example, we have experimentally studied the phonon modes [1,2] of disordered colloidal packings, and the role played by particular low-frequency quasi-localized phonon modes (“soft spots”) in driving particles to rearrange in response to compressive stress [3]. Our colloidal suspensions are composed of temprature-sensitive hydrogel particles, made from cross-linked poly(N-isopropyl acrylamide). By varying sample temperature, the colloid packing fraction is varied. Using video microscopy and particle tracking techniques, vibrational modes are derived from particle displacement correlations. New experiments that study correlations between the modes and the particle rearrangements due to laser-tweezer/thermally induced stresses will also be described.

8810-41, Session 8

Resonances arising from hydrodynamic memory: the color of Brownian motion

Sylvia Jeney, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Observation of the Brownian motion of a small probe interacting with its environment is one of the main strategies to characterize soft matter. Initially, the particle is driven by rapid collisions with the surrounding solvent molecules, referred to as thermal noise. Later, the friction between the particle and the viscous solvent damps its motion. Conventionally, thermal force is taken to be characterized by a Gaussian white noise spectrum. The friction is assumed to be given by the Stokes drag, suggesting that motion is overdamped at long times, when inertia becomes negligible.

Recently, we measured the noise spectrum of the thermal forces by tracking with high resolution a single micron-sized sphere suspended in a fluid, and confined by a stiff optical trap. Coupling between sphere and fluid gives rise to hydrodynamic memory and a resonance, equivalent to a colored peak in the power spectral density of the sphere’s thermal fluctuations. Our results reveal that motion is not overdamped, and the particle-fluid-trap system can be considered a nanomechanical resonator.

By bridging novel theoretical insights to model experiments with unprecedented accuracy, we are aiming at developing a novel type of multidimensional, time-resolved, near-field sensor for the study of soft and living matter.

8810-42, Session 9

Self-driven particles on asymmetric trap arrays

Lena M. Lopatina, Charles M. Reichhardt, Cynthia J. Olson

Reichhardt, Los Alamos National Lab. (United States)

In this work we propose a new way to manipulate active swimmers, such as bacteria or artificial swimmers. Self-propulsion, which is the main feature of active matter, produces a unique spectrum of novel properties in active matter. Previous research has been concentrated in the areas of extracting work from bacteria [1], sorting self-propelled particles/bacteria [2], and flocking, in which the addition of interactions between particles/bacteria leads to the formation of correlated groups/flocks [2].

In our work we demonstrate a new feature of self-propelled particles and bacteria - self-organization caused solely by self-propulsion, without any additional interactions in the matter. By means of computer simulations, we study how the density of swimmers affects this self-organization. Then, we show how, by placing just one additional object into the media, we can enhance the self-organization drastically. In addition to studying the phase diagram, we investigated how one can describe the system by measuring visually observable signals. This research will lead to a better understanding of the properties of the bacteria and artificial swimmers, which will lead to the development of new sensor technologies.

8810-43, Session 9

Real-time calcium measurements of live optically trapped microorganisms

Charlie Chandsawangbhuwana, Linda Z. Shi, Qingyuan Zhu, Michael W. Berns, Univ. of California, San Diego (United States)

A system has been developed that allows for the real-time measurement of calcium dynamics in swimming sperm. Specifically, the ratiometric dye Indo-I is used as a fluorescent indicator of intracellular calcium dynamics. The dual emissions are collected by a high-sensitivity back-illuminated CCD camera coupled to a Dual-View imaging system. From the CCD, the images are sent to a custom developed algorithm which processes the images and outputs the calci-um measurements in real-time. Additionally, sperm velocity and position data are processed and outputted in real-time. The velocity and position data are obtained using a separate coupled red light (>670 nm) phase contrast imaging setup that does not optically interfere with the fluorescent imaging. Using this system the effects of optical trapping on calcium dynamics was determined.

8810-44, Session 9

Optically-driven swimmers

Vincent L. Y. Loke, Alexander B. Stilgoe, Daryl C. Preece, Timo A. Nieminen, Halina Rubinsztein-Dunlop, The Univ. of Queensland (Australia)

Non-axisymmetric microstructures, immersed in a liquid, can be rotationally driven in optical trap. These objects can be either chiral or non-chiral. The chiral structures, due to its symmetry, potentially couples rotational fluid flow to translational fluid flow to produce thrust in the direction of its axis. An ideal optically driven swimmer exploits both optical torque and fluid flow to achieve swimming motion.

We investigate number of structures for their suitability as optically-driven swimmers. They take the form of helical, turbine or propeller-like structures. Theoretical models are used to aid the design of such structures. The optical forces and torques are calculated using a combination of discrete dipole approximation and the T-matrix method. Forces due to fluid flow are determined by solving Laplace's equation via the finite element method or other means.

Working in the low Reynolds number regime, the Scallop theorem predicts that any deformation of the swimmer must not be invariant under time reversal. On that score, a chiral structure, with no moving parts but rotating on its own axis, would be a suitable swimmer; it can also be used as a pump when held in place by a highly converging beam.

In conjunction with the results from the theoretical models, the optically-driven swimmers can be prototyped using two-photon photo-polymerization. This is a process where a receptacle containing resin is raster-scanned in 3D on a movable stage; the resin is selectively cured at the required coordinates. The uncured portion is washed away leaving the desired microstructure which can then be manipulated using optical tweezers. Optical forces and torques are subsequently measured.

8810-45, Session 9

Hydrodynamic synchronisation of rotating spheres

Simon Hanna, Luke J. Debono, Stuart J. Box, David B. Phillips, Stephen H. Simpson, Univ. of Bristol (United Kingdom); Nicolas Bruot, Jurij Kotar, Pietro Cicuta, Univ. of Cambridge (United Kingdom)

Hydrodynamic coupling is thought to play a role in the coordinated beating of cilia and flagella, and may inform the future design of artificial swimmers and pumps. In this study, holographic optical tweezers are used to investigate the hydrodynamic coupling between a pair of driven oscillators. The theoretical model of Lenz and Ryskin [1] is experimentally recreated, in which each oscillator consists of a sphere optically driven in a circular trajectory. The optical trap position is maintained ahead of the sphere to provide a tangential driving force. The trap is also moved radially to harmonically constrain the sphere to the circular trajectory. Analytically, it has been shown that two oscillators of this type are able to synchronize or phase-lock under certain conditions [2, 3]. We explore the interplay between synchronization mechanisms and find good agreement between experiment, theory and Brownian dynamics simulations.

8810-46, Session 9

Photonic force based investigations of filopodial dynamics

Felix Kohler, Alexander Rohrbach, Albert-Ludwigs-Univ. Freiburg (Germany)

Filopodia are needle-like highly dynamic cellular protrusions, which play an important role in many essential cellular processes like cell adhesion, cell migration, wound healing and phagocytosis. Filopodia constitute one of the most isolated substructures of a cell. These finger-like highly dynamic cell protrusions provide a system at an interesting level of complexity. However, only little is known about the mechanical properties and the dynamics of cellular subsystems like filopodia.

The exposed location of filopodia at the cellular surface makes these structures easily accessible for optical tweezers based cellular investigations. We use photonic force microscopy to investigate the mechanical concepts of filopodial dynamics during phagocytosis. Therefore, an optically trapped bead is attached to a filopodium. The fast and precise motion tracking of the bead reveals important information about the underlying mechanics driving the motion. The analysis of the mean displacement of the bead allows the determination of the velocities and forces that appear during the filopodial retraction as well as during the transport of a bead along a filopodium. It could be revealed that filopodia often show a spasmodic kind of retraction with intervals of fast and slow motions. This behavior helps to better understand the discrepancies between the reported filopodial retraction velocities that are based on measurements of different timescales. By means of the analysis of the beads fluctuations, various processes like the binding of the bead to the cell membrane, the possible release of a clutch and the arrival of the bead at the cell body could be identified.

Tutorial: studying single molecules with sub-nanometer precision: a review of techniques and applications *(Invited Paper)*

Thomas T. Perkins, National Institute of Standards & Technology (United States) and Univ. of Colorado (United States)

A specially commissioned review of high-precision optical trapping measurements for application to single molecule biophysics, in advance of publication of an Annual Review of Biophysics article on the subject.

8810-48, Session 10

Single molecule manipulation experiments: theory, analysis, interpretation *(Invited Paper)*

Olga Dudko, Univ. of California, San Diego (United States)

Single-molecule manipulation tools are making it possible to measure the response of individual biomolecules to external force - in real time and with unprecedented resolution - revealing information that is typically lost when studied though traditional "bulk" methods. I will present a general analytical theory of force-induced molecular transitions. The applications of the theory will be illustrated with data from single-molecule pulling experiments on (i) unfolding of riboswitches and (ii) unbinding of a receptor-ligand complex involved in blood clot formation with optical tweezers, (iii) unzipping of individual DNA hairpins with nanopores, and (iv) unfolding of proteins with an atomic force microscope.

8810-49, Session 11

Ultrafast force-clamp laser trapping of single molecular motors and DNA binding proteins

Marco Capitanio, Carina Monico, Francesco Vanzi, Francesco S. Pavone, Univ. degli Studi di Firenze (Italy)

Force plays a fundamental role in a wide array of biological processes, regulating, for example, enzymatic activity, kinetics of molecular bonds, and molecular motors mechanics. Single molecule force spectroscopy techniques have enabled the investigation of such processes, but they are inadequate to probe short-lived (millisecond and sub-millisecond) molecular complexes. Here, we present a novel force-clamp laser trap that is capable of applying constant loads to molecular complexes with lifetimes above ~10 μs [Capitanio et al., Nature Methods 9, 1013-1019 (2012)]. Such capability is enhanced by a detection strategy allowing the investigation of very short interactions (~100μs). Moreover, the high temporal and spatial resolution of the method enables us to probe sub-nanometer conformational changes with a time resolution of few tens of microseconds. We tested our method on molecular motors and DNA-binding proteins. We applied constant loads to a single motor domain of myosin before its working stroke was initiated (0.2–1 ms), thus directly measuring its load dependence. We found that, depending on the applied load, myosin weakly interacted (<1 ms) with actin without production of movement, fully developed its working stroke or prematurely detached (<5 ms), thus reducing the working stroke size with load. These results resolve the molecular mechanism underlying regulation of muscle contraction by force. Our technique could be straightforwardly applied to a wide variety of non-processive molecular motors, single domains of processive motors, protein-DNA and protein-RNA interactions, and conceivably to any short-lived protein-protein interaction, opening new avenues for investigating the effects of forces on biological processes.

8810-50, Session 11

Dynamic single-molecule force spectroscopy using optical tweezers and nanopores

Nadanai Laohakunakorn, Univ. of Cambridge (United Kingdom); Sebastian Sturm, Univ. Leipzig (Germany); Oliver Otto, Technische Univ. Dresden (Germany); Ulrich F. Keyser, Univ. of Cambridge (United Kingdom); Klaus Kroy, Univ. Leipzig (Germany)

Single-molecule force spectroscopy is a powerful technique for studying the detailed behaviour of biopolymers such as DNA and proteins. It takes advantage of tools such as the atomic force microscope and optical tweezers to apply pN-scale forces to individual molecules. The resulting response of the molecule enables properties such as conformations, folding pathways, and intermolecular interaction strengths to be determined. Traditionally these studies have been carried out under static tension. The dynamic response of polymers to a sudden change in force is experimentally more challenging as the polymer is often coupled to an external molecular handle, which suppresses important physics at short (~ms) timescales. Here we use a nanopore to electrically control the application of force to the end of a double-stranded DNA molecule; the other end of the molecule is attached to a bead held in an optical trap. By shutting off the voltage, the fast relaxation dynamics of the free polymer end can be studied. We observe for the first time an enhanced viscous friction which arises from the rapid internal contraction of the DNA, which is fully explained by theory. These studies pave the way for new dynamic force-spectroscopy experiments, such as investigations of tension propagation along biomolecules, which has applications for both polymer theory as well as biological systems such as the cytoskeleton where dynamic tension can affect cellular response.

8810-51, Session 11

Why soft UV A damages DNA: a laser microbeam study

Karl Otto Greulich, Fritz Lipmann Institute (Germany); Alexander Rapp, Technische Univ. Darmstadt (Germany)

Laser microbeam studies have solved a puzzle on DNA

damage and repair (1). Such knowledge is crucial for understanding cancer and ageing. So far it was not understood, why the soft UV component of sunlight, UV A, causes the dangerous DNA double strand breaks. The energy of UV A photons is below 3.5 eV, too low to directly cleave the corresponding chemical bonds in DNA. This is occasionally used to claim that artificial sunbeds, which mainly use UV A, would not impose a risk on health.

UV A is in a first step sufficient only for single strand breaks. The essential new observation is that, when on the opposite strand there is an other single strand break at a distance of up to 20 base pairs, these two breaks will be converted into a break of the whole double strand with all its known consequences for cancer and ageing.. However, in natural sun the effect is counteracted (2). Simultaneous red light illumination reduces UV induced DNA damages to 1/3. Since sunlight has a red component, skin tanning with natural sun is not as risky as might appear at a first glance.

8810-52, Session 11

Magnetic trapping of single molecules: principles, developments, and applications *(Invited Paper)*

Terence R. Strick, Ctr. National de la Recherche Scientifique (France)

Magnetic trapping provides a robust and highly parallelizable means for isolating and manipulating single biopolymers such as DNA, RNA and proteins. Here we will discuss basic principles of magnetic trapping; compare and contrast optical trapping and magnetic trapping for biomolecular applications; review recent developments in magnetic trapping approaches; and discuss the use of magnetic trapping for the study of complex, multicomponent biological reactions -- in particular for the analysis of DNA repair.

8810-53, Session 11

Probing ribosomal protein-RNA interactions with an external force *(Invited Paper)*

Pierre Mangeol, Mathilde Bercy, Ecole Supérieure de Physique et de Chimie Industrielles (France); Thierry Bizebard, Claude Chiaruttini, Marc Dreyfus, Mathias Springer, Institut de Biologie Physico-Chimique (France); Ulrich Bockelmann, Ecole Supérieure de Physique et de Chimie Industrielles (France)

Ribosomal (r-) RNA is well structured in the ribosome, but the role of r-proteins and enzymes in the assembly process is poorly understood. We address this question by using optical tweezers to unfold RNA fragments in the presence or absence of proteins.

We first studied the case of Escherichia coli L20, an early binding r-protein, whose globular C-terminal domain (L20C) recognizes the essential 991-1163 subdomain of the 23S rRNA. We found that L20C makes RNA fragments surrounding its binding sites more resistant to mechanical unfolding. The points of increased resistance coincide within two base pairs with the binding sites identified by conventional methods. Comparing unfolding and refolding traces and including studies with mutated RNA, we found that L20C acts as a clamp and not as a RNA chaperone.

Recent biochemical experiments in E.Coli indicate that SrmB, a DEAD-box protein that shows RNA helicase activity in the presence of ATP, assists ribosome assembly by favoring the in vivo folding of the 991-1163 subdomain. We are now trying to reproduce this effect in vitro with the optical tweezers and are extending the work to the other r-proteins that contact the same subdomain.

8810-54, Session 12

Active fluctuations of chromosomal DNA in E. Coli in vivo

Rudra P. Kafle, Jens-Christian D. Meiners, Univ. of Michigan (United States)

In E Coli, the genome is tightly compacted in a nucleoid of less than a cubic micron. The conformation of the DNA undergoes large- and small-scale changes during the life cycle of the cell, enabling replication, transcription, and the formation of highly specialized DNA-protein complexes that control biological processes.

The dynamics in the nucleoid are subject to a multitude of constraints, forces, and fluctuations. We study the conformational fluctuations of chromosomal DNA in live and dead Escherichia Coli cells by Fluorescence Correlation Spectroscopy (FCS) on in vivo labeled DNA, yielding the displacement of the DNA on time scales from microseconds to seconds and the corresponding viscoelastic properties of the nucleoid. We observe a substantial decrease in the displacement fluctuations in dead cells, compared to the live cells. The larger fluctuations in the living cells may indicate that they are driven by active processes involving molecular motors that generate forces by ATP hydrolysis. On shorter time scales, we see a little difference between live and dead cells, suggesting that faster processes rely primarily on thermally-driven diffusive mechanisms.

We interpret these data in comparison to in-vitro measurements with optical tweezers in which we have simulated the effect of motor-driven fluctuations by shaking the end of the DNA and measure the rate of protein-mediated DNA loop formation. Small additional fluctuations can substantially enhance these rates, suggesting that motor-driven intracellular noise may be critical to efficient cellular function.

8810-55, Session 12

On the fundamentally soft nature of the bacterial chromosome *(Invited Paper)*

Suckjoon Jun, Univ. of California, San Diego (United States)

Replicating bacterial chromosomes continuously demix from each other and segregate within a compact volume inside the cell called the nucleoid. Although many proteins involved in this process have been identified, the nature of the global forces that shape and segregate the chromosomes has remained unclear because of limited knowledge of the micromechanical properties of the chromosome. In the shorter first half of this talk, I will summarize the physics of polymer in confined space. In the second part, I will describe our recent experimental work that shows the bacterial chromosome in confined space remarkably behaves as a loaded entropic “spring”. In particular, comparison with the viral DNA in a capsid reveals the fundamentally soft nature of the bacterial chromosome.

8810-56, Session 12

Optical trapping of T cells

Amanda J. Wright, The Univ. of Nottingham (United Kingdom); David Glass, Niall McAlinden, Owain R. Millington, Univ. of Strathclyde (United Kingdom)

Since the first optical trap was reported in the late 1970s it has been shown to be a hugely versatile tool when it comes to biological applications and Life Science research. As the number of applications increases and the optical trapping technology becomes more advanced there is an increasing need to be able to perform accurate, quantitative experiments that directly trap the cell of interest without the need to introduce exogenous beads into the sample. The issue with trapping cells directly is that they are often larger than beads and are distinctly non-uniform with widely varying refractive indices. This has practical implications in terms of trapping the cell as a whole rather than just a small feature of the cell, preventing the cell from re-orientating during experiments and, most importantly, performing reliable measurements on the sample and cell which most often involve accurately tracking the cell’s position. We will present a series of experiments and mathematical models that aim to address these issues, highlighting novel beam shapes that can be used to trap the cell as a whole and fluorescent imaging techniques that allowing accurate cell position tracking. Our interest is in optically trapping T cells, which are part of the immune system, although the approaches presented are not limited to T cells and could easily be adapted to suit the sample of interest. Using the techniques developed we demonstrate how optical tweezers can be used probe the dynamic interactions that occur between cells in the adaptive immune system.

8810-57, Session 12

Contributions of actin and myosin to creep compliance of blood stem cells during differentiation

Andrew E. Ekpenyong, Technische Univ. Dresden (Germany); Graeme B. Whyte, Kevin J. Chalut, Stefano Pagliara, Lars Boyde, Chii J. Chan, Franziska Lautenschläger, Ulrich F. Keyser, Univ. of Cambridge (United Kingdom); Jochen R. Guck, Univ. of Cambridge (United Kingdom) and Technische Univ. Dresden (Germany)

Stem cells modulate their mechanical properties during differentiation. We recently showed that during the differentiation of hematopoietic stem and precursor cells into three different myeloid lineages, the cells alter their mechanical properties to suit their ultimate fates and functions. Although the mechanical properties of cells are largely determined by the cytoskeleton, how such properties derive from cytoskeletal details is still largely unclear.

Here, we show the relative contributions of filamentous actin and myosin II to cell compliance, measured with a microfluidic optical stretcher. Pharmalogical interventions using Cytochalasin D and Blebbistatin specifically disrupt the actin and myosin II components of the cytoskeleton, respectively. By monitoring the creep compliance of cells from induction of differentiation up to the emergence of fully differentiated cells, alongside these pharmacological interventions, we simultaneously quantified the changes in cellular mechanical properties due to differentiation and acto-myosin depolymerization.

Our results indicate that while all three mature lineages can be distinguished from the undifferentiated cells and from one another based on the creep compliance, the relative contributions of actin and myosin II are nearly constant and lineage-independent. Actin depolymerization leads to a significant increase in creep compliance while myosin II disruption engenders a significant decrease in creep compliance, for primary human cord blood derived hematopoietic stem cells (CD34+), cell line precursor cells (HL60) and all their differentiated lineages (neutrophils, monocytes and macrophages). In line with our earlier work showing the function-specificity of cell mechanical properties, the present results adumbrate the biomolecular basis of cellular mechanical properties.

8810-58, Session 12

New biodiagnostics based on optical tweezers: sub-typing red blood cells, and identification of drug resistant bacteria *(Invited Paper)*

Jia-Wen Chen, Feng Yuan Hospital (Taiwan); Chuen-Fu Lin, Shyang-Guang Wang, Yi-Chieh Lee, Chung-Han Chiang, Min-Hui Huang, Central Taiwan Univ. of Science and Technology (Taiwan); Yi-Hsiung Lee, Feng Chia Univ. (Taiwan); Guy Vitrant, IMEP-LAHC (France); Ming-Jeng Pan, Central Taiwan Univ. of Science and Technology (Taiwan); Horng-Mo Lee, Central Taiwan University of Science and Technology (Taiwan); Patrice L. Baldeck, Ctr. National de la Recherche Scientifique (France) and Central Taiwan Univ. of Science and Technology (Taiwan); Chih-Lang Lin, Central Taiwan Univ. of Science and Technology (Taiwan)

It has been previously demonstrated that optical tweezers forces on biological micro-objects can be used to develop innovative biodiagnostics methods. In the first part of the presentation, we present a new sensitive method to determine A, B, D types and subtype of red blood cells. Target antibodies are coated on glass surfaces. Optical forces needed to drag RBC from the glass surface increase when RBC antigens interact with their corresponding antibodies. Antibody dilutions are used to determine their interaction strengths with RBCs. We demonstrate that the sensitivity of this method is 16-folds higher than the agglutination method. Furthermore, the difference in sensitivity can be used to distinguish the major RBC types and subtypes.

In the second part, we present an original way to measure in real time the wall thickness of bacteria, that is one of the most important diagnostic parameters of bacteria drug resistance. In hospital diagnostics, it is still measured by TEM which is time consuming for critical diagnostics. We have found that the wall thickness of shell bacterias is directly proportional to their optical forces. After calibration with known bacteria, the method has been succefully applied to indentify, from blind tests, methicillin-resistant staphylococcus aureus, including VSSA (NETC 10442), VISA (Mu 50), and heto-VISA (Mu 3).

Evaluating cell matrix mechanics using an integrated nonlinear optical tweezer-confocal imaging system

Berney Peng, Tufts Univ. (United States); Carlo-Amadeo C. Alonzo, Tufts Univ (United States); Irene Georgakoudi, Mark Cronin-Golomb, Tufts Univ. (United States)

Studies have demonstrated that biophysical effects such as extracellular matrix (ECM) stiffening and remodeling can drive cancer progression and metastatic potential. As such, the ability to make microscale rheology measurements coupled with simultaneous optical imaging in 3D cultures can be critical when monitoring these physiological processes for mechanistic understanding. This paper describes the inclusion of optical tweezers based microrheology in a microscope that had been designed for nonlinear optical imaging of collagen networks in ECM. We show preliminary results using mammary gland epithelial cells.

8810-60, Session 13

Probing multiscale mechanics of collagen with optical tweezers

Marjan Shayegan, Naghmeh Rezaei, Benjamin P. B. Downing, Andrew Wieczorek, Nancy R. Forde, Simon Fraser Univ. (Canada)

Mechanical response is a key property of many types of materials, yet rational design of mechanical response remains an enormous challenge. By studying the mechanics of collagen, the fundamental structural protein in vertebrates, and how these are altered by changes in chemical composition, we hope to provide insight into the interplay between chemistry and mechanics. Because collagen is a self-assembling protein, we are characterizing its mechanics at various stages in its hierarchical assembly pathway, to provide insight into how they can be altered at different structural levels in aging, in disease, and in desirable ways to develop new biomaterials.

We have built optical tweezers instruments to manipulate and measure forces acting on microspheres, which we use either as handles to stretch single molecules of collagen, or as probes of the local viscoelastic environment in microrheology experiments. Because of collagen's relatively short length, care must be taken that forces measured in single-molecule stretching experiments reflect the behaviour of the tethered molecule, which we address through quantification of physical interactions and introduction of specific chemical labels. In microrheology experiments, we observe that collagen's chemical composition influences the dynamics and strength of interactions between collagens, which we quantify with simple viscoelastic models. We furthermore probe the development of mechanical heterogeneity at the microscale as collagen undergoes self-assembly into fibrillar networks.

8810-61, Session 13

Optical stretching of lipid bilayer membranes in dual beam optical trap

Roshni Biswas, Mehmet Solmaz, Shalene Sankhagowit, Camilo A. Mejia Prada, Noah Malmstadt, Michelle L. Povinelli, The Univ. of Southern California (United States)

The elastic deformation of lipid bilayer membranes underlies many basic physiological processes. Accurate techniques for measuring the bending modulus of lipid bilayers can thus yield crucial insight into membrane biology. Giant unilamellar vesicles (GUVs), spherical objects consisting of a single lipid bilayer, form a common model for probing membrane mechanics. In this work, we use a dual beam optical trap (DBOT) to trap and stretch GUVs. When trapped, the GUVs assume the shape of a prolate spheroid with an eccentricity that depends on the trapping power and the intrinsic elasticity, or bending modulus, of the GUV's lipid membrane. The bending modulus is extracted from the applied optical stress and resulting surface area strain. In our experiments, we analyzed two populations of GUVs with membranes composed of distinct lipids, one in liquid phase (POPC) and the other in gel phase (DPPC). It is expected that the bending modulus of the lipid in liquid phase will be substantially lower than that in the gel phase, and this fact is validated in our experiment. We also analyzed the effect of adding cholesterol to lipid membranes. We expect that the high-throughput, flow-through nature of the DBOT setup will allow the convenient collection of data on large numbers of GUVs, e.g. with varying size, composition, and/or biochemical environment. In this manner, this platform may also provide a method for quantifying the response of membrane mechanical properties to small molecules, drugs, nanoparticles, and other agents.

8810-62, Session 13

Optical manipulation of vesicles for optofluidic applications

Andreas E. Vasdekis, Ecole Polytechnique Fédérale de Lausanne (Switzerland) and Pacific Northwest National Lab. (United States); Evan A. Scott, Jeffrey A. Hubbell, Demetri Psaltis, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

In this talk, we will review our recent results in the optical manipulation of vesicles [1, 2]. We will first discuss more traditional approaches in vesicle manipulation using optical tweezers, which have enabled a wide range of vesicle studies, such as their dynamic manipulation, as well the study of their mechanical properties [2, 3]. We will then focus on our present work, which is based on utilizing the photon energy, rather than its momentum. Polymersomes, vesicles synthesized from block-copolymers, were sensitized by adding an oxidizing moiety on their membrane. The later converts incident photons to reactive oxygen species. This latter step enabled the complete destabilization of the vesicles and release of their contents under optical excitation, involving both coherent and incoherent radiation. Short light exposures lead to polymersomes re-organization into smaller diameter vesicles. Extended illumination leads to complete destabilization, and micelle formation. Single particle analysis revealed payload release takes place within seconds of illumination in an explosive burst. We will discuss the destabilization and payload release kinetics, as revealed by microscopy at the single particle level, and will end with applications including single cell biomodulation, as well as an outlook for future potential applications in optofluidics.

The influence of myosin-generated force to the intracellular microrheology in living cells

Ming-Tzo Wei, H. Daniel Ou-Yang, Lehigh Univ. (United States)

The mechanics of biological cells are governed by a network of cytoskeletal filaments and molecular motors forming a dynamic mechanical entity. A recent experimental study by Mizuno et al. showed that local shear modulus of a synthesized cytoskeletal network could increase as a result of myosin-generated internal stresses. To examine whether similar behaviors could take place in living cells we combined active and passive microrheology to measure the myosin-generated fluctuating force and intracellular shear modulus in HeLa cells. While our experiment did show an increase in the fluctuations of the shear modulus with increasing motor forces, the experiment did not find a direct correlation between the mean intracellular shear modulus and the motor-generated fluctuating force. Based on Mizuno et al's assumption that shear modulus is an increasing function of the local tension, the difference between the results obtained by the intracellular behavior and that obtained from the synthesized cytoskeletal network could be due to the existence of a steady-state intracellular tension that is stronger than the motor-generated fluctuating force. Unfortunately, our experimental method could measure only the fluctuating forces but not the steady-state tension in the system. Further studies that measure both fluctuating and steady-state forces at the same time may be required to address this problem.

8810-64, Session 14

Rotational optical microrheology of liquid interfaces

Matthieu Robert de Saint Vincent, Yoshihiko Arita, Kishan Dholakia, Univ. of St. Andrews (United Kingdom)

Complex interfaces are involved in many fields related to biological materials (cell membrane properties…), industrial processes (foam and emulsion stability, oil recovery…) as well as basic two-phase fluid dynamics problems. They indeed exhibit specific two-dimensional rheological properties which strongly influence macroscopic behaviour, and have motivated intensive research efforts over the past decades.

A popular approach to determine the interfacial shear viscosity of adsorbed monolayers consists in measuring the torque induced on a macroscopic rotating disk straddling the interface to be probed, which results from both contributions of bulk phases and monolayer. In this context, reducing the probe size benefits from a favourable scaling behaviour, therefore allowing for an enhanced sensitivity.

We propose a top-down version of this approach, where a birefringent particle straddling a liquid-liquid interface is set into rotation by a circularly-polarized laser beam in an optical trap. Such micrometre-scale rotating particle can indeed be viewed as equivalent to a scale-reduction of the rotating disk by four orders of magnitude. By simultaneously measuring the optical torque exerted upon the trapped particle and the resulting rotation rate, we can probe the surface shear viscosity of surfactant monolayers covering the interface. Viscosities within the 10-7 Pa s m range have thus been successfully measured at water-oil interfaces.

This high sensitivity, together with a high spatial selectivity, make this approach very promising for characterizing a wide range of inhomogeneous soft interfaces at the micron scale.

8810-65, Session 14

Oscillating droplets in optical traps

Stephen H. Simpson, Rory M. Power, Jonathan P. Reid, Univ. of Bristol (United Kingdom)

We report on the application and analysis of a powerful and novel form of viscometry, capable of measuring viscosities over a range of twelve decades. The technique relies on the use of holographic optical traps to induce coalescence between pairs of liquid micro-droplets. Immediately following such an event, the newly formed droplet undergoes shape oscillations whose evolution is determined by its physical properties. We show, using a combination of experiment and simulation, how this process can be monitored optically and describe how the liquid viscosity can subsequently be evaluated. In particular we present a detailed numerical analysis of light scattering from oscillating droplets. Two main observations are made. First of all, characteristic patterns of morphological resonances are observed for independent oscillation modes. The conditions for these resonances are shown to provide an accurate measure of particular dimensions of the droplet. Secondly, the back-scattered signal from a sufficiently large, trapped, oscillating droplet is shown to be strongly related to its height in the direction of the beam axis. These principles provide ways of monitoring oscillations, decomposing the motion into normal modes, and acquiring the fluid viscosity.

8810-66, Session 14

Laser trapping dynamics of 200 nm-polystyrene particles at a solution surface

Ken-ichi Yuyama, National Chiao Tung Univ. (Taiwan); Teruki Sugiyama, Instrument Technology Research Ctr. (Taiwan); Hiroshi Masuhara, National Chiao Tung Univ. (Taiwan)

Laser trapping due to radiation pressure of a focused laser beam has been widely employed to trap and manipulate nanoparticles in solution. Their researches have been carried out mainly inside the solution, while the importance of laser trapping at a solution surface is recently being recognized for our laser trapping crystallization experiments. In this work, we present a comparison of laser trapping behavior of 200 nm-polystyrene particles in a solution and at a surface layer. The sample solution (2–4x10^11 particles/ml) was prepared by adding D2O into the colloidal solution. When a continuous-wave laser beam of 1064 nm was focused into the inside of the solution film through an objective lens (60x magnification, NA=0.90), the particles were trapped and the resultant assembly was confined in the focal volume. On the other hand, upon focusing the laser at the solution surface, the particles were initially gathered at the focal spot, and then the assembly was extended to the outside and became much larger than the focal volume. Interestingly, the assembly prepared at the surface was observed as colored under halogen lamp illumination with a CCD video camera. The result indicates that the assembly has a periodic structure and can be deemed as a colloidal crystal. This formation process of the colloidal crystal is considered from the viewpoint of radiation pressure acting on nanoparticles at a solution surface. These findings will also lead to deep understanding of the mechanism for laser trapping-induced formation of molecular crystals at a solution surface.

8810-67, Session 14

An optical platform for the production, trapping, manipulation and visualisation of low interfacial tension emulsion droplets

Andrew K. Kirby, Alexander L. Hargreaves, Colin D. Bain, Gordon D. Love, Durham Univ. (United Kingdom); Andrew D. Ward, Rutherford Appleton Lab. (United Kingdom); Guido Bolognesi, Oscar Ces, Imperial College London (United Kingdom)

We discuss the design, implementation and performance of a novel platform for the production and optical control of ultra-low interfacial tension droplets in the 1-10 micron regime. A custom-designed integrated microfluidic system allows the production of oil-in-water emulsion droplets of controllable size and provides an optimised physical platform in which individual droplets are selected, trapped and shaped using a combination of holographic optical tweezers and extended optical landscaping. The structure of the shaped droplet is interrogated by a combination of conventional brightfield imaging and fluorescent structured-illumination sectioning. We detail the problems and limitations of closed-loop holographic control of droplet shape

8810-68, Session 14

Optical control of shape-morphing liquid crystal elastomeric particles

Ivan I. Smalyukh, Julian S. Evans, Bohdan Senyuk, Univ. of Colorado at Boulder (United States)

Robust optical control of shape of birefringent colloidal microparticles is of great fundamental and practical interest but so far has not been demonstrated. In our study, liquid Crystal (LC) elastomeric particles with initial cylindrical shapes and nematic director along the cylinder axis are obtained by means of soft lithography, polymerization in a strong magnetic field, and subsequent infiltration with gold nanospheres [1]. By utilizing nanoparticle-mediated photothermal energy transfer from laser light to heat and inherent coupling between the temperature-dependent ordering and shape, we bend and morph the elastomeric microparticles to obtain long-term-stable well-controlled complex particle shapes [2]. This manipulation is performed in both isotropic and anisotropic LC host fluids [1,2], allowing for a spontaneous elasticity-mediated realignment in the latter case. These findings may impinge on shape-controlled self-assembly of adaptive composite materials and development of light-driven micromachines.

8810-69, Session 14

Tunable optofluidic microlasers based on optically stretched emulsion droplets

Alper Kiraz, Alexandr Jonas, Koç Univ. (Turkey); Oto Brzobohatý, Institute of Scientific Instruments of the ASCR, v.v.i. (Czech Republic); Jan Jezek, Zdenek Pilat, Pavel Zemánek, Institute of Atmospheric Physics of the ASCR, v.v.i. (Czech Republic); Mehdi Aas, Koç Univ. (Turkey)

Dye-doped liquid microdroplets represent active ultrahigh-Q optical cavities that enable observation of dye lasing with threshold pump power significantly lower than that required for bulk samples. An important advantage of liquid micro-cavities over their solid counterparts lies in the possibility of readily adjusting their shape, size, and composition, which opens up the way towards controlled tuning of the emission spectral characteristics of liquid microlasers. However, despite demonstrations of spectral tuning of liquid micro-cavities surrounded by air or solid elastomer, fully reversible tuning of cavities formed by emulsion microdroplets has not been shown yet even though this configuration is of particular practical interest for integrated lab-on-a-chip applications.

Here, we introduce a tunable optofluidic microlaser based on dye-doped emulsion microdroplets confined in a dual-beam optical trap that is formed by two counter-propagating non-interfering Gaussian laser beams. Transparent emulsion microdroplets with refractive index higher than that of the host liquid are confined on the beam axes by the optical gradient force. Trapped droplets are then stretched along the beam axes as a result of the momentum balance of photons transmitted through the droplet / host liquid interface. In order to initiate dye lasing, the droplets are pumped with a pulsed green laser beam. Subsequently, droplet stretching deformation is changed by adjusting the power of the dual-beam trap which leads to the modification of the resonant modal path length and, thus, shift of the microlaser emission wavelength. Using this technique, we demonstrate reversible spectral tuning of the lasing modes.

8810-70, Session 14

UV-induced photopolymerization in the presence of radiation pressure

Syoji Ito, Hiroshi Miyasaka, Osaka Univ. (Japan); Yoshito Tanaka, Hokkaido Univ. (Japan); Hiroyuki Yoshikawa, Osaka Univ. (Japan); Hiroshi Masuhara, National Chiao Tung Univ. (Taiwan)

Almost applications of the optical trapping have been focused on manipulating small objects. In contrast, we show a new approach to control chemical reactivity by using radiation pressure in the present paper. We have induced photopolymerization (network formation) of an acrylate solution in the optical trapping potential of focused near-infrared (NIR) laser light to investigate the effect of radiation pressure on the solidification of the acrylate solution induced by ultraviolet (UV) exposure. The UV light irradiation to the initiator in the acrylate solution started the polymerization and the chain propagation followed. Although the radiation pressure had no apparent effect on monomers with a low molecular weight, it was able to collect rather long polymer chains under the propagation. In addition, the increase in the local concentration of propagating chains increased the chance of the termination of the polymerization at the focal point of the trapping laser beam. Owing to the collection of the polymer chains and the increase in the chance of chain-termination by the trapping potential, we successfully confined photoproducts in a narrow space, resulting in the solidified structure with the size of ca. 200 nm. Our approach enabled to produce solidification volumes smaller than those achievable with conventional one-photon polymerization, enabling the fabrication of tiny polymeric structures that are smaller than the diffraction limit of the trapping light. This is the first demonstration of a radiation pressure effect on a photopolymerization.

Time-averaged force fields for nonspherical particles using position-only measurements

Ann Bui, Alexander B. Stilgoe, Timo A. Nieminen, Halina Rubinsztein-Dunlop, The Univ. of Queensland (Australia)

Optical tweezers can exert and measure forces on the piconewton scale. They can trap and manoeuver microscopic particles. To measure forces, the optical trap needs to be calibrated. As a particle is held in the trap, it still undergoes Brownian motion. Its position distribution relates to the Boltzmann distribution, which allows us to map a potential, and force, to a position in the trap. This method of calibration, often referred to as the `equipartition method', does not assume a quadratic potential or a linear spring model.

Trapping a nonspherical particle would be more appropriate for purposes such as atomic force microscopy with an optically trapped probe. A more ideal shape would be something resembling a pointed cylinder. The difficulty with nonspherical particles is that optical forces depend on the orientation and we can no longer represent to force with a potential. We extend this equipartition method of calibration by trapping a nonspherical particle and calculating its potential averaged over orientation, its `pseudopotential'. This pseudopotential gives the average force field acting on the particle in the trap.

Here we simulate the calibration a trap with a cylindrical particle with the T-matrix method. We calculate the forces acting on an optically trapped cylinder undergoing translational and rotational Brownian motion. There is close agreement between the calculated averaged force and the actual force exerted on the cylinder, even for nonlinear regions of the trap.

Towards the absolute measurement of forces on arbitrary shaped particles in optical tweezers

Alexander B. Stilgoe, Halina Rubinsztein-Dunlop, Timo A. Nieminen, The Univ. of Queensland (Australia)

Recently there has been significant interest in using non-spherical probe particles in optical tweezers. Non-spherical particles experience forces not just as a function of position, but orientation as well. As a result calibration can be problematic due to the added complications. Here we present methodology towards measurement of force in optical tweezers in an absolute sense to minimize the amount of calibration required to characterize forces for different particles. In general this is difficult as the measured values from detectors have responses which are dependent on the particular configuration of the optcial set up used. Characterization of these variables will improve the accuracy of using a single (or small sample) particle-detector calibration. This investigation starts with highly-correlated position/force measurements and uses a particular calibration for one particle on another and determines if the calibration can indeed be made absolute.

Back focal plane interferometery detection method in optical tweezers: intensity pattern consists of two anti-correlated areas

Akbar Samadi, San Francisco State Univ. (United States) and Institute for Advanced Studies in Basic Sciences (Iran, Islamic Republic of); Seyed Nader Seyed Reihani, Institute for Advanced Studies in Basic Sciences (Iran, Islamic Republic of) and Sharif Univ. of Technology (Iran, Islamic Republic of)

Tightly focused linearly polarized laser beam through high Numerical Aperture (NA) objective lens, which is called ``Optical Tweezers" can trap small objects with a refractive index greater than that of the surrounding medium. Measurement of the trapped particle's position with nanoprecision allows unknown pico-Newton-range forces measurement. The most popular detection method, Back Focal Plane (BFP) interferometry is applicable by the using Quadrant Photodiode (QPD) located at the BFP of the condenser. This method provides 3D detection of the trapped object position with nanometer resolution.In this research we show, both by theory and experiment that the interference intensity pattern due to scattered and unscattered laser beam from trapped particle at the BFP of the condenser consists of two distinguishable areas with anticorrelated intensity changes when the bead is moved in the axial direction. So in order to obtain a reasonable axial sensitivity, one has to eliminate outer area of the aforementioned pattern by decreasing the NA of the condenser. This could significantly increase the axial sensitivity and that the axial calibration is not even possible when the whole intensity pattern is collected by QPD. We also show that the space angle defining the border of two areas linearly depends on the NA of the objective. Moreover we proposed a new Octant Photodiode(OPD), which could significantly improve the axial sensitivity along with maximal lateral sensitivity compared to the commonly used QPD technique.

8810-91, Session PWed

Hydrodynamic synchronisation of optically driven spheres

Stuart J. Box, Luke J. Debono, David B. Phillips, Stephen H. Simpson, Simon Hanna, Univ. of Bristol (United Kingdom); Nicolas Bruot, Jurij Kotar, Pietro Cicuta, Univ. of Cambridge (United Kingdom)

Coordinated motion at low Reynolds number is widely observed in biological micro-systems, but the underlying mechanisms are often unclear [1]. We use holographic optical tweezers to experimentally study this phenomenon, by employing optical forces to drive a pair of coplanar microspheres in circular orbits with a constant tangential force. We particularly explore the timescales of their synchronisation from large initial phase differences. We find that this timescale is dependent on how stiffly the microspheres are confined to their circular orbits, and our findings show good agreement with an analytical description of this system [2] and numerical simulations.

Creation of three-dimensional volume chain under high numerical aperture illumination

Jiming Wang, Liu Xuening, He Chongjun, Youwen Liu, Nanjing Univ. of Aeronautics and Astronautics (China)

In this paper, we propose a method to create three-dimensional volume chain under high numerical aperture illumination. We have investigated a reversal construction of desired focused field through designing an electric-magnetic dipole array and studying its reversal radiation. The dipole factor can be modulated and optimized purposefully. For the selected initial phase difference, amplitude ratio and adjacent space, the radiation of the electric-magnetic dipole array can be seen as a reversal construction of three-dimensional volume chain. The structure of the chain can be modulated freely by changing the dipole factor. We give a procedure to create this chain as an example by using a high numerical aperture (NA=0.95) objective lens obeying the sine condition and discuss its intensity distribution near the focus. This dipolar-shaped focus field will meet potential applications in multiple particles trapping, delivering and self-assembling.

8810-94, Session PWed

Surface-plasmon-based optical trapping of hard nanoparticles: two-dimensional closely packed assembly of polystyrene nanospheres on a metallic nanostructure

Tatsuya Shoji, Hokkaido Univ. (Japan); Hajime Ishihara, Osaka Prefecture Univ. (Japan); Yasuyuki Tsuboi, Hokkaido Univ. (Japan)

Localized surface plasmons (LSPs) have been investigated for applications such as highly sensitive spectroscopies and the enhancement of photochemical reactions. These applications are enabled by the enhancement effect of an incident resonant electromagnetic field (EMF) at the surfaces of noble metallic nanostructures. In particular, the application of LSP has recently attracted much attention for achieving the effective optical trapping of nanoparticles; this is called LSP-based optical trapping (LSP-OT). LSP-OT possesses several advantages; (i) the EMF enhancement effect of LSP enables the incident light intensity to be significantly reduced for stable LSP-OT, (ii) a nano-sized object can be trapped in a nano-space whose volume is much smaller than that of conventional optical tweezers (diffraction limit), (iii) a large and complicated optical set-up is not necessary, and (iv) this technique can potentially be combined with microfluidic devices. That is, plasmonic substrates can work as “double-functional” devices where biomolecules trapped by LSP-OT can subsequently be analyzed on the basis of SERS or fluorescence enhancement.Thus, LSP-OT could enable a new technique for manipulating not only nanoparticles, but also smaller molecules such as polymer chains, proteins and DNA. Here, we will present the demonstration of LSP-OT of fluorescent-labeled polystyrene nanospheres (PsNs). We discuss multiple optical trapping in which a closely packed 2D hexagonal assembly appeared on a metallic nanostructure.

8810-95, Session PWed

Optimization of the diffraction efficiency of a spatial light modulator through phase error minimization

David H. McIntyre, Matthew A. Cibula, Oregon State Univ. (United States)

Spatial light modulators (SLMs) are commonly used to diffract light beams for a variety of applications. In particular, optical tweezer trapping has greatly benefited from the advent of phase-mostly and phase-only SLMs to write holograms that produce multiple traps. We are using holographic optical tweezers to trap multiple sensor particles in a lab-on-a-chip measurement platform. As part of this program, we have developed a method for optimizing the diffraction efficiency of a SLM. This general method can be applied in situ and addresses the issues of nonlinear phase modulation and phase modulation less than 2π.

The method employs a one-dimensional blazed phase grating. For an ideal SLM, the phase shift is linear and covers 0-2π, yielding a diffraction efficiency of unity. For a realistic SLM with nonlinear or reduced phase shift, the diffraction efficiency is approximately η=1-δ^2, where δ^2 is the variance of the phase difference from the ideal case. Because each pixel contributes to the phase difference independently, this suggests a method to maximize the efficiency by adjusting the phase encoding of the SLM pixel-by-pixel. In practice, we do this by adjusting the gray-scale of each pixel while measuring the first-order diffraction. The collection of optimal gray values comprises the optimized gray-scale lookup table, which exhibits the nonlinearity required to produce a linear phase grating and the saturated phase encoding that maximizes the efficiency of phase limited SLMs. We have successfully applied this optimization method to two different SLMs.

8810-96, Session PWed

Combined single-molecule manipulation and localization for the study of lac Repressor 1D-diffusion along DNA

Gionata Belcastro, Carina Monico, Marco Capitanio, Francesco Vanzi, Francesco S. Pavone, Univ. degli Studi di Firenze (Italy)

Lac repressor (LacI) is a protein representative of a family of DNA binding proteins called transcription factors. These proteins regulate gene expression upon binding to a specific DNA sequence, called target or cognate. LacI cognate site is called operator. The association rate to the target is limited by the time required to search the short operator sequence within the whole genome. A theoretical calculation, based on random collision during 3D-diffusion, gives a rate of 108M-1s-1. Nevertheless, the first measurements of association rate produced a value of 1010M-1s-1, two orders of magnitude faster than the theoretical value. The most accredited model to explain this discrepancy is the ‘facilitated diffusion’ model, according to which the protein, before encountering the target sequence, alternates between 3D-diffusion and random association to non-cognate DNA; during such non-specific interactions the protein undergoes a 1D-diffusion along DNA.

Here we analyzed diffusion properties of LacI under varying force applied to a single DNA molecule. This was made possible by an experimental set-up combining single molecule nanometric localization and optical trapping to track a single fluorescently labeled LacI molecule bound to a DNA molecule suspended in solution, far from the cover slip. The double optical tweezers employed allow application of controlled tension on DNA. To localize the protein, we used a rapid and accurate algorithm based on the calculation of the radial symmetry center. We obtained the 1D diffusion coefficient and sliding length under different DNA tensions.

Resonant optical trapping utilizing nonlinear optical effects

Tetsuhiro Kudo, Hajime Ishihara, Osaka Prefecture Univ. (Japan)

During recent years, the size of targets of optical manipulation is shifting to nanometer scale. For this matter, our group has previously proposed the optical manipulation by using electronically resonant optical response of nanostructures to enhance a radiation force and to select particular kinds of nanoparticles via quantum confinement effect [1]. Further, recently, we have proposed nonlinear resonant laser manipulation, which coherently elucidates recent reported puzzling phenomena contradicting with the conventional understanding of the resonant optical trapping [2]. In addition, we have demonstrated some unconventional forms of the optical manipulation utilizing nonlinear optical effects [2].

In this contribution, on the basis of our theory, first, we describe a method to trap single organic molecules utilizing nonlinear effects that is more effective than ever before. Then, we show it possible to sort single organic molecules by their energy levels using a pulling force. The results demonstrate that the resonant optical trapping utilizing the nonlinear optical effects has advantages in trapping single organic molecules and enhancing the degree of freedom to manipulate nano-objects.

Ray optics in combination with the Gaussian beam propagation method for optical trapping of free-shaped particles in microfluidic systems

Diane De Coster, Heidi Ottevaere, Hugo Thienpont, Vrije Univ. Brussel (Belgium)

In this paper we present a novel model for optical trapping, in which different assets are combined to realize a flexible model for the calculation of optical forces and torques on free-shaped particles relevant to cell applications. The actual optical force and torque estimation, based on a ray optics approach, of the optical trap can easily be integrated in the scheme simulating the surrounding microfluidic chip with integrated micro-optics. The propagation of the trapping laser light exiting the optical fibers and going through this micro-optical chip is ensured by the Gaussian Beam Propagation Method. It allows a realistic propagation of Gaussian beams in and near the Rayleigh range. Various beam profiles can be implemented using this method. Back-reflected rays into and outside the particle are considered by using a non-sequential ray-tracing model. We present the flexibility of our model from different points of view and validate it. Our model enables the prediction of circumstances in which cells are trapped and how they behave in the optical trap. Consequences of alignment errors in the optical trap device can be efficiently simulated. Therefore, our model would suit for designing an integrated dual fiber optical trap into a microfluidic chip. The ultimate goal of this model is to introduce it for micro-optical systems for biomedical applications, in particular the identification of single cells.

8810-99, Session PWed

Numerical simulation of Brownian particles in optical force fields

Giorgio Volpe, Institut Langevin (France); Giovanni S. Volpe, Bilkent Univ. (Turkey)

Some randomness is present in most phenomena, ranging from biomolecules and nanodevices to financial markets and human organizations. However, it is not easy to gain an intuitive understanding of such stochastic phenomena, because their modeling requires advanced mathematical tools, such as sigma algebras, the Itô formula and martingales. Here, we discuss a simple finite difference algorithm that can be used to gain understanding of such complex physical phenomena. In particular, we simulate the motion of an optically trapped particle that is typically used as a model system in statistical physics and has a wide range of applications in physics and biophysics, for example, to measure nanoscopic forces and torques. First, we will explain how to simulate a random walk and how to treat the white noise term within a finite difference framework. We will then describe how to simulate the free diffusion of a Brownian particle and study its transition from the ballistic to the diffusive regime due to the presence of inertial effects at short time scales, and examine the effect of an optical trap on the motion of the particle. We also outline how to use simulations of optically trapped Brownian particles to gain understanding of nanoscale force and torque measurements, and of more complex phenomena, such as Kramers transitions, stochastic resonant damping, and stochastic resonance.

8810-100, Session PWed

Intracavity optical trapping with feedback locked diode lasers

Giovanni Volpe, Bilkent Univ. (Turkey); Onofrio M. Maragó, Pietro Gucciardie, Maria G. Donato, Rania Sayed, Istituto per i Processi Chimico-Fisici (Italy); Yazgen Tuna, Bilkent Univ. (Turkey)

The first optical tweezers (OT) was realized using a laser beam strongly focused by a high numerical aperture objective lens. In these systems, a particle is trapped in the focal region by the radiation forces arising from the particle's light scattering. Since then, OT have been extensively used for applications in cellular and molecular biology, soft matter, nanotechnology and physics. The ability to apply forces in the range of femto- to picoNewton on nanoparticles and to measure their displacements with nanometer precision is crucial for the investigation of colloidal and condensed matter systems. More recently OT have been also used to manipulate, rotate and assemble a variety of nanostructures, such as carbon nanotubes, nanowires, polymer nanofibers, graphene flakes dispersed in water and metal nanoparticles and aggregates. Here we demonstrate a novel approach to optical trapping based on optical feedback-locking that can be applied with low numerical aperture lenses (NA= 0.35, 0.45). In this novel configuration the optical feedback on the diode laser source is controlled by the light scattering from a trapped particle. When no particle is in the trap, the optical feedback from a dielectric mirror (external mirror) posed above the microscope objective will increase the trapping power in the focal spot. Instead, when a particle falls in the trap, the trap will work at low power preventing damage and relaxing the stringent conditions on high numerical aperture for standard OT. In this novel configuration we can achieve stable optical trapping at very low power (0.3 mW) with injected current close to the threshold current of the diode laser, with a large field of view and a long working distance. This technique is very useful for dealing with biological samples which need very low power to prevent photodamage.

Rayleigh scattering correlation spectroscopy on diffusion dynamics of nanoparticles under intense laser irradiation

Ping-Yu C. Hee, National Chiao Tung Univ. (Taiwan); Takayuki Uwada, Josai Univ. (Japan); Kazunori Okano, Atsushi Miura, Hiroshi Masuhara, National Chiao Tung Univ. (Taiwan)

White light continuum generated by focusing femtosecond laser pulses (100 fs, 800 nm, 80 MHz) to a photonic crystal fiber is an excellent probe light for Rayleigh scattering spectroscopy. By using white light we have developed light scattering spectroscopy and imaging system for studying nano-materials, single living and plant cells, and so on. Here we report Rayleigh scattering correlation spectroscopy on diffusion dynamics of various nanoparticles in solution under intense laser irradiation. Diffusion time was estimated by conventional analysis under various conditions. In case of gold nanoparticles with a diameter of 100 nm, the diffusion time measured with 35 uW probe light intensity is constant at observation wavelength range of 500-700 nm. This indicates that no additional effect is involved upon irradiation of surface plasmon resonance (SPR) band. On the other hand, however, the diffusion time measured with higher probe intensity gives interesting wavelength dependences. At 532 nm the diffusion time decreases to one-fourth when the intensity was increased from 1 to 100 mW, while no clear dependence was obtained at 800 nm. As SPR band of this nanoparticle is located around 580 nm, we consider that the probe light absorbed by the gold nanoparticle results in photothermal heating, leading to vigorous diffusion. Such heating effect is not appreciable at 800 nm, but gradient force may be exerted at 100 mW. We are examining such complex diffusion dynamics of various nanoparticles under intense laser irradiation and will report how SPR will affect diffusion through heating and trapping.

Rotation of optically trapped plasmonic nanoparticles by circularly polarized light

Anni Lehmuskero, Robin Ogier, Chalmers Univ. of Technology (Sweden); Lianming Tong, Chinese Academy of Sciences (China); Tina Gschneidtner, Chalmers Univ. of Technology (Sweden); Peter Johansson, Örebro Univ. (Sweden); Mikael Käll, Chalmers Univ. of Technology (Sweden)

The fact that light carries spin and orbital angular momentum can be utilized in rotating nanoparticles simply by targeting them with a beam of light. The spin angular momentum is transferred to a particle by absorption which induces a torque to the absorbing particle. The torque is counteracted by the drag force in the case of viscous medium resulting in constant rotation frequency of the particle about its own axis.

Sub-wavelength sized particles have optical properties that are significally different from their macroscopic counterparts. Noble metal nanoparticles are particularly interesting in this respect because they support surface plasmon resonances that have profound influence on the optical force interactions. Plasmonic particles have also high absorption close to their resonance which makes them interesting candidates for the rotation experiments.

In this work, we have used a single Gaussian beam laser tweezers constructed around an inverted optical microscope to trap particles two-dimensionally and investigate the interaction between circularly polarized light and plasmonic nanoparticles. The particles are illuminated with dark field condenser and the scattered light is detected with avalanche photo diode and analyzed by an autocorrelator. The rotation frequency is analyzed from the autocorrelation signal of the scattered intensity.

The particles used in the measurements consist of plasmonic nanowires, nanorods and nanobeads made of silver and gold. As we demonstrate, the nanowires reach rotation rate of few turns per second whereas for the nanobeads the rotation frequency is considerably higher. Fast rotation of nanopartices could be beneficial in biophysics, microfluidics and in sensing technology.

Optical trapping of anisotropic nanocylinder

Paul Brule-Bareil, Yunlong Sheng, Univ. Laval (Canada)

For modeling optical trapping of an anisotropic nano-particle we first used the point matching method to compute the T-matrix coefficients based on the boundary condition for the normal componants of D-fields. In the anisotropic media, where the divergence of E-field is non-zero, the Maxwell wave equations was sloved in the Fourier space. Thus, the plan waves with angular spectrum amplitude distributions can be expanded into the orthogonal and complete set of the Vector Spherical Wave Functions. The E-field eigenvectors can be obtained by the characteristic equation. In the point-matching mthod however we do not need to solve the entire internal field in the anisotropic particle, but an expression of the unknown internal field at the boundaries. We computed the stress distribution on the interfaces of an anisotropic nanocylinder and the related total lateral torque, spin torque and total force in the optical tweezers in order to put in evidence for mecanism of the optical trap of the anisotropic particle. The trapping beam was modeled as the vector Gaussian beam with high order corrections. After solving the scattered field the radiation stress was computed through the Maxwell stress tensor for anisotropic media by Robinson. Our calculation showed that optical stress can be not normal to the interface of anisotropic media. Our calculation predicted that when the optical axes of the anisotropic nanocylinder are not aligned with the cylinder axis, the nanocylinder can be trapped inclined with respect to the beam axis at an equilibrium position. Preliminary experimental observations came to support this prediction.

Sorting bacteria of different shape by specially designed optical traps

Anna S. Bezryadina, San Francisco State Univ. (United States); Shima Fardad, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States) and San Francisco State Univ. (United States); Drew Bischel, Joseph C. Chen, Zhigang Chen, San Francisco State Univ. (United States)

We demonstrate optical trapping and sorting of Bacillus thuringiensis and Micrococcus luteus bacteria. We can select from between two types of Gram-positive bacteria by using novel beams which trap only one of two separate morphologies. In our research we looked at rod and spherical shaped bacteria to develop a sorting method, which can be later applied for more dangerous bacterium such as Bacillus anthracis, which is the etiologic agent of anthrax. We use a holographic optical tweezer system with custom designed beam profiles created to optimally fit and optically manipulate predominately only one type of bacteria and not another. This technique allows us to specificity trap only one strain of bacterium in order to look at the cytokinesis of each type of bacteria independently and separate pairs of bacteria from each other.

Analysis of sperm energetics and motility in viscous solutions using optical tweezers

Nicholas Hyun, Sean Lee, Charlie Chandsawangbhuwana, Univ. of California, San Diego (United States); Qinyuan Zhu, Linda Z. Shi, Institute of Engineering in Medicine (United States); Michael W. Berns, Beckman Laser Institute (United States) and Univ. of California, Irvine (United States)

We have previously reported that increasing viscosity physically affects the mechanical properties of human sperm motility. When sperm encounter a viscous environment their swimming force increases with increasing viscosity while their curvilinear velocity (VCL) decreases with increasing viscosity. Additionally, sperm probed with the mitochondrial membrane potential dye DiOC6 showed no increase in aerobic respiration while under these conditions.

The aim of the present was to characterize sperm energetics while closely monitoring the sperm's swimming force and VCL, and at the same time inhibit aerobic and anaerobic metabolic pathways. Multiple sperm were optically trapped using a 1064 nm Nd:YVO4 continuous wave laser and tracked in increasing viscous solutions while inhibiting the sperm's anaerobic pathway using 2-deoxy-d-glucose (DOG). Additionally experiments were done using carbonyl cyanide m-chlorophenyl hydrazone (CCCP) to inhibit the aerobic pathway. Analysis of the data showed that inhibiting either pathway caused a decrease in swimming force and VCL when compared no inhibition-controls. The trend of swimming force increasing with increasing viscosity was still observed when inhibiting either energetic pathway. When both inhibitors were used simultaneously, the sperm motility was either reduced to zero or dramatically decreased. These results support our hypothesis that viscosity affects the sperm physically rather than through the metabolic pathways associated with ATP production.

Monolithic PMMA stretcher chip with integrated DUV induced waveguides

Maria Khoury Arvelo, Christoph Vannahme, Kristian Tølbøl Sørensen, Anders Kristensen, Kirstine Berg-Sørensen, Technical Univ. of Denmark (Denmark)

The design and implementation of a monolithic microfluidic optical stretcher and manipulation chip is presented. The microfluidic chip is fabricated in a low cost polymer, poly(methyl metacrylate) (PMMA), by hot embossing, and integrated waveguides are defined by deep UV (DUV) exposure of the PMMA. The DUV absorption alters the refractive index of the PMMA locally and enables monolithical integration of single mode optical waveguides into the microfluidic chip. The DUV induced waveguides exhibit propagation losses in the range of dB/mm, comparable to other integrated polymer waveguides. The fabrication procedure, characterization of the optical waveguides, and initial trapping and manipulation experiments are presented. A Matlab script was developed for tracking manipulated particles and used to characterise the optical forces in manipulation and trapping experiments.

The device layout is compact and is easily extendable to multiple-waveguide trap configurations integrated with microfluidic sample preparation. Moreover, the fabrication is upscalable, pointing to cheap, single-use chips.

Manipulation of yeast cells with DOE-modulated crescent-shaped and optical bottle laser beams

Mikhail A. Rykov, Roman V. Skidanov, Image Processing Systems Institute (Russian Federation)

This work is dedicated to the study of micromanipulation techniques using DOE-modulated laser beams. Two kinds of crescent-shaped and optical bottle beam kinds are covered. The numerical model for the calculation of light damage and optical forces exerting by the modulated beams on a trapped particle is provided. The study also contains experimental results on the trapping and manipulating of yeast cells with modulated laser beams. They show that modulated beams are in some cases are more efficient than widely used Gaussian beam: crescent beams are able to achieve better trap stiffness than Gaussian at the price of altered spatial distribution of that stiffness. Optical bottles are beneficial for their ability to hold the trapped object by its edges therefore decreasing amount of light energy absorbed by the microbiological samples.

One of the significant features of the work is that the DOE for the beam modulating is not a dynamic modulator but actually etched on the glass relief. This technique gives better energoefficiency and higher quality of the beam profile.

The theoretical part of the work consists of the numerical modulation of the capturing process using RO-regime and ray-tracing algorithms to compute light propagation through the cell model. The model takes into account inner cell structure and ray-tracing is also used to project optical damage.

The experimental part consists of series of actual trapping and manipulating with Saccharomyces cerevisiae cells. For all the beam types trap stiffness is measured.

Crescent beams give 2-4 times better trap stiffness than Gaussian beams.

8810-108, Session PWed

Direct measurement of formation of loops in DNA by a human tumor suppressor protein

Amy Migliori, Douglas E. Smith, Samuel C. Kung, Univ. of California, San Diego (United States); Danielle Wang, Univ. of California, Irvine (United States)

In previous work we developed methods using optical tweezers to measure protein-mediated formation of loops in DNA, structures that can play an important role in regulating gene expression. We previously applied this method to study unusual restriction endonucleases, which were convenient model systems for studying this phenomenon. Here we report preliminary work in which we have applied this method to study p53, a human tumor suppressor protein, and show that we can measure formation of loops. Previous biophysical evidence for loops comes from relatively limited qualitative studies of fixed complexes by electron microscopy. Our results provide independent corroboration and future opportunities for more quantitative studies investigating structure and mechanics.

8810-109, Session PWed

Longterm effects of inertia on a Browian particle studied by optical tweezers

Giuseppe Pesce, Univ. degli Studi di Napoli Federico II (Italy); Giorgio Volpe, Institut Langevin (France); Antonio Sasso, Univ. degli Studi di Napoli Federico II (Italy); Giovanni S. Volpe, Bilkent Univ. (Turkey)

The effects of the inertia on a Brownian particle diffusing in a fluid are usually considered negligible. Only at very small times, i.e. times of the order of magnitude of the ratio m/gamma, deviations from the Einstein-Smoluchowsky law have been recently reported taking into accounts also the effects of the fluid displacement. Using blinking optical tweezers and fast video microscopy we show that these effects are measurable even at long times, up to few tenths of seconds. In particular the deviation from the Einstein-Smoluchowsky law increases with the time.

Testing a structural model for viral DNA packaging motor function by optical tweezers measurements, site directed mutagenesis, and molecular dynamics calculations

Nicholas A. Keller, Douglas E. Smith, Gaurav Arya, Univ. of California, San Diego (United States); Venigalla Rao, The Catholic Univ. of America (United States); Amy Migliori, Univ. of California, San Diego (United States)

Many double-stranded DNA viruses employ a molecular motor to package DNA into preformed capsid shells. Based on structures of phage T4 motor proteins determined by X-ray crystallography and cryo-electron microscopy, Rao, Rossmann and coworkers recently proposed a structural model for motor function. Specifically, they proposed that DNA is ratcheted by a large conformational change driven by electrostatic interactions between charged amino acids at an interface between two globular domains. We are currently working on testing this model by studying the effect of site-directed changes altering the charges of these amino acids on packaging dynamics measured in detail with optical tweezers. We are also use molecular dynamics simulations to predict alterations in free-energies caused by these changes. We report preliminary work in which several amino acid changes are predicted to have significant effects and are indeed clearly observed to alter the measured motor dynamics.

8810-111, Session PWed

Evidence for non-equilibrium dynamics in viral DNA packaging from optical tweezers measurements

Zachary Berndsen, Nicholas A. Keller, Douglas E. Smith, Univ. of California, San Diego (United States)

Tight confinement of double-stranded DNA molecules in viruses is an energetically unfavorable process driven by a powerful molecular motor complex. Here we present preliminary results that suggest a significant influence on these forces of non-equilibrium dynamics of the confined DNA. In one approach we measure changes in the packaging dynamics of single complexes following stalling and restarting of the motor. In a second complementary approach, we analyze heterogeneity in packaging dynamics within a large ensemble of individual complexes. Both measurements suggest the formation non-equilibrium DNA conformations with very long relaxation times compared with free DNA.

8810-112, Session PWed

Analysis of single-molecule mechanical measurements with high spatio-temporal resolution

Marco Capitanio, Lucia Gardini, European Lab. for Non-linear Spectroscopy (Italy); Francesco S. Pavone, Univ. degli Studi di Firenze (Italy)

Optical tweezers allow recording mechanical data from single biological molecules such as molecular motors, DNA processing enzymes, nucleic acids. Such data consist of time series that are dominated by thermal noise and such noisy recordings require proper analysis to correctly extract kinetic and mechanical information. Several different analysis approaches have been established in the past years. Here, we propose an analysis method for optical trapping recordings of non-processive motor proteins. The method does not assume any particular interaction kinetics, allows detection of sub-millisecond interactions and quantification of the number of false and lost events. Precise alignment of interaction events and ensemble averaging allow the investigation of the stepping dynamics of non-processive motors with a temporal resolution of few tens of microseconds and a spatial resolution of few angstroms. Our analysis is applied to the study of the motor protein myosin from fast skeletal muscle. Thanks to the high spatio-temporal resolution, we can distinguish three mechanical pathways in the acto-myosin interaction, with several orders of magnitude different kinetics, which contribute in a load-dependent manner to the myosin working stroke.

8810-71, Session 15

Optical manipulation using speckle fields

Giorgio Volpe, Institut Langevin (France); Giovanni S. Volpe, Bilkent Univ. (Turkey); Sylvain Gigan, Institut Langevin (France)

Current optical trapping techniques rely on carefully engineered optical systems; since the quality of the trapping is strongly dependent on the quality of the focus, these systems have to be very carefully aligned and optimized. It is therefore still a challenge to manipulate a large number of particles when the environment is not well controlled and known a priori such as in most biological, biomedical and microfluidic applications. Here, we developed a novel technique for optical manipulation based on speckle light fields. These fields arise naturally when coherent light impinges on scattering systems (biological tissues, turbid liquid, non-transparent microfluidic devices or rough surfaces) and, while the produced speckle pattern is random, it has well-defined statistical properties, such as its distribution of intensity and correlation length. We experimentally show how to take advantage of such properties in order to perform optical manipulation tasks such as trapping, guiding and sorting. In particular, we demonstrated the sorting of Brownian particles of different size and refractive index in a microfluidic device. To perform such tasks, an incident laser power as little as a tenth of milliwatt per square micrometer is needed, and, apart from the excitation laser, all the components needed to generate the speckle pattern can be integrated in the walls of the microfluidic chamber. The simplicity of this technique will foster its application in biological and biomedical applications where automated and turn-key techniques are especially appreciated.

8810-72, Session 15

Adaptive optics and aberration correction in optical tweezers

Amanda J. Wright, The Univ. of Nottingham (United Kingdom); Caroline Müllenbroich, Niall McAlinden, Univ. of Strathclyde (United Kingdom)

Optical aberrations are a well-known problem in optical tweezers, particularly when users wish to take quantitative measurements at depth into samples. Without any aberration correction the strength and quality of the trap can be seen to clearly deteriorate with trap depth. Here we use a technique called Adaptive Optics, common in optical astronomy, to correct for the optical aberrations in an optical tweezers system. Adaptive Optics works on the principle of shaping the incoming wavefront with the equal but opposite distortion to that caused by the optical system and the sample so as to restore image quality, or in this case trap strength. The Adaptive Optics system used here is a sensor-less system, with a deformable membrane mirror as the correction element and a random search optimisation algorithm that determines the aberration correction required. Crucial to the success of this technique is the choice of merit factor the algorithm uses as a measure of improvement. The novel merit factor employed here is determined by measuring the displacement of a bead from its equilibrium position when exposed to a viscous drag force. The benefit of this merit factor is that it is inversely proportional to the stiffness of the optical trap, the property we aim to improve. We demonstrate the success of this technique by increasing our maximum trapping depth from 136 µm to 166 µm and increasing the trap strength by a factor of 4.37 and 3.31 for the x- and y- axis respectively at a depth of 131 µm.

8810-73, Session 15

Spatial light modulation for improved microscope stereo vision and 3D tracking

Michael P. Lee, Boulder Nonlinear Systems (United Kingdom) and Univ. of Glasgow (United Kingdom); Graham M. Gibson, Univ. of Glasgow (United Kingdom); David B. Phillips, Univ. of Bristol (United Kingdom); Stefan Bernet, Monika Ritsh-Marte, Innsbruck Medical Univ. (Austria); Miles J. Padgett, Univ. of Glasgow (United Kingdom)

We present a new type of stereo microscopy which can be used for tracking in 3D over an extended depth. The use of Spatial Light Modulators (SLMs) in the Fourier plane of a microscope sample is a common technique in Holographic Optical Tweezers (HOT). This set up is readily transferable from a tweezer system to an imaging system, whereby the tweezing laser is replaced with a camera. Just as a HOT system can diffract many traps of different types, in the imaging system many different imaging types can be diffracted with the SLM. The type of imaging we have developed is stereo imaging combined with lens correction. This approach has similarities with human vision where each eye has a lens, and it also extends the depth into the sample that we are capable of accurately tracking particles.

8810-74, Session 16

Optical binding induced assembly of Ag nanoparticles in shaped light fields

Zijie Yan, Raman Shah, Uttam Manna, The Univ. of Chicago (United States); Gray Stephen, Matthew A. Pelton, Argonne National Lab. (United States); Norbert F. Scherer, The Univ. of Chicago (United States)

Optical binding interactions can lead to spatial arrangements of particles in light fields via the potential gradients created by the interference of incident and scattered light,1 and the phenomenon has been widely studied for micron and sub-micron size particles.2, 3 Here we show optical binding of multiple Ag nanoparticles with diameters of 40 nm in solution using shaped light fields with a wavelength of 800 nm, and extend the demonstration of optical binding into the Rayleigh regime where the particles can be well approximated as point dipoles.4 Specifically, ordered clusters were formed in cylindrically symmetric optical traps, and linear chains were formed in line traps. We extended the coupled-dipole model to describe optical binding of multiple particles, and the model successfully predicted many experimental results. Moreover, for Ag nanoparticles with diameters of ~100 nm, the strong optical binding forces can assemble the particles into regular arrays, and for Ag nanoparticles with diameters of ~150 nm, optical binding can lead to stable lattices of Ag nanoparticles. These stable lattices, in turn, can serve as templates to trap other smaller objects, e.g., semiconductor quantum dots, in the regions of large field gradients created by multiple scattering and interference. These results demonstrate the possibility to fabricate new hybrid assemblies with strong nonlinear-optical and quantum-optical properties by all-optical methods.

8810-75, Session 16

Pair interaction and optical binding in 3D random electromagnetic fields

Sergey V. Sukhov, Kyle M. Douglass, Aristide C. Dogariu, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

One of the well-known consequences of particle-particle interaction in an external electromagnetic field is optical binding (OB). OB has traditionally been observed between scattering particles located in a controlled, beam-like geometry. As a result of the interaction, they experience attractive or repulsive forces depending on their mutual position. Notably, there are stable positions where the binding force acting on the particles is zero. OB has been comprehensively studied for single wave and counter-propagating wave excitation geometries.

The question whether the interaction between particles and optical binding still exists in incoherent fields is not trivial. It's not clear how the particle-particle interaction is affected by partially coherent illumination or by fields whose correlation length is anisotropic. Furthermore, since the OB force disappears in a temporally incoherent field, one might think that it does so in a spatially incoherent field as well. We have found, however, that this interaction does survive in a fully spatially incoherent field and, moreover, it is a long-range interaction. The finite coherence length of the external field introduces certain peculiarities that will be discussed in the talk, such as the dependence of the magnitude and the periodicity of the interaction potential on the coherent properties of light. The application of the calculated interaction potential for the study of particle dynamics in a cavity will be also discussed.

The non-vanishing force between particles in random, three-dimensional fields has important implications for many field-coupled systems, such as optically-active matter and protein-membrane dynamics in cells.

8810-76, Session 16

Near-field manipulation of interparticle forces through resonant absorption, optical binding, and dispersion forces

David S. Bradshaw, David L. Andrews, Univ. of East Anglia Norwich (United Kingdom)

The relative motions of two or more neutral particles, subject to optical trapping forces within a beam, are influenced by intrinsic inter-particle forces. The fundamental character of such forces is well-known and usually derives from dispersion interactions. However, the throughput of moderately intense (off-resonant) laser light can significantly modify the form and magnitude of these intrinsic forces. This optical binding effect is distinct from the optomechanical interactions involved in optical tweezers, and corresponds to a stimulated (pairwise) forward-scattering mechanism. In recent years, attention has begun to focus on optical binding effects at sub-micron and molecular dimensions. At this nanoscale, further manipulation of the interparticle forces is conceivable on the promotion of optically bound molecules to an electronic excited state. It is determined that such excitation may influence the intrinsic dispersion interaction without continued throughput of the laser beam, i.e. independent of any optical binding. Nevertheless, the forward-scattering mechanism is also affected by the initial excitation, so that both the optical binding and dispersion forces can be manipulated on input of the electromagnetic radiation. In addition, the rate of initial excitation of either molecule (or any energy transfer between them) may be influenced by an off-resonant input beam which, thus, acts as an additional factor in the modification of the interparticle force. A possible experimental set-up is proposed to enable the measurement of such changes in the interparticle force, based on adapted AFM instrumentation.

8810-77, Session 16

Optical binding of non-spherical colloids

Stephen H. Simpson, Univ. of Bristol (United Kingdom); Philip H. Jones, Univ. College London (United Kingdom); Onofrio M. Maragó, Istituto per i Processi Chimico-Fisici (Italy); Simon Hanna, Univ. of Bristol (United Kingdom)

Optical binding effects provide a means of steering the self organization of colloidal particles. Almost all existing studies make use of colloidal spheres. Despite the relative simplicity of this system, a plethora of intriguing observations have been made. For example bistability and hysteresis [1] have been observed in pairs of optically coupled beads, whilst lattice and pattern formation can be achieved for arrays of spheres [2,3]. More recently, extremely strong binding has been observed for spherical metallic nano-particles [4]. Spoiling the spherical symmetry of the particles under consideration adds an additional layer of complexity. Previously, binding forces have been computed between pairs of carbon nano-tubes, using quantum electrodynamics [5]. Here, we classically examine the forces and torques between pairs of low symmetry particles in counter-propagating plane waves. Equilibrium configurations are located and their stability examined. The theoretical results are compared with existing experimental work, and the potential for self organization of novel structures is discussed.

8810-78, Session 16

Optical sorting due to optical binding

Vitezslav Karasek, Matin Siler, Oto Brzobohaty, Pavel Zemánek, Institute of Scientific Instruments of the ASCR, v.v.i. (Czech Republic)

When several particles are illuminated by intense laser fields there exist also additional optical forces between the particles induced by scattered fields.

This effect is called optical binding and the particles due to their mutual forces induced by light may create optically bound structure.

As these forces are of second order (in comparison to forces induced by the incident fields) they are very sensitive to size or shape of the particles.

We have previously experimentally studied the optical binding in the configurations employing two counter-propagation Bessel beams.

These results were sufficiently supported by our numerical simulations (Coupled dipole method CDM).

We study how the difference of sizes of two spherical particles influences their spatial stable separation.

Even small changes in the limits of particle-size distribution of used particles may lead to experimentally verifiable differences.

The intensities of the two beams must be also tuned to achieve sufficient stability of the whole couple in the experimental sample.

By variation of mutual intensities we may also move the couple along the common optical axis.

Another results may serve for detection of particles of different composition or shape.

Very exciting configuration of "Optical tractor beam" offers another and simple means of optical sorting.

Our numerical results indicate that the behaviour is very sensitive to particles size.

Here we present numerical studies how the sizes of individual particles (within the range of the particle-size distribution) influences the particles dynamics in various optical trapping configurations.

8810-79, Session 17

Micro-assembling with optical tweezers: provisioning solutions for micro manufactured 2PP building blocks

Sarah Isabelle Ksouri, Andreas Aumann, Reza Ghadiri, Sebastian Baer, Andreas Ostendorf, Ruhr-Univ. Bochum (Germany)

Holographic optical tweezers manipulate structures in micrometer range with highest flexibility and precision. As is well known non-spherical assemblies can be trapped and controlled by laser light and assembled with an additional light modulator application, where the incident laser beam is rearranged into flexible light patterns in order to generate multiple spots. The complementary polymer assemblies are generated by a two-photon-polymerization (2PP) process and are not equipped with spherical trapping points. The possibilities of manufacturing arbitrary building blocks and the potential of HOTs lead to the idea of combining manufacturing techniques with manipulation processes. In this work we present how generated structures can be disassembled for replacing defective building blocks for example as well as a sorting solution for 2PP assemblies is introduced. A purpose-built sample holder is developed for a manual intake of 2PP building blocks. The long-term objective is to automate the feeding and provisioning of several different 2PP micro assemblies to realize an automated assembling station.

8810-80, Session 17

Fashioning microscopic tools: the development of a passive force clamp using particle shaping

David B. Phillips, Univ. of Bristol (United Kingdom); Miles J. Padgett, Univ. of Glasgow (United Kingdom); John G. Rarity, Simon Hanna, Mervyn J. Miles, Stephen H. Simpson, Univ. of Bristol (United Kingdom)

By moulding optical fields, holographic optical tweezers are able to generate structured force fields with magnitudes and length scales of great utility for experiments in soft matter and biological physics. Optically induced force fields are determined not only by the incident optical field, but by the shape and composition of the particles involved. Indeed, there are desirable but simple attributes of a force field, such as rotational control, that cannot be introduced by sculpting optical fields alone. We show how force-extension relations for particles in Gaussian traps can be deliberately engineered by fashioning colloids of particular geometries. To demonstrate this, we describe the design, fabrication and application of a passive force clamp, capable of applying a constant force over several microns. The non-linear force-extension characteristics of our sensor can be characterised by rapidly switching the optical trap positions and observing the velocity of the sensor's return to equilibrium. We demonstrate how such a device can be used to image surfaces while exerting a constant force, without the need for feedback control.

8810-81, Session 17

Heat in optical tweezers *(Invited Paper)*

Daniel Jaque Garcia, Blanca del Rosal, Patricia Haro, Laura Martinez Maestro, Univ. Autónoma de Madrid (Spain); William T. Ramsay, Heriot-Watt Univ. (United Kingdom); Emma Martin Rodriguez, Concordia Univ. (Canada); Lynn Paterson, Ajoy K. Kar, Heriot-Watt Univ. (United Kingdom); José García Solé, Univ. Autónoma de Madrid (Spain)

The presence of laser-induced thermal loading in optical traps and tweezers is a well known phenomenon that should be known in detail in order to minimize its effects on trapped objects such as living cells. In this work Quantum Dot based nano-thermometry has been used to determine the magnitude of such heating during single cell trapping. It has been possible to find evidence of the existence of an optimum wavelength that minimizes cell damage. we will show how this optimum trapping wavelength results from the simultaneous minimization of both photo-thermal and photo-chemistry damage. We also present first results on the optical manipulation of plasmonic-based micro heaters and of rare earth doped nano-thermometers (nano-particles) for controlled in vivo photo-thermal treatments. Optically controllable micro-heaters consists on hybrid dielectric particles conjugated with metallic nano-particles capable of efficient heating when excited at the plasmon resonance wavelength. The nano-thermometers are dielectric nano-particles doped with rare earth ions whose luminescence is strongly dependent on environmental temperature.

8810-82, Session 17

Optical tweezers for precise control of micro-bubbles arrays

Tristan Burns, Daryl C. Preece, Timo A. Niemenen, Haliina Rubinsztein-Dunlop, The Univ. of Queensland (Australia)

We use highly focused laser beam to create micro-bubbles. The size of the bubbles is highly controllable and a full optical control is attained. Multiple bubbles can also be created and their size changed independently. The dynamics of such multi-bubble systems are studied. Such bubble systems generate strong flows such as marangoni convection and also large thermal gradients.

However, this can be exploited for the purposes of measurement.

Since the size of such micro-bubbles is highly dependent on the supplied temperature, we anticipate that such systems can be used for precise temperature control of samples. These methods can become of potentially great use when the exact and local temperature profiles are of importance. Furthermore, since bubble expansion can generate orders of magnitude more force than conventional optical forces. Such systems have application in manipulation of particles that cannot be moved by other means. We present methods based on optical tweezers for using the generated bubbles as thermal sensors and as opto-mechanical transducers.

Femtosecond optical trapping of dielectric nanospheres: three-dimensional mapping of their directional ejections

Wei-Yi Chiang, Anwar Usman, Hiroshi Masuhara, National Chiao Tung Univ. (Taiwan)

By replacing conventional continuous wave- to femtosecond pulsed-laser beam in optical trapping experiment of 50-nm-sized polystyrene beads, we found that the nanoparticles are ejected from the trapping site in directions perpendicular to the laser polarization.1 This phenomenon has been elucidated in detail by using theoretical modelling and numerical approaches of the optical forces based on interaction between single nanoparticles with electromagnetic field of a single pulse, by which we have shown that attractive force components spatially resolved in directions orthogonal to laser polarization are completely overcome by respective repulsive forces.2 These forces may also be important for manipulating or controlling the dynamics of nanoparticles. Assessment of the repulsive forces can be quantitative when migrations of nanoparticles can be visualized in three-dimensions. Since our experimental system uses a single objective lens for both laser trapping and light scattering imaging to observe only the dynamics of nanoparticles at the trapping plane, three-dimensional migrations of the nanoparticles were evaluated by shifting the focal plane along the vertical direction, above and below the trapping site, immediately after the trapping beam was turned off. By doing so, we indeed observed the directional migrations of nanoparticles out of the trapping site in three dimensions. The results suggest that trajectories of the ejected nanoparticles take the shape of a cone with its vertex at the focal center and its axis of symmetry on the plane perpendicular to the laser polarization. This finding leads to a new perspective of optical trapping of nanoparticles by ultrashort laser pulses.

8810-84, Session 17

Measuring colloidal osmotic compressibility of nanoparticle suspension by optical trapping

Jinxin Fu, Vural Kara, H. Daniel Ou-Yang, Lehigh Univ. (United States)

Particle interactions determine the stability of nanoparticle suspensions and the phase separation of particle-polymer mixtures. However, due to the small sizes of the dispersed nanoparticles, it is not easy to directly measure interaction forces between particles in a colloidal suspension. In this paper, we propose an “Optical Bottle” approach to quantify these particle interactions in a suspension by measuring the colloidal osmotic compressibility of the nanoparticles. Virial expansion of the colloidal osmotic compressibility yields virial coefficients of different orders. The second order virial coefficient of aqueous suspensions of colloidal polystyrene nanospheres in the presence of high-salt (KCl) and polyethylene glycol (PEG) is found to decrease with increasing PEG concentration, suggesting an attractive depletion interaction between the PEG-crowed polystyrene particles.

8810-85, Session 17

Optical trapping of high refractive index semiconductor nanocrystals: nanoscale force probes without the heating

Ana Andres Arroyo, Fan Wang, Wen Jun Toe, Peter J. Reece, The Univ. of New South Wales (Australia)

Recent research into developing nanoscale optical trapping force probes has primarily focused on the use of noble metals nanoparticles, such as gold and silver, as they have considerably greater polarizability then standard dielectric spheres of equivalent dimension. The fundamental limitation of this approach is that unavoidable heating is linked with dissipation induced surface plasmons. This heating can be severe at the optical powers required for trapping and can cause non-physiological cell responses. We explore theoretically and experimentally the possibility of using high refractive index semiconductor nanoparticles as a possible alternative to achieving high polarizability whilst operating at a trapping wavelength that is below the band-gap energy where the particles have negligible absorption.

8810-86, Session 17

Optical trapping for tissue scaffold fabrication

Anna M. Linnenberger, Boulder Nonlinear Systems (United States)

We investigate holographic optical trapping combined with step-and-repeat maskless projection stereolithography for fine control of 3D position of living cells within a 3D microstructured hydrogel. C2C12 myoblasts are positioned in the monomer solution with multiple optical traps at 1064 nm and then encapsulated by photopolymerization of monomer via projection of a 512x512 spatial light modulator illuminated at 405 nm. High 405 nm sensitivity and complete insensitivity to 1064 nm was enabled by a lithium acylphosphinate (LAP) salt photoinitiator. These wavelengths, in addition to brightfield imaging with a white light LED, could be simultaneously focused by a single oil immersion objective. Large lateral dimensions of the patterned gel/cell structure are achieved by x and y step-and-repeat process. Large thickness is achieved through multi-layer stereolithography, allowing fabrication of precisely-arranged 3D live cell scaffolds with micron-scale structure and millimeter dimensions. Cells are shown to retain viability after the trapping and encapsulation procedure.

Nanoscale confinement enables precision spectroscopy of biomolecules *(Invited Paper)*

Sabrina R. Leslie, McGill Univ. (Canada)

Imaging weak interactions and slow dynamics of biomolecules presents a challenge to existing single-molecule microscopy techniques. We dramatically improve single-molecule imaging by developing a new suite of devices which combine smoothly varying confinement with nanolithography. Using nano-positioners and microfluidics, we dynamically tune the chamber geometry and sample insertion, enabling enable precise and temporally resolved studies of molecular interactions under previously inaccessible conditions. In this talk, we report on the design and performance of a suite of new automated single-molecule imaging devices, suitable for a wide range of applications in biophysics, bioengineering, and materials science. Taking advantage of the continuum of applied confinement (from the nanometer to micron scale), we demonstrate precision spectroscopy of the confinement potential experienced by biomolecules. Further, we demonstrate the suitability of this system in sizing molecules and particles on the nanometer scale, which presents a challenge to existing approaches.

8811-2, Session 1

Characterization and manipulation of the secondary structure of surface-bound peptides *(Invited Paper)*

Lauren Webb, The Univ. of Texas at Austin (United States)

Proteins display a tremendous range of specific biological function. Applying this function to sensing, chemical catalysis, and biofuel generation would profoundly expand and change these traditional fields. This goal requires that the protein of interest be effectively integrated with inorganic materials such as a crystal surface in a controlled and oriented manner without altering its three-dimensional fold or compromising function, a challenging biomaterials problem. In the research described here, we chemically functionalize gold surfaces with peptides of known secondary structure. These surfaces are chemically characterized through X-ray photoelectron spectroscopy, ellipsometry, surface infrared spectroscopy, and scanning tunneling microscopy. Furthermore, we use surface infrared and circular dichroic spectroscopies to characterize the structure and orientation of the peptide on the surface. We demonstrate that correctly functionalized surfaces induce a alpha-helical secondary structure on a peptide that is disordered in solution. Demonstration of the control over a desired secondary structure of helical elements at a chemically functionalized surface is an important advance in preparing robust biologically mimetic surfaces and is expected to lead to an entirely new mechanism through which biological and inorganic materials can be coaxed to interact.

8811-3, Session 1

DLC coating in micro fluid channel with biochip

Ali S. Alanazi, King Saud Univ. (Saudi Arabia); Satoshi Murata, Kenji K. Hirakuri, Tokyo Denki Univ. (Japan)

Many polymers are applied to biomaterials by using the micro electro mechanical systems (MEMS) processing. SU-8 (acrylic-epoxy resin) is one of candidates for the photoresist materials in the nano-imprint lithography because of the workability, mechanical and photosensitive properties. It is required to miniaturize the biochip in various industry fields although the surface of the SU-8 is not enough to fit it to the biochip. The flow of the micro fluid in biochips should be controlled by changing the surface condition and structure of the channel. In order to make flat surface for smooth flow, diamond-like carbon (DLC) coating was carried out to the micro fluid channel with biochip because DLC has much attractive characteristics such as chemical inertness, low friction, biocompatibility, controllable wettability, optical transparency, and low surface roughness.

In biochip with SU-8 materials and Si substrate, DLC films have been prepared in the micro channel with the width size of 10 ?m by the photo lithography process. Radio frequency plasma enhanced chemical vapor deposition (rf-PECVD) technique is used for coating of the DLC film. DLC film has been investigated by Electron Dispersive X-ray spectroscopy (EDS), Scanning electron microscopy (SEM), Optical Raman spectroscopy, and contact angle measurement for wettability. In the EDS measurement, carbon peak around 4 keV was confirmed from the surface of the DLC coated channel. Sufficient adhesion between the DLC film and channel surface is obtained when coating condition of the DLC film was appropriately tuned. Wettability of the channel is also controllable from hydrophilic state to hydrophobic state by the selection of hydrophilic and hydrophobic DLC coating.

8811-4, Session 1

The method of capturing CO2 green house gas in cellulose matrix

Kwang Sun Kang, Kyungil Univ. (Korea, Republic of)

Reducing greenhouse gas has been important issue in recent years. Capturing CO2 gas in polymer matrix is attractive method to reduce the green house gas and use as a natural resource, such as polymer-CaCO3 composite. Calcium carbonate (CaCO3) and cellulose composite has been synthesized by bubbling CO2 gas into the mixture of cellulose acetate (CA) and Ca(OH)2 solution. Completely dissolved and transparent Ca(OH)2 solution was prepared to react stochiometric reaction of Ca(OH)2 and CO2. Since the strong absorption peak of the CA in infrared spectra, it is difficult to identify the existence of the CaCO3. To conform the existence of CaCO3 in the cellulose matrix, the CA was removed by dissolving and centrifuging the reaction composite. The characteristic absorption peaks of CaCO3 at 1450, 875 and 712 cm-1 were obtained for the residual composite. Field emission scanning electron microscope (FESEM) images show the shape and size of the CaCO3 particles in the cellulose matrix. Therefore, using cellulose and Ca(OH)2 matrix is one of the effective method capturing the CO2 green house gas.

8811-5, Session 1

H2O/D2O exchange in the presence of CO over SnO2 nanomaterials: operando DRIFTS and resistance study for gas sensor applications

Roman Pavelko, Joong-Ki Choi, Kyushu Univ. (Japan); Atsushi Urakawa, ICIQ - Institut Català d’Investigació Química (Spain); Masayoshi Yuasa, Tetsuya Kida, Kengo Shimanoe, Kyushu Univ. (Japan); Noboru Yamazoe, Kyushu University (Japan)

Modulation excitation DRIFTS together with resistance measurements have been carried out to study how the surface hydroxylation degree of SnO2 materials changes upon exposure to CO in air at 300oC and whether these changes correlate with the generation of free carriers.

We compare two materials synthesized via hydrothermal treatment and different only in their precursors: SnO2Ac synthesized from tin(IV) hydroxide acetate and SnO2Cl from tin(IV) chloride pentahydrate. DRIFTS and resistance measurements were performed simultaneously in an environmental chamber at 300oC and in a flow rate of 50 cm3/min. The experiments assumed consecutive 20 cycles of isotopic exchange: 1.3vol.% H2O was replaced with 1.3vol.% D2O in the background of pure air as well as in 100-500 ppm CO in air.

The materials were found to have similar particle sizes (16±7 nm), crystallite sizes (12±2 nm) and pore size distribution (16±1 nm). The biggest difference concerned the pore volume, which was about 40% higher for SnO2Ac. Sensor tests showed that the latter material, manifesting higher resistance change upon exposure to CO, also had better selectivity in the presence of water vapors. The reasons seem to stem from surface chemistry. In the case of SnO2 Ac, bridging ODs decreased upon exposure to CO at a rate similar to the resistance drop (240±50 and 200±30 ppm-1, resp.). For SnO2Cl no correlations were found between spectra evolution and resistance. Our results suggest that more basic character of surface OH groups on SnO2Ac results in the observed differences between the materials.

8811-6, Session 2

High efficiency solar water splitting with nanostructured oxide tandem cells *(Invited Paper)*

Kevin Sivula, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

A device that can convert solar energy into a chemical fuel with good efficiency while also offering high stability and the capability to be constructed with widely available materials using inexpensive processing techniques is urgently needed. Here we describe new advances that allow the construction of simple dual-absorber tandem cell using either Fe2O3 or WO3 as a photoanode. In order to give an insight into the electro-optical limitations and routes for improvement of these devices, the current-voltage characteristics as well as the spectral responses of the component parts, in addition to being measured in situ, are evaluated based on measured incident to photon efficiencies (IPCEs), transmittances of the photoanodes and photon flux on each active area. Finally, the actual performance of devices is evaluated and the highest-to-date solar-to-hydrogen conversion efficiency for dual-absorber oxide-based solar water splitting (3.1% overall) is reported.

8811-7, Session 2

Photoinduced processes in lead iodide perovskite sensitized solid-state solar cells

Arianna Marchioro, Jan C. Brauer, Joël Teuscher, Michael Grätzel, Jacques-Edouard Moser, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Recently, a new type of solid-state mesoscopic heterojunction solar cell has been reported, employing nanoparticles of organometallic halide perovskites as the light absorbing material. This system was shown to provide remarkable solar conversion efficiencies, up to 9%, in conjunction with the well-known spiro-OMeTAD as the hole transport material.[1]

Remarkably, Lee et al. found that replacement of the mesoporous n-type TiO2 with insulating Al2O3 gave excellent power conversion efficiency, up to 10.9%.[2] The aluminum oxide being an insulator, no electron injection can happen from the perovskite to the metal oxide semiconductor, and the Al2O3 purely acts as a mesoporous scaffold for the perovskite/spiro-OMeTAD system.

The mechanistic processes in the device using mesoporous TiO2 are still under debate, as these organometallic halide perovskite cumulate both functions of light absorption and n-type conduction.

Herein we report an optical spectroscopy study of solid-state methyl ammonium lead iodide (CH3NH3)PbI3 based cells. Characterization of the material has been performed through integration sphere measurements and Photo-Induced Absorption Spectroscopy technique. Femtosecond Transient Absorption Spectroscopy and Terahertz Spectroscopy have been applied to both TiO2 and Al2O3-based cells in order to unravel the processes of charge separation and recombination following light absorption in the device. Luminescence of the perovskites was found to be one of the principal spectral features and its quenching could be correlated with the efficiency of the charge separation.

High refractive index, solution processable molecular hybrid material targeted for use in photonic applications

Andrew Strang, Imperial College London (United Kingdom); Manuela Russo, Imperial College London (United Kingdom) and ETH Zurich (Switzerland); Walter R. Caseri, ETH Zurich (Switzerland); Donal D. C. Bradley, Imperial College London (United Kingdom); Natalie Stingelin-Stutzmann, Imperial College London (United Kingdom) and ETH Zurich (Switzerland); Paul N. Stavrinou, Imperial College London (United Kingdom)

Photonics is an emergent area of interest in the scientific community in which solution processability offers many advantages over the often highly intricate protocols that are required for the manufacture of current technologies. In this work we demonstrate a solution processable molecular hybrid material whose tunable refractive index is used to produce one and two dimensional photonic structures such as distributed Bragg reflectors (DBRs) and waveguides respectively. We employ an organic/inorganic hybrid material, developed by Russo et al.: titanium oxide hydrate cross-linked polyvinyl alcohol (PVA). The material's refractive index can be tuned from 1.5 to greater than 1.8 by controlling the inorganic content of the material, yet without inducing significant optical losses. The properties of the material can be further modified after deposition: annealing can increase the refractive index to over 2.1. This shows that the refractive index of these hybrids can be tuned over a similar window as the best high index, organic materials previously reported. Furthermore, annealing of the material has been shown to affect the cross-linking behavior, allowing control of the interface dynamics of the inorganic species when depositing multi-layer structures. This makes patterning of the hybrid material's index in two, or possibly three, dimensions possible and therefore the production of waveguides, integrated optics and many other photonics applications.

8811-9, Session 2

Interfaces modulate open-circuit voltages of hybrid CH3NH3PbI3 perovskite/organic solar cells

Tzung-Fang Guo, National Cheng Kung Univ. (Taiwan)

The deposition of a thin C60 (acceptor) layer in vacuum on methylammonium lead iodide (CH3NH3PbI3) (donor) perovskite creates a hybrid planar heterojunction for fabricating all-solid-state solar cells. Applying acceptor layer of varied lowest unoccupied molecular orbital (LUMO) level at the heterojunction interface modulates the open-circuit voltage (Voc) of CH3NH3PbI3 perovskites/organic hybrid solar cells. The CH3NH3PbI3/C60 hybrid solar cell exhibits the promising photovoltaic performance of open-circuit voltage VOC = 0.55 V, short-circuit current JSC = 5.21 mA/cm2, fill factor FF = 0.57, corresponding to a power conversion efficiency (PCE) of 1.6% under standard 1 Sun AM 1.5

simulated solar irradiation. The magnitudes of Voc and PCE elevate to 0.65 and 0.75 V, 2.4 and 2.1 % using [6,6]-phenyl C61-butyric acid methyl ester (PCBM) and indene-C60 bisadduct (ICBA), respectively. These results suggest that photovoltaic parameters of CH3NH3PbI3 perovskite/C60 or C60 derivatives cells are controlled by the level position offset of donor and acceptor. Additionally, applying an indium-tin-oxide (ITO)/glass substrate of the relatively higher work function improves the electrode interface and further elevates Voc of the hybrid cells. Voc of CH3NH3PbI3/PCBM cell elevates from 0.65 to 1.06 V. We report an optimized hybrid cell of Voc = 0.92 V, short-circuit current JSC = 7.93 mA/cm2, fill factor FF = 0.62, corresponding to a PCE of 4.5% under standard 1 Sun irradiation. Our findings demonstrate the design rules and the possible development of newly structured, hybrid, efficient solar cells.

8811-10, Session 3

Spectroscopic probes of transport and trapping in colloidal quantum dot photovoltaics

John B. Asbury, Kwang S. Jeong, The Pennsylvania State Univ. (United States)

High external quantum efficiencies have been obtained in the visible region in lead chalcogenide CQD photovoltaics. However, the corresponding efficiencies in the near-infrared lag behind because the thickness of CQD photovoltaic layers is limited by short carrier diffusion lengths. Time resolved infrared (TRIR) spectroscopy in conjunction with electrical characterization methods are used to demonstrate twenty-fold enhancement of the mobility-lifetime products of minority carriers in PbS CQD films passivated with various ligands. Mid-infrared electronic transitions measured by TRIR spectroscopy provide information about charge trap densities and energetic distributions. Direct observation of the vibrational features of ligands attached to surface trap states provide unique insights into the nature of charge traps and helps define pathways for their elimination. These findings demonstrate that TRIR spectroscopy provides a means to directly probe the electronic properties of charge trap states and the underlying ligand-nanocrystal interactions that give rise of those states.

8811-11, Session 3

In-situ investigation of adsorption of dye and coadsorbates on TiO2 films using QCM-D, fluorescence and AFM techniques

Hauke A Harms, Nicolas Tétreault, Kislon Voitchovsky, Francesco Stellacci, Michael Grätzel, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Recently, dye-sensitized solar cells have achieved a record power conversion efficiency of 13.1% (0.5 sun) and 12.3% (1 sun) using a Co(II/III)tris(bipyridyl)–based redox electrolyte in conjunction with donor - π-bridge – acceptor (D-π-A) zinc porphyrin dye as sensitizer (YD2-o-C8) and Y123 as cosensitizer.(1) Beyond panchromatic light harvesting, new sensitizers have to comply with one-electron redox couples that not only allow for high photovoltage, but also entail the challenge of fast recombination with photoinjected electrons from the TiO2 conduction band. The improvements in photocurrent and photovoltage are assumed to be due to better packing of dye molecules on the TiO2 surface. Yet we know alarmingly little about the dynamics of dye adsorption, self-assembly of the monolayer, and formation of multilayers or aggregates. In addition, several reports have pointed out the role of molecular coadsorbates like chenodeoxycholic acid that positively affect interfacial recombination and reduce aggregation.

Herein, we use a quartz crystal microbalance with dissipation technique (QCM-D) to study dynamically and quantitatively dye sensitization of TiO2 in situ.(2) We studied dye loading for a Ru(II) polypyridyl complex (Z907), of a triphenylamine-based D-π-A dye (Y123), and of a state-of-the-art porphyrin sensitizer (YD2-o-C8). By combining the QCM-D technique with fluorescence measurements, we quantify molar ratios between the above dyes and various coadsorbates like chenodeoxycholic acid and CTAB. Furthermore, we will present first studies using liquid-phase AFM on the adsorbed dye monolayer, thus obtaining complementary microscopic information that may lead to understanding of the adsorption mechanism on the molecular scale.

Exciton dynamics in colloidal CdSe/CdS core-shell nanostructures

Olivier Pare-Labrosse, Laura-Isabelle Dion-Bertrand, Univ. de Montréal (Canada); Aurora Rizzo, CNR-INFM (Italy); Carlos Silva, Univ. de Montréal (Canada)

We have studied excitons in films of colloidal CdSe/CdS nanorods that produce efficient LED in the visible region. These samples feature strong oscillator strength of optical transitions, which make these materials promising for a range of further photonic devices such as classical (photon) lasers and polariton emitters. We have performed temperature-dependent steady-state photoluminescence experiments. The CdSe/CdS nanorod photoluminescence intensity displays strong temperature dependence, with increasing intensity with increasing temperature, and the maximum emission energy exhibits a temperature-dependent blue shift. This maximum shifts from 2.06 eV at 290 K to 2.13 eV at 10 K, which represents a shift of 67 meV. We attribute this shift to the interaction of the exciton with the interface that creates excitonic traps at lower energies. As the temperature rises, thermally activated detrapping for temperatures above 38 K. Such detrapping processes rationalise the counterintuitive increase of photoluminescence intensity with temperature. In this presentation, we will discuss trapping and detrapping dynamics. Furthermore, we will address the role of coherence in determining early-time exciton dynamics, and its effect on exciton surface trapping, by means of ultrafast phase-locked two-pulse coherent studies, in which the time-integrated photoluminescence spectral intensity is measured as a function of delay and relative phase between the phase-locked pulses.

8811-13, Session 3

Modulation of silicon by (multi-)interfaces and by local nanostructurations leading to a new specific phase of material (metamaterial) for light-to-electricity conversion

Zbigniew T. Kuznicki, Univ. de Strasbourg (France)

Because Si is, and undoubtedly will remain, a basic material for converting light into electricity, challenging research has been underway for years to overcome innate optoelectronic constraints of its indirect bandgap. Exploiting soft photon-electron-electron interactions to add to the well characterized hard photon-matter interactions offers one possible area where conversion efficiency might be improved. Following this approach, we have found that a Si-derived metamaterial obtained by multiple nanotransformations, leading to a nanoscale Si-layered system with multiinterface interactions, can furnish low-energy mechanisms. The energy flow starts with the incoming light (h ≥ 1.40 eV) being transformed by different superposed nanosystems. The design of these multiinterface devices had to take into account several interrelated mechanisms intervening in the light-to-electricity conversion. This structure forms the basis of a multistage conversion cycle observed for the first time that depends on interactions of hot electrons with active interfaces and conditioned crystalline defects transformed into Si metamaterial units that we call "segtons" (unity for secondary electron generation tuned on nanoscale). We will describe the background, modeling and complete 1D simulations of all optoelectronic features of this new cell. Simulations and experimental data coincide almost perfectly. Thus a useful exploitation of energetic photons seems to be possible due to a multiple generation of secondary electrons with a low characteristic energy, whereas today a large part of an energetic photon's energy is wasted on device heating. With the additional carrier generation per absorbed photon, the efficiency of these cells can be said to result from giant photoconversion.

8811-14, Session 4

Relation of structure and charge transport in 'single-stack' organic nanowires *(Invited Paper)*

Holger Frauenrath, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Organic nanowires may provide insights into the fundamental processes of charge generation and transport in organic semiconductors under nanoscopic confinement. Here, we demonstrate how a simple molecular design results in nanowires with defined lateral dimensions that comprised a single stack of tightly π–π stacked chromophores at their core. Moreover, we prepared well-defined microfibers that exhibited hierarchical structure formation with a remarkably high degree of internal order and enabled us to obtain detailed structural information on all length scales with molecular level precision. The nanowires and microfibers nanowires showed light-induced formation of radical cations that behaved like positive polaron charge carriers. The nanofibrils were semiconducting, showed space-charge injection-limited conductivity behavior, and exhibited photo-current generation, relating their macroscopic electric properties to the spectroscopically characterized charge carriers. Our results, thus, provide an example of a universal organic nanowire model system that successfully links molecular design, well-defined supramolecular structure formation, charge carrier generation, and finally macroscopic charge transport.

8811-15, Session 4

Organic nanostructures for plastic electronics: control and characterisation *(Invited Paper)*

Ji-Seon Kim, Imperial College London (United Kingdom)

Organic semiconductors such as small molecules and conjugated polymers have been demonstrated as the active material in various optoelectronic and electronic devices including light-emitting diodes, transistors, and photovoltaic cells. For these organic semiconductor devices, a great deal of the physics occurs at the organic-organic interfaces. Therefore, understanding the organic-organic interfaces, in particular in terms of the structure-property relationships of nanostructures in thin films, is essential in designing efficient and stable devices. In this talk, the role of these organic nanostructures, with an important focus on molecular-scale electronic structures and electronic processes across these nanostructures will be discussed. In particular, the effects of degree of local molecular order, thin film morphology and nature of interfaces on the optoelectronic and charge transport properties will be addressed. As one of the most valuable characterisation techniques for organic nanostructures, we have extensively used Raman spectroscopy. Raman spectroscopy is a non-destructive technique which can deliver valuable chemical/ structural information together with optical properties of materials with sub-micrometer spatial resolution from surface films as well as from buried layers in the devices. We will show some examples of our Raman studies performed on various organic nanostructures in thin films and devices [1-8]. The application of non-resonant, resonant and polarized Raman spectroscopy to the characterisation of reaction, composition, crystallinity and orientation of molecules will be also discussed.

Designing hybrid nanocolloids for nanothermy and multimodal imaging

Pascal André, Univ. of St. Andrews (United Kingdom) and RIKEN (Japan); Chen Shu, Univ. of St. Andrews (United Kingdom); C. Hoskins, Lijun Wang, Michael P. MacDonald, Institute for Medical Science & Technology (United Kingdom) and Univ. of Dundee (United Kingdom)

Multimodal nanoparticles (nPs) are a growing component of biomedical research activity with for instance dual imaging demonstration taking advantage of designing nanoparticles with combined optical and magnetics properties.[1]

Stepping aside of imaging we have recently demonstrates that hybrid nanocolloids can be designed and used to create nanoprobes for remotely sensing temperature of aqueous media. Such multi-modal nanocolloids combine development opportunities not only for multimodal magnetic-optical imaging but also for non-invasive and remote absolute temperature optical monitoring suitable for hyperthermia treatments and cell poration.

Along the potentials associated with combining several properties within a single nanocolloid, the presentation will build on and discuss the synthesis and characterization of biocompatible FePt nPs suitable for biomedical applications.[2,3]

Covalent functionalization of carbon nanotubes and its effect on transport properties

Delphine Bouilly, Janie Cabana, François Meunier, Univ. de Montréal (Canada); Maxime Desjardins-Carrière, Ecole Polytechnique de Montréal (Canada); François Lapointe, Univ. de Montréal (Canada); Philippe Gagnon, Ecole Polytechnique de Montréal (Canada); Francis L. Larouche, Univ. de Montréal (Canada); Elyse Adam, Ecole Polytechnique de Montréal (Canada); Matthieu Paillet, Richard Martel, Univ. de Montréal (Canada)

Covalent chemistry on carbon nanotubes generates stable functionalities that are valuable for improving their processing and tailoring their affinity with other molecules. However, the covalent bonding deeply alters the nanotubes electronic properties, which is a critical drawback for device applications. We first describe how the addition of monovalent groups affects the transport properties of single-walled carbon nanotubes (SWNTs), and we discuss the underlying mechanism and its reversibility. We then introduce two new approaches that allow extensive covalent functionalization of carbon nanotubes without compromising on their electronic properties. For each case, we demonstrate the fabrication of functional carbon nanotube devices. First, double-walled carbon nanotubes (DWNTs) are functionalized using a monovalent reaction with aryldiazonium salts. Absorption and Raman spectroscopy along with electrical measurements are performed to show that functionalization occurs strictly on the outer wall and preserves the optical and transport properties of the inner wall. Functionalized-DWNT devices are shown to operate with similar characteristics as pristine single-walled carbon nanotube devices [1]. Second, SWNTs are functionalized with a different type of addends using a carbene reaction, which forms a divalent bond with the nanotube surface. For both metallic and semiconducting species, electrical measurements performed on a large number of functionalized and unfunctionalized SWNT devices show identical characteristics [2].

8811-18, Session 4

Probing the transient fate of C-N bonding in hydrazine-treated carbon nanotubes by synchrotron photoelectron spectroscopy

Pen-Cheng Wang, National Tsing Hua Univ. (Taiwan); Yu-Chun Liao, National Tsing Hua Univ. (Taiwan) and National Synchrotron Radiation Research Ctr. (Taiwan); Li-Hung Liu, National Tsing Hua Univ. (Taiwan); Yu-Ling Lai, Ying-Chang Lin, National Synchrotron Radiation Research Ctr. (Taiwan); Ching-Yuan Su, National Tsing Hua Univ. (Taiwan); Yao-Jane Hsu, National Synchrotron Radiation Research Ctr. (Taiwan)

The properties of hydrazine-treated carbon nanotubes (CNTs) were investigated by synchrotron photoelectron spectroscopy. The surfactant-free CNTs used in this study were synthesized by alcohol catalytic chemical vapor deposition. When the CNTs subject to the vapor-phase hydrazine treatment and the 80ºC-baking treatment were probed by ultraviolet photoelectron spectroscopy (UPS), the results showed (i) damaged π-bonding and (ii) the shift of the CNTs' Fermi level toward the conduction band. A further 350ºC-baking treatment on the hydrazine-treated CNTs could restore the damaged π-bonding and cause the CNTs' Fermi level to shift back toward the valence band. The results obtained from UPS indicated that the above interaction between hydrazine and CNTs was a thermally metastable chemical adsorption. When the CNTs subject to the vapor-phase hydrazine treatment and the 80ºC-baking treatment were probed by X-ray photoelectron spectroscopy (XPS), the results showed a significant increase in the spectral intensity of the signal corresponding to C-N bonding in the XPS profile. A further 350ºC-baking treatment on the hydrazine-treated CNTs could essentially eliminate the spectral intensity of the signal corresponding to C-N bonding in the XPS profile. Our experimental results show that the transient fate of the thermally metastable C-N bonding is associated with the nitrogenous radicals, such as nitrene and amidogen, thermally decomposed from hydrazine. The chemical association of nitrogenous radicals with CNTs generates metastable amino/aziridino derivatization on the surface of CNTs, which will disrupt the continuum of CNTs' graphitic domains. Upon further baking, the disruptive functionalization can be eliminated to restore the graphitic sp2-carbon bonding structure.

8811-19, Session 4

Fabrication of nanoparticle single-electron transistors and photoinduced modulation in the charge transport property

Yutaka Noguchi, Makoto Yamamoto, Masanori Kobo, Hisao Ishii, Chiba Univ. (Japan); Toshifumi Terui, National Institute of Information and Communications Technology (Japan); Keisuke Imazu, Kaoru Tamada, Kyushu Univ. (Japan); Kenji Matsuda, Kyoto Univ. (Japan)

Metal and semiconducting nanoparticles (NPs) have attracted significant attention because of their excellent properties and potential applications in bottom-up electronics. To examine the charge transport properties of single or small number of such NPs and their interactions with external stimuli, single-electron transisotor (SET) strucures can be a powerful tool. We report here fabrication of Au- and CdSe/ZnS-NP SETs and their charge transport properties. Remarkably, we have demonstrated a method to modulate the transport properties by molecular doping followed by light irradiation.

Nanogap electrodes on the SiO2 (50 nm)/p-deped Si substrate were formed by an electromigration method. Au- and CdSe/ZnS-NP (6 nm in diameter) were adsorbed on the electrode through octanedithiol. Copper phthalocyanine (CuPc) was then evaporated submonolayer on the Au-NP devices to induce a photoresponse. The charge transport properties and their photoresponse were meausred at 13 K.

We successfully observed Coulomb diamond originated from single-electron transport in the Au- and CdSe/ZnS-SETs. In the Coulomb diamond of CdSe/ZnS-SET, a large conductance gap appeared probably due to the energy gap of CdSe/ZnS NP. In charge transport properties of the CuPc-doped Au-SETs, conductance switching was observed between two specific states induced by light irradiation and applied voltages. We also examined the current response at a constant drain voltage under light irradiation. The current fluctuation was induced by the light irradiation, especially at 550 to 700 nm corresponding to the optical absorption band of CuPc. A change in the potential of Au-NP is responsible for conductance switching, and is resulted from photoinduced charging of CuPc.

8811-20, Session 5

Interfacial modification for organic electronic applications *(Invited Paper)*

Seth R. Marder, Stephen Barlow, Jean-Luc Brédas, Jared Delcamp, Anthony J. Giordano, Song Guo, Bernard Kippelen, Hong Li, Swagat Mahopatra, Sergio A. Paniagua, O'Neil Smith, Yadong Zhang, Georgia Institute of Technology (United States); Antoine L. Kahn, Yabing Qi, Wei Zhao, Princeton Univ. (United States)

Organic semiconductors have attracted interest for electronic applications due to their potential for use in low-cost, large-area, flexible electronic devices. Here we will report recent developments pertaining to surface modifiers and dopants that could impact the charge collection processes in organic light emitting diodes, organic field effect transistors, and organic photovoltaic devices. In particular, we will examine how phosphonic acids assemble on ITO substrates, the impact of the surface dipole on the work function of the ITO and electron transfer kinetics across surface modifiers. We will also discuss the development of metallocene based dimers as n-dopants and Molybdenum as p-dopants for organic semiconductors and their impact on device performance.

8811-21, Session 5

Electronic structure of conducting oxide-organic and organic-organic interfaces of relevance to OLED and OPV devices *(Invited Paper)*

Jean-Luc Bredas, Georgia Institute of Technology (United States)

In this presentation, we intend to cover two main topics:

(i) The electronic structure at interfaces between a conducting oxide electrode or interlayer and an organic layer, such as those found in organic light-emitting diodes and solar cells. In particular, we will discuss the mechanism by which self-assembled (mono)layers can modify the electrode work function of the conducting oxide electrode and the interfacial energy-level alignment. These parameters directly impact the charge-injection barrier [1].

(ii) The organic-organic interface. We will describe our recent progress in the description of the structural configurations at the interface between the donor and acceptor components in an organic solar cell and the impact that variations in these configurations have on the nature of the interfacial charge-transfer states [2].

Photo-induced charge transfer across an organic /contact interface: polaronic state spectroscopy

Austin L. Carver, Bruce W. Alphenaar, Hemant M. Shah, Buddika K. Abeyweera, Sowmya Kolli, Univ. of Louisville (United States)

Photo-induced charge transfer across an organic / contact interface: polaronic state spectroscopy

Photo-induced charge transfer from an Indium Tin Oxide (ITO) contact into [6,6]-phenyl-C61-butyric acid methyl ester (PC60BM) and [6,6]-phenyl-C71-butyric acid methyl ester (PC70BM) is measured using capacitive photocurrent spectroscopy. PC60BM is drop cast onto an ITO coated glass slide, which is affixed to a copper block inside an evacuated optical cryostat. A current amplifier is connected between the ITO layer and the copper block and the ac photocurrent is monitored as the ITO / PC60BM interface is exposed to light from a tunable pulsed laser source. Optically generated electron-hole pairs separate across the PC60BM / ITO interface, under the force of an applied dc potential combined with any built-in potential due to trapped charged and the difference in electron affinity between PC60BM and ITO. Charge transfer peaks are observed for a series of excitation energies below the PCBM absorption edge. To demonstrate that charge transfer is necessary to observe the CPS signal, measurements were performed on samples containing an LiF insulating layer separating the PC60BM and ITO. The current drops off exponentially with LiF thickness, as would be expected for Fowler-Nordheim tunneling through the insulating barrier. Bias dependent measurements indicate that the capacitive photocurrent signal is due to negative charge transfer from the ITO into the PC60BM. The observed transitions are similar to those predicted by theoretical calculations of the absorption spectra for negatively charged c60 and c70 chains. This suggests that charge transfer occurs preferentially at the poloronic transition energies in the PCBM, providing a means for polaronic state spectroscopy.

8811-23, Session 6

Energy level pinning and electric field distribution at organic/inorganic interfaces *(Invited Paper)*

Norbert Koch, Humboldt-Univ. zu Berlin (Germany) and Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany)

Inducing Fermi-level pinning in an organic semiconductor at the interface to another material results in accumulation or depletion of electrons at the interface. Examples for the resulting band-bending at pinned organic/electrode interfaces and organic/inorganic semiconductor heterojunctions will be introduced. The key roles of inorganic semiconductor surface termination and doping level on level pinning will be discussed. The energy level alignment at organic/organic semiconductor heterojunctions is essentially independent of deposition sequence, as long as supporting electrodes do not induce energy level pinning. When the energy levels become Fermi-level pinned due to an initial electronic non-equilibrium situation, long-range charge transfer can result. This creates an electric field right at and beyond the heterojunction. This effect is exemplified for prototypical donor and the acceptor interfaces, which are relevant for photovoltaic cells. Furthermore, it is demonstrated that light absorption induced charge separation at an organic heterojunction can be measured directly with photoemission spectroscopy.

8811-24, Session 6

Energetics and dynamics in organic photovoltaics: the role of the contacts *(Invited Paper)*

Erin L. Ratcliff, The Univ. of Arizona (United States); Sarah R. Cowan, National Renewable Energy Lab. (United States); Brian Zacher, Jeremy L. Gantz, The Univ. of Arizona (United States); Dana C. Olson, National Renewable Energy Lab. (United States)

The primary function of the contacts in organic photovoltaics is efficient extract of charges while maintaining the open circuit voltage (VOC) through Fermi level offsets. In bulk heterojunction organic photovoltaics, surface recombination and loss mechanisms, including leakage, decrease power conversion efficiencies. It is well understood that implementation of the selective interlayers can be used to mitigate leakage of undesired charges across the active layer/contact interface. Thermodynamic selectivity for holes (electron blocking) is obtained using a material with a work function at or greater than the charge transport level for holes and a conduction band closer to vacuum than the transport level for electrons. However, little is understood about how the device performance is influenced by the hole-collection rates at the interlayer/active interface, relative to rates of recombination. Time-delay collection field measurements may be used to measure charge extraction and recombination dynamics in organic photovoltaics. An initial voltage is applied near VOC and carrier density is controlled via a white light bias. A nanosecond laser pulse is used to perturb the system and generate excess charges, which will either recombine or be extracted using an extraction voltage after a known time delay from the laser pulse. By monitoring the dynamics of the carriers as a function of applied voltage, background white light bias, and fluence from the laser pulse, we are able to isolate differences in recombination and extraction rates as a function of the selectivity of the contact.

8811-25, Session 6

Work function and open circuit voltage modulation via self-assembled interface modification of zinc oxide electron collection layer in polycarbazole-based organic solar cells

Sarah R. Cowan, National Renewable Energy Lab. (United States); Philip Schulz, Princeton Univ. (United States); Erin L. Ratcliff, The Univ. of Arizona (United States); Andres Garcia, National Renewable Energy Lab. (United States); Anthony J. Giordano, Georgia Institute of Technology (United States); Stefan Oosterhout, Bradley A. MacLeod, David S. Ginley, National Renewable Energy Lab. (United States); Seth R. Marder, Georgia Institute of Technology (United States); Antoine L. Kahn, Princeton Univ. (United States); Dana C. Olson, National Renewable Energy Lab. (United States)

Zinc oxide (ZnO) is a low-cost semiconductor made from earth-abundant materials; multiple routes to sol-gel processing enable the formation of thin films, making the material a promising candidate for an electron collection layer for next-generation thin-film photovoltaics. However, previous research has observed ZnO to be easily etched via a number of simple solvents. Degree of crystallinity, exposed crystal face, sol-gel precursor, and thermal treatment all play a role in determining thin film chemical resistance of zinc oxide. Poor chemical resistance has minimized work function modification of ZnO via dipole interface modifiers such as benzyl phosphonic acid (BPA), shown to modify the work function of ITO and to modulate the open circuit voltage in full devices. We demonstrate that work function modification of the ZnO interface via spincast dipole interface modifiers translates into a proportional modulation of the open circuit voltage in BHJ solar cells. Spincasting minimizes exposure of the ZnO to the acidic solution, allowing reproducible, non-destructive deposition, as assayed by XPS, PM-IRRAS, and UPS / IPES of modified ZnO. Modulation of the work function and evidence of charge transfer is shown by UPS of thin films of polymer bulk heterojunction on cast onto ZnO modified by the self-assembled BPA dipole. The deposition of BPAs is shown here to increase the open circuit voltage and to have no impact on the lifetime of poly[N–9'-hepta-decanyl-2,7-carbazole-alt-5,5-(4',7'-di-2-thienyl-2',1',3'-benzothiadiazole)] (PCDTBT) : [6,6]-phenyl C71-butyric acid methyl ester (PC70BM) inverted devices over the testing period of 30 days storage in air.

8811-26, Session 6

A convenient solution processing route to high mobility CdS films

Bright J. Walker, Ulsan National Institute of Science and Technology (Korea, Republic of)

Solution-processed CdS field effect transistors (FETs) and solar cells are demonstrated via the spin-coating and thermal annealing of soluble cadmium thiolate compounds. The synthesis is carried out in one simple step using cadmium oxide and tertiary alkane thiols. The cadmium thiolates are soluble in organic solvents such as chloroform and may be spin-coated, like organic semiconductors, to form thin films. The cadmium thiolate films decompose rapidly at 240 oC to yield semiconducting cadmium sulfide films. Field effect transistors are easily fabricated using these films and exhibit electron mobilities of up to 64 cm2 V-1 s-1, which compare favorably to FETs prepared from other solution-processed materials such as organic semiconductors, inorganic nanoparticles or chalcogenide films. Initial attempts to prepare hybrid, bilayer solar cells were successfully realized by spin-coating a p-type semiconducting polymer layer on top of the n-type CdS film. These devices show significant photocurrent response from both the CdS and polymer layers, indicating that the CdS films are able to participate in photo-induced electron transfer from the polymer to the CdS layer as well as photo-induced hole transfer from CdS to the polymer layer.

8811-27, Session 7

Electronic properties of cationic narrow band gap conjugated polyelectrolytes *(Invited Paper)*

Jung Hwa Seo, Dong-A Univ. (Korea, Republic of)

We report the design, synthesis, optical and electronic properties of two novel narrow band gap conjugated polyelectrolytes (NBGCPEs) based on a poly[2,6-(4,4-bisalkyl-4H-cyclopenta-[2,1-b;3,4-b']-dithiophene)-alt-4,7-(2,1,3-benzothiadiazole)] donor-acceptor backbone. A comparison to the properties of the neutral precursor material shows that the ionic component in these cationic NBGCPEs leads to a red shift in the absorption spectra and to a modification of the polymer electronic energy levels. Both the HOMO and the LUMO are lowered in energy, with the net effect being dependent on the choice of counterion, i.e. bromide vs. tetrakis(1-imidazolyl)borate. Moreover, we find the unexpected observation of n-type transport in thin film transistors, which differs from the widely studied p-type transport in neutral systems with isoelectronic backbones. These observations lead one to conclude that unique opportunities for materials design are possible upon introduction of ionic functionalities adjacent to semiconducting polymers that exhibit charge transfer excitations.

8811-28, Session 7

Charge transport and recombination in organic light emitting transistors *(Invited Paper)*

Ebinazar B. Namdas, The Univ. of Queensland (Australia)

Light emitting field effect transistors (LEFETs) are a class of next generation devices which combine the switching properties of field effect transistors (FET) with light emitting capabilities of organic light-emitting diodes (OLEDs) in a single device architecture. LEFETs have significant potential in a number of applications such as active matrix displays, sensors, and even in electrically pumped lasers. However, current LEFET architectures suffer from inefficient charge injection of electrons and holes from opposite source and drain electrodes, leading to unbalanced charge transport and hence poor device performance. This talk will show our recent progress in the design and fabrication of high-performance solution-processed LEFETs. Comparative studies will be presented over a wide range of device architecture, including novel materials. On the basis of these data, I will address the parameters that influence charge injection, charge transport and recombination processes in these devices. State-of-the-art materials, design and performance will be presented and discussed in this talk.

Using EGaIn to uncover new phenomena in molecular tunneling junctions

Davide Fracasso, Univ. of Groningen (Netherlands)

This talk focuses on charge transport studies using Eutectic Gallium Indium (EGaIn), a method that we introduce in 2008[1], to reveal intrinsic properties of molecules into SAMs.

The ability to control the flow of charge at the quantum level through organic synthesis is a tantalizing prospect that draws researchers from myriad sub-disciplines of chemistry and physics to molecular electronics (ME).

Chemistry is replete with cases where seemingly minor changes in the chemical structure of a molecule result in significant changes in a physical property of the system.

Particularly conjugated molecules are interesting since relationship between parts of the molecules and physical properties can be found.

In a earlier work we did, for the first time, show evidence of quantum interference (i.e., the influence of conjugation patterns) in tunneling junctions comprising SAMs of aryethynylene thiolates using EGaIn as a conformal top-contact[2]. We found good qualitative agreement between experiment and theory.

In a more recent work we could demonstrate that EGaIn can resolve the differences between SAMs that differ by only a single atom. This sensitivity is made possible by the collective properties of the molecules in the SAMs (e.g., torsional angles) and is therefore an intrinsic property of the SAMs; we would not expect the same results from tunneling experiments on single molecules.

For these reasons mentioned above and more, EGaIn has been recognized as a new ease molecular electronics tool.

Electrolyte-gated transistors based on light-emitting solution-processable films

Jonathan J. Sayago, Ecole Polytechnique de Montréal (Canada); Yuvaraj Sivalingam, Univ. degli Studi di Roma Tor Vergata (Italy); Mitesh Patel, Fabio Cicoira, Clara Santato, Ecole Polytechnique de Montréal (Canada)

Organic Field Effect Transistors (OFETs) are the key elements for low-cost flexible electronics, such as flexible displays, sensor arrays and radio frequency identification tags [1,2]. The replacement of conventional gate dielectrics (e.g. SiO2) with an electrolyte gating media is an effective approach to induce high charge density, in the transistor channel, upon application of low electric bias [3,4]. We report on electrolyte-gated transistors based on thin light-emitting films of organic polymers, such as poly[2-methoxy-5-(2-ethylhexyloxy)-1,4-phenylenevinylene], or metal oxides, such as zinc oxide. As the electrolytes different ionic liquids were considered, based on 1-butyl-3-methylimidazolium [BMIm] or 1-ethyl-3-methylimidazolium [EMIm] as the cation, and bis(trifluoromethylsulfonyl) imide [TFSI] or hexafluorophosphate [PF6] as the anion. The light-emitting properties of the films in contact with the ionic liquids were investigated, in inert atmosphere. The transistor electrical characteristics were correlated to the ionic conductivity, viscosity and ion size of the electrolyte.

Effect of film nanostructure on in-plane charge transport in organic bulk heterojunction materials

Eric Danielson, The Univ. of Texas at Austin (United States); Zien Ooi, A*STAR Institute of Materials Research and Engineering (Singapore); Ananth Dodabalapur, The Univ. of Texas at Austin (United States)

Charge transport parameters of organic bulk heterojunction (BHJ) materials are greatly affected by the nanomorphology of these materials. A complete understanding of this relationship is needed to design organic photovoltaic (OPV) devices with high power conversion efficiencies. Parameters such as carrier mobilities, carrier concentrations, and the recombination coefficient have traditionally been successfully measured using vertical structures similar to organic photovoltaic (OPV) cells. We have developed a lateral BHJ device which complements these vertical techniques by allowing spatially resolved measurement along the transport direction of charge carriers. This is essential for evaluating the effect of nanoscale structure and morphology on these important charge transport parameters. Nanomorphology in organic BHJ films has been controlled using a variety of methods, but the effect of these procedures has been rarely correlated with the charge transport parameters of the BHJ material. Electron beam lithography has been used to create lateral device structures with many voltage probes at a sub-micron resolution throughout the device channel. By performing in-situ potentiometry, we can determine both carrier mobilities and valuable information about the recombination mechanism and coefficient. Spin coated and inkjet printed P3HT:PCBM films are measured using these lateral devices to determine the effect of solvent additives such as DIO, the P3HT:PCBM weight ratio, and the annealing methodology. These measurements are correlated with the observed effect on the film nanostructure, obtained from AFM imaging.

8811-34, Session 8

The local enviroment affects the exciton dynamics in Rubrene single crystals

Bjorn Gieseking, Teresa Schmeiler, Benjamin Muller, Carsten Deibel, Bernd Engels, Vladimir Dyakonov, Jens U. Pflaum, Julius-Maximilians-Univ. Würzburg (Germany)

As for its inorganic counterparts the future developments in organic electronics are driven by an advanced device miniaturization. Therefore, the opto-electronic behavior of up-to-date devices is progressively governed by the local structural environment. However, there is a lack of organic semiconductor materials providing access to the fundamental structure-functionality relation, either due to limitations by their inherent growth or their optical characteristics.

In this work we present a systematic investigation of the optical states, so-called excitons, and their temporal evolution in the prototypical organic semiconductor rubrene by means of time and temperature dependent photoluminescence studies. This material offers the unique possibility of preparing well-defined morphologies with adjustable degree of confinement. By this approach we are able to confirm the direct influence on the temperature dependent optical processes with picosecond resolution already for a spatial localization of excitation on the µm length scale. While in bulk single crystals the exciton decay dynamics are governed by thermally activated singlet fission, excitons created in microcrystals are trapped by dark states localized on the surface and leading to a pronounced enhancement of their average lifetime.

Our results highlight the impact of the local environment on the excitonic states and their dynamics in organic semiconductors. With respect to the spatial dimensions of organic thin film devices, this correlation and the reported effects emerging by the confinement have to be considered upon further miniaturization and in the development of innovative device concepts, such as photovoltaic cells based on triplet-harvesting.

8811-35, Session 8

Photoexcitation and photochemical stability of organic photovoltaic materials from first principles

Na Sai, The Univ. of Texas at Austin (United States); Kevin Leung, Sandia National Labs. (United States)

The development of high efficiency organic photovoltaics (OPV) has recently become enabled by the synthesis of new photoactive materials including, e.g., the lower band gap conjugated polymers that allow light absorption over a broader range of the spectrum. On the other hand, stability of these new polymers, a key requirement for commercialization, has not yet received sufficient attention. Here, we investigate the material stability and degradation mechanisms in OPV materials with the hope to discover OPV candidate materials with improved photochemical stabilities. We report first-principles theoretical modeling of photo-induced degradation of OPV polymers carried out using ab-initio density functional theory and quantum chemistry methods. We report photooxidation routes and reaction products for reactive species including superoxide oxygen anions and hydroxyl groups interacting with the standard workhorse OPV polymer, poly(3-hexyl-thiophene) (P3HT). We discuss theoretical issues and challenges affecting the modeling such reactions in OPV polymers. We also discuss the application of theoretical methods to low-band-gap polymers, and in particular, the effect of the incorporated silicon atom on the photoexcitation and photochemical reactions in these new polymers.

This work is supported by the Energy Frontier Research Center funded by the U.S. DOE Office of Basic Energy Sciences under Award number DE-SC0001091. Sandia National Laboratories is a multi-program laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000.

8811-37, Session 8

The principles of manipulating the phase transformations and solid-state order of organic semiconductors to and its effects on their photophysical properties

Natalie Stingelin-Stutzmann, Imperial College London (United Kingdom)

We will present a survey on the principles of how to manipulate the phase transformations and solid-state order of organic semiconductors to tailor and manipulate their final "morphology" from the liquid phase targeted towards technological and practical applications. Focus will be on how microstructural changes affect the electronic landscape in this class of materials, including charge generation, charge recombination and photovoltaic processes in general. We will show, for instance, that the evolution of a semicrystalline structure with well-defined interfaces between amorphous and crystalline domains of the polymer is required for spatial separation of the electron and hole. This structural characteristic largely controls the yield of free charges, but also serves as a recombination center where mobile holes encounter a bath of dark electrons resident in the amorphous phase and recombine with quasi first-order kinetics. We will present in addition a range of photophysical, electrochemical and physicochemical data that provide evidence that formation of a crystalline phase of at least one component is necessary for driving the spatial separation of photogenerated charges. We discuss this on the example of the fullerene component and demonstrate that its crystallisation results in an increase in electron affinity, providing an energetic driving force for spatial charge separation.

8811-54, Session 8

THz time domain spectroscopy of charge carrier dynamics in conjugated polymers

Mariateresa Scarongella, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Understanding the process of charge generation in polymer:fullerene bulk heterojunction (BHJ) blends is the key to improve the efficiency and the performance of organic solar cells1. There is still a lot of debate about the origin of free charges inside the blended materials. According to a simple picture, the exciton after travelling to an interface, undergoes charge separation to a Coulomb bound charge-transfer state which relaxes in 100 fs to its lowest vibrational level. After a time scale of 5 ns the bound charges can geminately recombine or completely separate to the polymer and fullerene phases2. Recently a more complex mechanism has been experimentally proven: the free charges are created after exciton quenching in a time shorter than 100 fs from hot delocalized charge transfer states before relaxation2,3. The charge separation happens in a mixed phase where the polymer and the fullerene are not pure and completely separated4. THz time domain spectroscopy gives information on the lifetime of generated charge carriers and on recombination dynamics. Specifically, it is more selective to detect the contributions of free charges with femtosecond time resolution. However, this technique also allows us to have access to the spectrally resolved photoconductivity, from which it is possible to distinguish between the presence of bound charges (in the exciton or charge transfer state) and free charges. In particular, we studied thin films of neat and blended (with fullerene) conjugated donor?acceptor copolymers, changing the excitation wavelength and the laser intensity.

Femtosecond stimulated resonance Raman study of excited state reorganization in organic semiconductors *(Invited Paper)*

Sophia C. Hayes, Univ. of Cyprus (Cyprus)

Understanding the ultrafast dynamics of electronic excited states of π-conjugated oligomers and polymers is of fundamental importance in chemical physics to underpin the design of next generation polymeric semiconductors for applications in optoelectronics. A direct probe of structural changes that eventually dictate the dynamics e.g. governing power conversion efficiencies in solar cells is essential for such understanding. Femtosecond Stimulated Raman (FSRS) spectroscopy offers a unique time-resolved Raman probe that has been used in recent years in time-resolved studies of ground and excited states, offering a great alternative to traditional Raman scattering methods, especially for fluorescent samples. The major advantage of FSRS is its ability to follow early-time (tens of femtoseconds) structural dynamics with mode-specific resolution (~15 cm-1), thus constituting it a powerful method for the investigation of excited state structure and dynamics in π-conjugated materials. Furthermore, the experimental setup allows for simultaneous collection of FSRS spectra of the excited state and transient absorption (TA) dynamics, which provides a direct correlation of excited state absorption changes to structural changes in oligomers/polymers. Here, we will exemplify the power of this spectroscopic method to elucidate excited state reorganization using known oligomeric/polymeric systems as models.

8811-38, Session 9

Synthesis and characterization of 3,4-ethylenedioxythiophene and 2-(3-thienyl) ethanol copolymer

Shuyun Zhou, Technical Institute of Physics and Chemistry (China)

The chemical polymerizations/copolymerizations of thiophene derivatives have been widely investigated in polymer field and many derivatives of polythiophene have been prepared in the past few decades. As a representative derivative of polythiophene, poly(3,4-ethylenedioxythiophene) (PEDOT) has been utilized in a large variety of applications due to its excellent characteristics. However, the extensive applications of PEDOT have been limited because of its poor solubility and adhesion. It's known that the involved functional groups in the polymer can greatly affect the properties of the chain, such as hydroxyl. In order to improve the performances of PEDOT, the copolymerization between 3,4-ethylenedioxythiophene (EDOT) and 2-(3-thienyl) ethanol had been adopted, and a new copolymer poly[(3,4-ethylenedioxythiophene)-2-(3-thienyl) ethanol] had been synthesized via the traditional chemical polymerization. In this study, the 2-(3-thienyl) ethanol had been esterified firstly to avoid side reactions. After EDOT monomer and 2-(3-thienyl) ethyl acetate were mixed, both of them began to copolymerize. The copolymer of EDOT monomer and 2-(3-thienyl) ethanol had been obtained when the pre-product had been hydrolyzed and purified. The characterization of copolymer was measured and the related application was explored.

Performance improvement of polymer solar cells by ternary blending of amorphous and semi-crystalline polymer analogues with PCBM

Christian Kästner, Technische Univ. Ilmenau (Germany); Silke Rathgeber, Univ. Koblenz-Landau (Germany); Daniel A. M. Egbe, Johannes Kepler Univ. Linz (Austria); Harald Hoppe, Technische Univ. Ilmenau (Germany)

Ternary blending of amorphous and semi-crystalline anthracene-containing poly(p-phenylene-ethynylene)-alt-poly(p-phenylene-vinylene) (PPE-PPV) copolymers (AnE-PVs) with PCBM was investigated in bulk heterojunction solar cells. In general, a strong impact on all photovoltaic parameters was observed by increasing the amount of amorphous AnE-PVba-derivative in relation to its semi-crystalline counterpart AnE-PVab. Interestingly, small additions of the amorphous copolymer were beneficial for overall solar cell performance. The observed performance increase of the ternary blend could be related to an improved open-circuit voltage, despite the fact that the binary blend of the amorphous copolymer and [6,6]-phenyl-C61-butyric acid methyl ester (PCBM) did not exhibit a larger photovoltage than the binary blend based on the semi-crystalline copolymer. These results indicate that a certain amorphous fraction of the donor polymer may be required for obtaining optimal bulk heterojunction morphologies, yielding maximum photovoltaic performance.

In-situ Raman spectroscopy, a new probe to monitor phase transformation and intercalation during spin-casting of bulk heterojunction solar cells

Maged Abdelsamie, Ahmed E. Mansour, Buyi Yan, Aram Amassian, King Abdullah Univ. of Science and Technology (Saudi Arabia)

The microstructure and morphology of the bulk-heterojunction photoactive layer of organic solar cells plays a critical role in determining the photovoltaic performance. In certain types of polymer-fullerene blend systems, the fullerene can intercalate between the side chains of the donor polymer forming a mixed phase (solid state solution) in the place of or in addition to pure phases of the materials. Bimolecular crystals, also known as co-crystals, represent an ordered model system of the mixed phase in the bulk heterojunction layer, such as in case of PC71BM fullerene intercalation in the polymer poly(2,5-bis(3-hexadecylthiophen-2-yl)thieno[3,2-b]thiophene) (pBTTT-C16). The goal of this study was to investigate intercalation as it happens during spin-coating of the photoactive layer and to reveal its mechanism. Raman spectroscopy shows distinctive fingerprints for pure pBTTT and for the intercalated phase of pBTTT-PC71BM, including shifts in peak position and changes in relative peak intensities. In situ Raman spectroscopy was performed during spin-coating of pBTTT-PC71BM (1-1) in dichlorobenzene at 1000 rpms, showing a pure pBTTT phase present immediately from the beginning of the process, followed by intercalation of PC71BM into pBTTT near the end of the film formation process. The results suggest that PC71BM intercalation occurs after formation of the pure phase of pBTTT, rather than by crystallization of the intercalated phase from solution.

The challenges of modeling organic molecular materials *(Invited Paper)*

Clemence Corminboeuf, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

The performance of organic devices (e.g., charge-carrier mobility in field-effect transistors) depends heavily upon the organization and electronic structure of π-conjugated molecules or chains at the molecular level. To achieve the full potential of such materials, technological developments require fine-tuning of the specific intermolecular interactions spanning small ranges of distances, lateral displacements, and π-conjugated moiety orientations. The discovery pace of novel materials can be accelerated, considerably, by using efficient computational schemes where key characteristics are evaluated in silico. Our research focuses on the realization of efficient and accurate computational methods capable of simulating π-conjugated systems relevant to the field of organic electronics. The apparent simplicity of the chemical composition of π-conjugated systems contrasts the complexity of their electronic structure, where the most commonly used framework (i.e., density functional approximations) suffers from obvious failures. To achieve accurate predictions of organic molecular materials, we address lingering difficulties in describing charged radical oligomers (i.e., charge carrier), charge-transfer interactions, close π-stacking interactions, and near-degenerated electronic states.[1-3]

In addition to the quantum chemical aspects, focus is placed on mutliscale computational schemes capable of identifying key structure-property relationships in large assemblies of π-conjugated systems.

The influence of sterics and molecular orientation on the open-circuit voltage in organic photovoltaics *(Invited Paper)*

Aram Amassian, King Abdullah Univ. of Science and Technology (Saudi Arabia)

Increasing the open-circuit voltage (VOC) in organic photovoltaics (OPVs) remains one of the key challenges to achieving higher power conversion efficiencies (PCEs); however, routes to achieving this increase are not well understood. In this presentation, we explore and discuss the roles of sterics and molecular conformation at the donor-acceptor interface in three model systems, namely (1) rubrene/C60 versus tetracene/C60, (2) ZnPc/C60 versus CuI/ZnPc/C60, as well as (3) PBDTTPD/C60 with systematically varying sidechains.

8811-41, Session 10

Organic photovoltaics at the nanoscale

Zeno Schumacher, Jessica Topple, Antoni Tekiel, Peter Grutter, McGill Univ. (Canada)

Nanoscale thin film morphology has been identified as an important factor in organic solar cell device functionality and efficiency. The understanding of loss mechanisms and structure-function relationships are key features on the way to more efficient organic solar cells.

However, it is difficult to study this effect in molecular solar cell devices. Therefore, one has to work on submonolayer molecular coverage and single molecule heterojunctions to study the behavior at the molecular length scale. We will present our latest achievements in fabricating and characterizing small molecule heterojunction on atomically flat alkali halide substrates in the nanoscale. We have reproducibly fabricated a Pentacene monolayer with lateral dimension of hundreds of nanometer. Furthermore, we grow Pentacene/3,4,9,10-perylenetetracarboxylic diimide (PTCDI) heterojunction in different orientations on the same sample. This enables us to study big ensembles of molecular interfaces under the exact same conditions. Additionally, each heterojunction can be observed individually due to the use of scanning probe microscopy.

Our system allows us to fabricate and characterize samples in ultra high vacuum, without exposing to air. To measure the structure-function relationship, a non-contact atomic force microscope (AFM) is used. Local electronic information is obtained by using Kelvin probe force microscopy (KPFM) while scanning the topography of the sample. Illuminating the sample with laser light during these measurements gives us further insight to the charge generation in organic solar cells.

This powerful combination of molecular heterojunction, AFM/KPFM measurements and laser illumination will help to better understand charge generation in organic photovoltaic.

8811-42, Session 10

Effects of the solvent additive dipole moment on bulk heterojunction solar cells based on low band-gap polymers

Olesia Synooka, Technische Univ. Ilmenau (Germany); Florian Kretschmer, Martin D. Hager, Friedrich-Schiller-Univ. Jena (Germany); Harald Hoppe, Technische Univ. Ilmenau (Germany)

The effect of the dipole moment of various solvent additives on the performance of photovoltaic devices, comprising of two different low band-gap polymers, namely benzothiadiazole-diketopyrrolopyrrole (BTD–DKPP) and poly[N-900-hepta-decanyl-2,7-carbazole-alt-5,5-(40,70-di-2-thienyl-20,10,30-benzothiadiazole (PCDTBT), combined with phenyl-butyric acid methyl ester (PCBM), has been investigated. In contrast to the common approach of using high boiling point solvent additives for control of fullerene aggregation after evaporation of the host solvent, we applied methanol and others in order to widely vary the molecular dipole moment. We found that the application of an additive concentration inversely proportional to the dipole moment yielded improvement of all solar cell parameters. The attribution of this effect is discussed on the basis of spectroscopic, electrical and morphological analysis.

8811-44, Session 11

Ultrafast IR-induced conductivity probing the dynamics of molecular systems *(Invited Paper)*

Artem A. Bakulin, FOM Institute for Atomic and Molecular Physics (Netherlands); Akshay Rao, Richard H. Friend, Univ. of Cambridge (United Kingdom); Huib J. Bakker, FOM Institute for Atomic and Molecular Physics (Netherlands)

Many organic and biological macromolecular systems like conjugated polymers, molecular crystals, photochromic proteins, or ionic membrane channels can be integrated into macroscopic electrical circuits using electrochemical cells or by developing an organic/protein monolayer diode structure [1]. In the latter case, the transmitted current can be used as a reporter for their structure and functionality, provided that the current flux is coupled to the local electronic or/and vibrational modes. This concept enables the study and control of the structure, dynamics, and conductivity of macromolecular systems by measuring changes in electric current that result from an optical excitation ('push') with IR light.

To study the coupling between conductivity and optical IR excitation we have developed an IR-push -- photocurrent probe technique [2]. We applied this technique to a wide range of molecular systems, including plastic photovoltaic cells and organic monolayer based diodes. For photovoltaic cells [2,3] the excitation with IR light leads to the promotion of charges to delocalised states. Although such states are extremely short-lived (<1ps), their excitation enables the charges to overcome the Coulomb attractive interaction and to become separated.

We also observe a strong change of the conductivity after excitation with IR light in the spectral region of C-C vibrational modes at ~1400-1600 cm-1. The physical phenomena underlying this effect are currently under investigation.

Efficient free charge carrier generation from charge-transfer states in organic solar cells *(Invited Paper)*

Koen Vandewal, Stanford Univ. (United States)

Efficient organic solar cells combine a high yield of photo-induced free charge carriers with a minimum of amount of energy lost in the electron transfer process from electron donor (D) to electron acceptor (A) materials. Decay of the photo-excitations at the D-A interface via interfacial charge transfer (CT) states can result in quantum yields of free charge carrier generation less than unity. Here we investigate the role of the lowest energy, relaxed charge transfer state (CT0) in the free charge carrier generation process by comparing the quantum yields of charge generation obtained from selective excitation of CT0 to that from the higher energy excited states. We use the electroluminescence spectra (EL) of solar cell devices to identify the lowest energy emissive excited state, (CT0), and develop a method to measure the photon energy dependence of the quantum yield of free carrier generation when exciting these low energy states. Additionally, we use a time delayed collection field technique with variable excitation wavelength to compare the electric field dependence of the charge generation process for above polymer gap excitations with direct CT state excitation. For a series of polymer:fullerene, small molecule:C60 and polymer:polymer photovoltaic devices, we find that the field dependence and absolute quantum yield for free carrier generation is essentially independent of whether or not states with higher energy than CT0 are excited. This result indicates that excess energy is not needed to obtain a high yield of free charge carriers from CT states at D-A interfaces.

Neighbor effect in charge-transfer complex formation in conjugated polymer: acceptor blends

Andrew Y. Sosorev, Olga D. Parashchuk, Sergei A. Zapunidi, Lomonosov Moscow State Univ. (Russian Federation); Igor F. Perepichka, Bangor Univ. (United Kingdom); Grigoriy S. Kashtanov, Dmitri Yu. Paraschuk, Lomonosov Moscow State Univ. (Russian Federation)

Weak intermolecular charge-transfer complex (CTC) in the electronic ground state can be formed between a conjugated polymer and low-molecular-weight acceptor. The CTCs can influence the photophysics, polymer conformation and blend morphology. Formation of conjugated polymer CTCs is a much more complex process compared to that in low-molecular-weight blends [1]. Specifically, in solution of the MEH-PPV:(2,4,7-trinitrofluorenone) (TNF) blend, CTC concentration CCTC shows a threshold increase with the acceptor content Ca, in contrast to a gradual increase typically observed in low-molecular-weight blends. The threshold-like behavior was assigned to the neighbor effect: new CTCs are preferentially formed near the existing ones [1].

In this work, we show that the recently proposed analytical neighbour effect model [2] describes absorption, thermochromic, and PL quenching data of conjugated polymer:acceptor blends' solutions. Firstly, we present absorption data for different blends and show that the model explains CCTC(Ca) dependences obtained from them. We discuss how the neighbor effect depends on the acceptor molecular skeleton, substituents, electron affinity, donor concentration and solvent. Secondly, we show that the model [2] describes qualitatively main features of the CCTC dependence on temperature: a threshold-like curve shape and hysteresis in cooling and heating. Thirdly, we present an analytical model of photoluminescence (PL) quenching by acceptor. This model explains the observed moderate quenching that implies formation of CTC aggregates [3].

The influence of the donor-acceptor interface on charge-transfer state energies and the open-circuit voltage in organic photovoltaics

Kenneth R. Graham, King Abdullah Univ. of Science and Technology (Saudi Arabia) and Stanford Univ. (United States); Patrick Erwin, The Univ. of Southern California (United States); Dennis Nordlund, Stanford Synchrotron Radiation Lightsource (United States); Koen Vandewal, Stanford Univ. (United States); Ruipeng Li, Guy O. Ngongang Ndjawa, King Abdullah Univ. of Science and Technology (Saudi Arabia); Eric T. Hoke, Alberto Salleo, Stanford Univ. (United States); Mark E. Thompson, The Univ. of Southern California (United States); Michael D. McGehee, Stanford Univ. (United States); Aram Amassian, King Abdullah Univ. of Science and Technology (Saudi Arabia)

The power conversion efficiencies (PCEs) of organic photovoltaics (OPVs) currently suffer from relatively large energetic losses between the optical gaps of the absorbing materials and the open-circuit voltage (VOC). If these energetic losses could be decreased, the V¬OC, and thus the PCE, could be increased. Previously it has been proposed that the VOC can be increased by decreasing the electronic coupling between donor and acceptor molecules, with support for this claim coming from current-voltage modeling utilizing forms of the ideal diode equation. In our work, tetracene/C60 and rubrene/C60 bilayer systems were analyzed and the electronic coupling parameters measured directly from sub-bandgap external quantum efficiency measurements. Analysis of these systems reveals that the VOC differences correspond directly with the differences in the charge transfer state energies (ECT), with little to no influence from electronic coupling. Furthermore, based on near-edge X-ray absorbance fine structure spectroscopy and grazing incidence X-ray scattering measurements to probe molecular orientation, the electronic coupling differences can be ascribed to the edge-on and more face-on orientations adopted by tetracene and rubrene respectively. To address the question of what determines ECT, we probe the HOMO levels and ECT of both crystalline and amorphous systems, with results showing that ECT is influenced both by HOMO-LUMO levels and the degree of crystallinity.

Ultrafast hot exciton dissociation at organic interfaces *(Invited Paper)*

Giulia Grancini, Daniele Fazzi, Istituto Italiano di Tecnologia (Italy); Margherita Maiuri, Politecnico di Milano (Italy); Annamaria Petrozza, Istituto Italiano di Tecnologia (Italy); Daniele Brida, Univ. Konstanz (Germany); Giulio Cerullo, Politecnico di Milano (Italy); Guglielmo Lanzani, Istituto Italiano di Tecnologia (Italy)

Interface physics is at the heart of photovoltaics (OPV). Common knowledge suggests that at the interface photons get absorbed and charge separation takes place within 100fs. However, the actual charge generation mechanism on such a short timescale is still hot debated.

Here, we monitor for the first time, thanks to sub-15-fs pump-probe spectroscopy, the exciton dissociation pathways in a low-band gap polymer: fullerene (PCPDTBT:PCBM) blend.

We find that exciton dissociation leads to both bounded interfacial CTS and free polarons within a time scale of 20-50fs, with a branching ratio that depends on the excess energy. In particular, upon band-gap excitation, the resonant lower-energy CT1 state and polarons are populated. However, in the first 500fs, the CT1 does not evolve, indicating that it does not contribute to the early-time charge dissociation yield. On the other hand, by above-gap excitation, a fast conversion to the hot CTS* manifold happens (t=22fs). Such hot CTS* are more delocalized in nature, thus more prone to further separate into polarons (t=150 fs), before thermalization to CT1. Thanks to stronger coupling between high-energy-states and hot CTS*, we demonstrate the opening of additional paths for charge generation that would otherwise be quenched by internal conversion to the lowest-lying states. Providing a large excess energy amount, the higher-lying polymer singlet states dissociate before internal conversion, ultimately leading to a higher fraction of polarons. Our results provide a new framework to understand charge generation in OPV system, suggesting that hot dissociation is a strategic option to enhance the photovoltaic conversion.

8811-49, Session 12

Ultrafast dynamics of photogeneration and motion of excitons and charges in conjugated polymers and blends for photovoltaics *(Invited Paper)*

Laurens D. A. Siebbeles, Technische Univ. Delft (Netherlands)

We studied the nature and dynamics of photoexcited states in blends of the polymer poly(3-hexyl-thiophene) (P3HT) and the electron acceptor PCBM by ultrafast optical and terahertz spectroscopy. The relative initial yield of free charges and excitons increases with photon energy. The yield of charges produced promptly upon photoexcitation is independent of temperature. This is attributed to charge delocalization causing the electron-hole Coulomb attraction to be negligible.[1,2]

The near IR part of the solar spectrum can be harvested by adding PbS quantum dots to yield ternary P3HT:PCBM:PbS blends. Using ultrafast optical spectroscopy, we found that photoexcitation of PbS quantum dots leads to hole transfer to P3HT and electron transfer to PCBM.3 However, we found from terahertz photoconductivity measurements that the excess charges in the organic components are immobile. This is explained by Coulomb interaction with charges or induced dipoles on the quantum dots.

The spatial delocalization and diffusion of excitons along MDMO-PPV chains was studied with ultrafast optical spectroscopy and density functional theory. We infer that photoexcitation leads to excitons that are initially largely delocalized along a polymer chain over ~ 100 monomers. Annihilation of two excitons produced within this distance on the same polymer chain decay within a few hundred femtoseconds. Interchain exciton diffusion and second order exciton-exciton annihilation occurs on longer times.

Optical probes of charge generation and recombination in low-bandgap polymer: fullerene organic solar cells *(Invited Paper)*

Frédéric Laquai, Max-Planck-Institut für Polymerforschung (Germany)

I will discuss the photophysics of state of the art bulk heterojunction thin films using different low-bandgap polymers as electron donors. By using a broadband probe and near-infrared detection scheme we are able to monitor the hitherto unobserved near-infrared spectral probe region between 1000-2000 nm. This allows us to identify the individual spectral contributions and dynamics of singlet and triplet excitons, charge-transfer (CT) states as well as free and mobile charge carriers in low-bandgap polymer:fullerene blends. We observe that in addition to ultrafast (<100 fs) charge generation a common feature of these blends is delayed charge generation caused by diffusion-limited exciton dissociation mainly occurring from PCBM-rich domains of the photoactive layer. Furthermore, a generic feature of these blends appears to be nanosecond geminate recombination of interfacial CT-states causing a reduction of the short circuit current. We find that in efficient photovoltaic blends the extraction of free charges is mainly competing with non-geminate charge recombination thereby determining the device fill factor, while field-dependent charge generation processes only play a minor role. By modeling our experimental data we can extract the fraction and formation rate of CT-states and free charges, the recombination rate of interfacial CT-states and the non-geminate recombination coefficient as well as the order of the non-geminate recombination process. Additionally, by using a novel time-delayed double pump technique we can determine the charge carrier mobility, get insights into the bias dependence of non-geminate recombination and validate the non-geminate recombination coefficients obtained by TA spectroscopy.

8811-51, Session 12

Coherence, uncertainty, and opportunity for organic photovoltaics

Loren G. Kaake, Alan J. Heeger, Univ. of California, Santa Barbara (United States)

Transient absorption measurements were performed on organic bulk heterojunction films comprised of different materials and employing different donor-acceptor ratios. The hole generation dynamics were measured by integrating a region of photoinduced absorption. The spectral assignments were in accord with previous literature reports, and coincided with our observation of long lived photoinduced absorption signals which represent the signature of shallowly trapped charge carriers. The charge generation dynamics show an ultrafast charge generation component and a component of charge generation which follows exciton diffusion. Surprisingly, the number of carriers generated on ultrafast timescales and the number of carriers produced following exciton diffusion show a ratio which is independent of the constituents of the bulk heterojunction. This indicates that simplistic models of exciton diffusion fail at ultrafast timescales. The effect is explained by stating that coherence provides for a spatially delocalized initial photoexcited wavefunction . This interpretation is further supported by similar measurements on a simpler donor-acceptor bilayer.

8811-52, Session 13

Multi-THz spectroscopy of mobile charge carriers in P3HT:PCBM on a sub-100 fs time scale *(Invited Paper)*

David G. Cooke, McGill Univ. (Canada); Frederik C. Krebs, Peter U. Jepsen, Technical Univ. of Denmark (Denmark)

The dynamics of mobile charge carrier generation in polymer bulk heterojunction films is of vital importance to the development of more efficient organic photovoltaics based on conjugated polymers. As with conventional semiconductors, the optical signatures of mobile carriers lies in the far-infrared (1 – 30 THz) although the electrodynamics deviate strongly from Drude. The key time scales for the process are picoseconds to sub-100 fs, and therefore becomes a challenge to perform low energy spectroscopy on these time scales as it is less than the period of oscillation for the probing light.

In this work, we demonstrate sub-100 fs spectroscopy of a polymer bulk heterojunction film P3HT:PCBM using a single-cycle, phase-locked and coherently detected multi-THz transient as a probe pulse following femtosecond excitation at 400 nm. By observing changes to the reflected THz transients from the film surface following photoexcitation, we can extract the complex optical conductivity spectrum for the film in snapshots of 40 fs following photoexcitation. We find that for our excitation conditions, mobile charges are created in less than 120 fs and are characterized by a spectrum which is consistent with that of a two-dimensional delocalized polaron. Approximately 2/3 of these initially mobile carriers relax to a localized state on a 1 ps time scale while the remainder remain mobile over much longer time scales. We conjecture that the fast decay is a signature of the re-formation of the exciton and therefore a major loss channel for polymer photovoltaics.

8811-53, Session 13

The driving force for electron transfer in conjugated polymers and blends with novel fullerenes *(Invited Paper)*

Garry Rumbles, National Renewable Energy Lab. (United States)

The driving force for electron transfer between a donor conjugated polymer and a fullerene acceptor is often given as the LUMO offset between the two species. While this is a reasonable approximation, it does not correctly include the exciton binding energy associated with the excited state, or exciton. This presentation will examine the role that the electron affinity of the acceptor plays in controlling the photo-induced electron transfer process of an excited state resident on either the conjugated polymer or the fullerene. Using the technique of flash photolysis, time-resolved microwave conductivity (fp-TRMC) the process of generating separated, or uncorrelated electron-hole pairs, will be discussed.

The presentation will examine charge carrier generation in blends of conjugated polymers with a number of perfluroalkyl-substituted fullerenes, with substitution motifs that control both the steric hinderance around the fullerene, as well as the electron affinity. In addition to the driving force for the electron transfer, the impact that the substitution pattern has on the microwave electron mobility will also be discussed.

8811-55, Session 13

When is hot CT state dissociation important in organic photovoltaics?

John B. Asbury, The Pennsylvania State Univ. (United States)

The dynamics of charge separation in photovoltaic polymer blends following photoinduced electron transfer from the conjugated polymer, regioregular-P3HT, to electron acceptors are observed with ultrafast vibrational spectroscopy. The investigators take advantage of a solvatochromic shift of the vibrational frequency of the carbonyl (C=O) stretch of the acceptors to directly measure the rate of charge transfer state dissociation to form charge separated states. Two acceptor classes are examined – functionalized fullerenes (PCBM) and perylene diimides (PDIs). Charge separation in rr-P3HT:PCBM blends occurs through activationless pathways and occurs on the sub-nanosecond time scale – too slow for hot CT state dissociation to be important. In contrast, rr-P3HT:PDI blends exhibit activated charge separation on the picosecond time scale where hot CT state dissociation may influence the yield of separated electrons and holes. The variation in charge separation mechanism arises from differences in the degree of electron delocalization that the electron acceptors can support.

8811-59, Session 13

The nature of long-lived charges in co-crystallized and phase-segregated polymer: fullerene blends

Fei Dou, Ecole Polytechnique de Montréal (Canada) and Univ. de Montréal (Canada); Ester Buchaca-Dormingo, Imperial College London (United Kingdom); Maciej Sakowicz, Univ. de Montréal (Canada); Xinping Zhang, Beijing Univ. of Technology (China); Natalie Stingelin-Stutzmann, Imperial College London (United Kingdom); Carlos Silva, Univ. de Montréal (Canada)

The optoelectronic properties of donor-acceptor conjugated polymer blends are highly dependent on film solid-state microstructure, which can be fantastically complicated. In particular, in semicrystalline polymer:fullerene blends, several combinations of morphologies are possible between the two components (i.e. crystalline/crystalline, crystalline/amorphous, etc.). Deep understanding of how these contrasting morphologies affect optoelectronic processes, like charge generation and recombination processes, is a fundamental issue in plastic electronics in order to optimize material design and exploiting them in efficient organic semiconductor devices. In this work, we focus on two contrasting microstructures: co-crystallized and phase-segregated poly(2,5-bis(3-tetradecyllthiophen-2-yl)thieno[3,2,-b]thiophene)(pBTTT):phenyl-C61-butyric acid methyl ester (PC60BM) blends, achieved by use of additives that exclude PCBM from the pBTTT crystal, to study the nature of long-lived charges by quasi-steady state photoinduced absorption (PIA) spectroscopy. We find that triplet-excitons and polarons are generated in both microstructures. However, polarons in the co-crystallized film are more highly localized than in phase-separated microstructures. By means of the quasi-steady-state solution of a mesoscopic rate model, we demonstrate that the polaron generation efficiency is higher than the triplet-exciton generation efficiency in these two blends, and that both the polaron generation efficiency and recombination rates are higher in the co-crystallized blend than in the phase-separated blend.

8811-56, Session 14

Dual channel photocurrent harvesting in organic solar cells *(Invited Paper)*

Paul Meredith, Paul L. Burn, Ajay K. Pandey, Yuan Fang, Chen Tao, The Univ. of Queensland (Australia); Nikos Kopidakis, Alex Nardes, National Renewable Energy Lab. (United States)

Organic solar cells contain two essential components in the active junction region: a high electron affinity electron acceptor and a lower electron affinity electron donor. The interface between these two components provides the driving force to separate the Coulombically bound photoexcitation (exciton) into free carriers for extraction to the external circuit (i.e. the generation of photocurrent). In conventional organic solar cells, the electron donor has predominantly provided the photon absorbing function and photocurrent is generated by the so-called Channel I pathway of photo-induced electron transfer (PET). These interfacial dynamics are complex and thought to be mediated via charge transfer (CT) states. However, more recently, it has been proposed and demonstrated that the so-called Channel II process can be an equally efficient current generating pathway whereby photon absorption occurs in the electron acceptor followed by photo-induced hole transfer (PHT) [1]. In principle, with the appropriate design of acceptor and donor, both Channels can operate simultaneously and one can realise the concept of "complementary absorbers" in a single junction organic solar cell. In my talk I will discuss our recent efforts to both demonstrate the utility of the Channel II process and design complementary acceptor-donor pairs. I will discuss the individual elements of both current generating pathways using Channel I and Channel II state diagrams, and furthermore estimate the contributions to photocurrent from each channel. The concept of complementary acceptor-donor pairs is another tool that we can use to further improve the overall efficiency of organic solar cells.

What controls exciton dissociation in polymeric donor-acceptor solar cells? *(Invited Paper)*

Anna Kohler, Univ. Bayreuth (Germany)

Efficient exciton dissociation at a donor-acceptor interface is a necessary condition for obtaining high efficiency polymeric solar cells. Despite its importance, this step is still not fully understood. A central question is how and why, after photoexcitation of the donor and transfer of an electron onto the acceptor, the the e-h pair can overcome their considerable mutual Coulomb potential. Possibilities that are currently discussed include the role of the excess energy, liberated when the excited donor electron transfers to the acceptor, the degree of delocalization of both an exciton and a charge in a conjugated polymer, interfacial dipoles that may exist at the donor-acceptor interface in the ground state, and the degree of energetic and structural order/disorder. In this talk I will show how we combine insight gained from ultrafast pump-probe spectroscopy, field dependent photocurrent measurements, photoemission measurements and modeling to assess which factors control the dissociation process.

Exciton diffusion and charge separation in conjugated polymers and fullerenes *(Invited Paper)*

Ifor D. W. Samuel, Alexander J. Ward, Zarifi Masri, Arvydas Ruseckas, Univ. of St. Andrews (United Kingdom)

The generation of charge in organic semiconductors requires the diffusion of excitons to an acceptor. We present a detailed study of this process including separating contributions from direct energy transfer and diffusion to an interface. We compare and contrast a range of methods for measuring exciton diffusion notably surface quenching, exciton-exciton annihilation and volume quenching. In all cases time-resolved fluorescence measurements are used to learn about this important process and relate it to polymer solar cell materials and devices.

Electrocatalytic bulk heterojunction materials

Matthew P. Gustafson, Monash Univ. (Australia)

This project has synthesised and characterised poly(thieno[3,2-b]thiophene) (PTT) and poly(dithieno[3,2-b:2',3'-d]thiophene) (PDTT) via vapour phase polymerisation (VPP). These conducting polymers (CPs) possess adequate light absorption in the UV-visible range to promote solar excitation making them ideal candidates to help form a light-enhanced 3D bulk heterojunction material.

Furthermore, their unique structure allows for slight alterations in configuration to provide alternate band gaps in an attempt to 'tune' the material to the operational window specific to a particular reaction. Once characterisation was complete, PTT was combined successfully with poly(3,4-ethylenedioxythiophene) (PEDOT) forming a composite mixture. Preliminary testing indicates the two CPs have a certain level of spontaneous interaction. The trend is seen in the absorption spectra where the increased ratio of PTT leads to the n-n* transition shifting towards the PTT spectrum while retaining the characteristic PEDOT 'tail'. This was the first indication that the combination of CPs via VPP had been successful and that both characteristics typical of each polymer could be sustained. It is important to note that VPP is convenient for this application as it allows one film to be polymerised into another. This could not be achieved through chemical means as a co-polymer may be produced.

It then follows that a combination of these polymers will result in significant advantages owing to their complimentary properties; PTT/PDTT increasing light absorption while PEDOT providing a junction to aid in charge separation and avoiding recombination. Thus, a beneficial blend can be produced and the 3D junction optimised.

Passivated aluminum: structure and energy level alignment at surfaces and interfaces

Eung-Gun Kim, Dankook Univ. (Korea, Republic of); Jean-Luc Bredas, Georgia Institute of Technology (United States)

We present a structural model for the Al2O3(0001)/Al(111) interface based on DFT calculations. By removing a sub-nm, finite-size effect that made a more stable structure less accessible in the smaller surface unit cells commonly used in theoretical calculations, we have been able to determine a new model for the interface. Unlike the structure previously proposed, our calculations underline that the interface consists of a metal-like layer and an oxide-like layer, which now makes the structural transition across the ultrathin interface gradual. Calculations based on the new interface structure successfully reproduce the experimental barrier height of 3.2 eV, and predict a work function reduction of 0.49 eV in passing through the oxide at both the interface and the surface. We expect that this new interface model will serve as a useful platform to further explore this fundamentally and technologically important interface in such emerging areas as organic electronics, where the passivated Al metal, in combination with SAMs, finds applications as high-performance cathode and gate materials.

Plasmonic enhanced lasers of nano-colloidal fluids

Pascal André, Univ. of St. Andrews (United Kingdom) and RIKEN (Japan); Neda Ghofraniha, Istituto Nazionale di Fisica Nucleare (Italy) and Univ. degli Studi di Roma La Sapienza (Italy); Andrea Di Falco, Univ. of St. Andrews (United Kingdom); Claudio Conti, Univ. degli Studi di Roma La Sapienza (Italy)

Localized surface plasmon resonances have recently attracted considerable attention due to their ability to dramatically enhance near-field optical intensities and boost nanoscale light-matter interactions. Here we demonstrate unambiguously that polyhedral silver nanoparticles can be tailored to promote enhanced coherent emission from organic dye dispersions in a cavity. In particular, we observe that nanoparticles supporting resonances close to the absorption peak of the dye yield to more efficient lasing, up to one order of magnitude, which is also evidenced by the narrowing of the emission spectral line down to 3 nm. Moreover we observe emission saturation and energy dependent spectral shifts associated with Kerr effects, which demonstrates the general relevance of non-resonant nonlinearities in plasmonic enhanced laser emissions. Works in this area will contribute to the design of novel kind of laser sources providing ultra-short pulsed operation and structural tunability.

Preparation and characterization of cobalt ferrite nanoparticles for immobilization

Priscyla L. Andrade, Valdeene A. J. Silva, Jackeline Maciel, Univ. Federal de Pernambuco (Brazil); Nelson O. Moreno, Univ. Federal de Sergipe (Brazil); Luis Valladares, Univ. of Cambridge (United Kingdom); Angel B. Dominguez, Univ. Nacional Mayor de San Marcos (Peru); Maria da Paz Silva, José Albino Aguiar, Univ. Federal de Pernambuco (Brazil)

Cobalt ferrite has attracted considerable attention in recent years due to its unique physical properties such as high Curie temperature, large magnetocrystalline anisotropy, large magnetostrictive coefficient, excellent chemical stability and mechanical hardness [1]. On the other hand, enzymes immobilization is considered to be an important tool to enhance thermal and operational stability, easy separation from the reaction mixture during down streaming and reusability for industrial applications [2]. An important requirement for protein immobilization is that the matrix should provide a biocompatible and inert environment, i.e. it should not interfere with native structure of the protein, which thereby could compromise its biological activity [3]. The purpose of this work was to study preparation and functionalization of cobalt ferrite nanoparticles and their application as solid supports for enzymes immobilization. Magnetic particles were prepared in the presence of oleic acid. Aqueous suspension of magnetic particles were prepared by coprecipitation of Fe(III) and Co(II) in the presence of NaOH. The samples were characterized by X-ray diffraction, electron scanning microscopy (SEM), FTIR spectroscopy, mossbauer spectroscopy and magnetization

measurements. Our results indicate that oleic acid produces changes in the size and morphology of the cobalt ferrite nanoparticles and in the magnetization properties. These magnetic nanoparticles were tested as matrix for enzyme immobilization. The immobilized trypsin enzyme in cobalt ferrite with oleic acid presented a specific activity of 38% after 10 reuses.

Insulating conduction in amorphous silicon-chromium films

Abdelhamid El Kaaouachi, Mohamed Errai, Abdelfattah Narjis, Said Dlimi, Abdelghani Sybous Jr., Lhoussine Limouny, Univ. Ibn Zohr (Morocco); Hassan El idrissi, Hassan II Univ. (Morocco)

In this work we focus on the problem of the low temperature transport in insulating amorphous Si1-xCrx films (x=10.9, 12.7 and 14.9%). The conductivity is best described by the relation σ=σ0exp[-(T0/T)p] with p≈1/4. This behavior can be explained by Mott Variable Range Hopping model where the transport occurs by hopping between localized states in the vicinity of the Fermi level without creation of the Coulomb Gap. This is found to be true for the three alloys, but the temperature range where this model is valid decreases with increasing chromium fraction

8811-65, Session PWed

Probing the Coulomb gap in 2D Si-MOSFETs

Abdelhamid El Kaaouachi, Lhoussine Limouny, Abdelfattah Narjis, Abdelghani Sybous Jr., Said Dlimi, Univ. Ibn Zohr (Morocco); Hassan El Idrissi, Hassan II Univ. (Morocco); Gerard Biskupski, Univ. des Sciences et Technologies de Lille (France)

We investigate the temperature dependence of the electrical resistivity down to 0.2 K of a two dimensional electron system in n-channel Si-MOSFETs at zero magnetic field, and at low electron densities, near the metal-insulator transition point from the insulating side. Our results show the existence of a crossover from Mott regime at very low temperature, where ρ= ρ0 exp(TM /T)1/3 to Efros-Shklovskii variable range hopping (ES-VRH), witch is consistent with the existence of a Coulomb gap, where ρ= ρ0 exp(TES /T)1/2. With ρ0 is a Pre-exponential factor that is found to be close to 2 (h/e2), this crossover occurs when the value of temperature oscillates around 1 K.

Generation of spin-polarized atomic clusters: high-precision calculations with modified SV5LYP method

Xuan Liu, Haruhiko Ito, Tokyo Institute of Technology (Japan)

The spin clusters made up of a small number of alkali-metal atoms are stable in the lowest spin state and become unstable as the total spin of the system increases. The calculation value is in good agreement with the experimental data in the lowest spin state. On the other hand, the former differs by more than 80 % from the latter in the highest spin state, although there are only a few experimental results on dimers and trimers. To show the possibility of the formation of the spin clusters in the highest spin state, we perform computations of the binding energy of the spin clusters, Rbn and Csn with n=2 to 14, using the density functional method as precise as possible. Indeed, by changing the parameter values of both the local exchange energy and the non-local correlation energy appearing in the SV5LYP method, the difference from the experimental data is reduced to less than 1 % in both cases of dimers and trimers in the highest spin state. The cluster geometry changes with the total spin. The tetramers are parallelogram in the lowest spin state and tetrahedral in the highest spin state. Such variation between planar structures and steric structures is caused by the change of the exchange energy. When the dihedral angle is 70.53 degree, namely the regular tetrahedron, the exchange energy of the tetramers in the highest spin state reaches a peak.

Improved device performance of TIPS-pentacene field effect transistors incoporating solvent additives

Giljo Chae, Seunghyon Jung, Jeonghoon Baek, Dong-A Univ. (Korea, Republic of); Bright J. Walker, Ulsan National Institute of Science and Technology (Korea, Republic of); Chungkun Song, Jung Hwa Seo, Dong-A Univ. (Korea, Republic of)

Improved device performance of 6,13-bis(triisopropylsilylethynyl) pentacene (TIPS-pentacene) field effect transistors (FETs) was achieved via solvent additives, where diphenly ether (DPE) and chloronaphthalene (CN) were used. The hole mobilities increased from 0.2 cm2V-1s-1 for the pristine device to 0.75 cm2V-1s-1, when TIPS-pentacene FETs processed with DPE and CN were optimized at annealing temperature of 46°C and 60°C, respectively. The concentration of both DPE and CN critically affects the device performance. To understand the effect of additives on surface morphology, molecular ordering and crystallinity of TIPS-pentacene, scanning electron microscopy (SEM), X-ray diffraction (XRD) and optical microscopy measurements were carried out. Appropriate amount of additive induced the formation of well-ordered crystalline domains in TIPS-pentacene, leading to efficient hole transport. Additionally, reduced contact resistance were observed in devices processed with additives compared to neat TIPS-pentacene FET devices. Our findings suggest therefore that the use of additives constitutes a new and effective methodology for the fabrication of OFETs with improved performance

Characterization of fucan and oleic acid-fucan coated magnetite nanoparticles for Sarcoma-180 treatment

Valdeene A. Silva, Priscyla L. Andrade, Univ. Federal de Pernambuco (Brazil); Luis Valladares, Univ. of Cambridge (United Kingdom); Ivone Souza, Karen Cavalcanti, Univ. Federal de Pernambuco (Brazil); Angel B. Dominguez, Univ. Nacional Mayor de San Marcos (Peru); Maria da Paz Silva, José Albino Aguiar, Univ. Federal de Pernambuco (Brazil)

In recent years, there has been a growing interest in the development of Fe3O4 -based nanoparticles as prospective candidates for the diagnosis and targeted therapy of cancer [1]. The optimization and functionalization of these magnetic nanoparticles are very promising for vast applicability. They are usually presented in core-shell configurations: a magnetic nucleus coated with organic or polymeric shells [2]. Fucans are sulfated polysaccharides that possess many biological activities such as anticoagulant, antiviral, antitumoral, anti-inflammatory, and thus good candidates for the functionalization of Fe3O4 nanoparticles [3]. On the other hand, oleic acid is often used as a surfactant and has higher affinity to the surface of superfine magnetite [4]. The objective of this work was to synthesize fucan and fucan-oleic acid coated magnetite nanoparticles by co-precipitation methods, to characterize and to analyze any modification on nanoparticles' surface, and to test them for antitumoral activity. The samples were characterized by scanning electron microscopy (SEM), infrared spectroscopy (FTIR), x-ray diffraction (XRD), magnetization measurements and Mössbauer spectroscopy. The SEM showed that the nanoparticles (around 10 nm size) present heterogeneous morphology. The coating efficiency of fucan and oleic acid on the surface of the magnetite nanoparticles was analyzed by FTIR.

The functionalization of the Fe_3O_4 nanoparticles is demonstrated by FTIR and XRD The magnetization curves indicate typical superparamagnetic behavior for all the samples and this property is originated by the core Fe_3O_4 . The uncoated and coated magnetite nanoparticles were applied for antitumoral activity in mice with Sarcoma 180.

Positive magnetoresistance and spin susceptibility in two-dimensional electron gas in GaAs

Hassan El Idrissi, Hassan II Univ. (Morocco); Abdelhamid El Kaaouachi, Abdelfattah Narjis, Said Dlimi, El Fatmi Daoudi, Abdelghani Sybous Jr., Mohamed Errai, Lhoussine Limouny, Univ. Ibn Zohr (Morocco)

In this work, positive magnetoresistance (PMR) of a dilute two-dimensional electron gas in GaAs is studied at very low temperature in presence of parallel magnetic fields B on the metallic side far away from the metal insulator transition (MIT). It turns out that the normalized resistivity curves, $\chi(B)/\chi(0)$, merge together when we scale the field according to B/B_χ where B_χ is assumed to be the field in which full spin polarization of electrons is reached. It is also shown that the saturation field, Bsat, determined by resistivity saturation, deviates to lower values than B_χ with increasing electron density, which cannot be explained in terms of filling of the upper electron subbands in the fully spin-polarized regime. The spin susceptibility, χ, is assessed by extracting the product g^*m^* where g^* and m^* are the effective Landé factor and electron mass, respectively. The behaviour of χ with increasing electron density is still the subject of required theoretical attention.

8811-70, Session PWed

Granular and intergranular conduction in granular oxides La0.67Ca0.33MnO3 and La0.5Sr0.5CoO3

Abdelhamid El Kaaouachi, Abdelfattah Narjis, Lhoussine Limouny, Said Dlimi, Abdelghani Sybous Jr., El Fatmi Daoudi, Mohamed Errai, Univ. Ibn Zohr (Morocco); Hassan El Idrissi, Hassan II Univ. (Morocco)

Electrical transport is studied in nanocrystals of $La_{0.67}Sr_{0.33}MnO_3$ (LCMO) and $La_{0.5}Sr_{0.5}CoO_3$ (LSCO) in the temperature range 0.4-5 K. In both samples, two distinct behaviors of the conductivity are observed. In LCMO sample, the Variable Range Hopping regime is observed for T>1 K with enhancement of the relative permittivity. On contrary, for LSCO sample, there is no latitude at all that could allow the possibility of this model being valid. For T<1 K, the transport model in both samples is considered in the two component model of metallic-like droplets embedded in dielectric matrix where the negative magnetoresistance can be explained by considering the Spin Polarization Tunneling phenomenon in the intergranular regions.

Observation of screening-induced metallic behavior in n-AlAs

Abdelhamid El Kaaouachi, Abdelfattah Narjis, Said Dlimi, Mohamed Errai, Abdelghani Sybous Jr., El Fatmi Daoudi, Univ. Ibn Zohr (Morocco)

The nature of the metal-insulator transition at zero magnetic field in two-dimensional systems has remained a controversial enigma since the pioneering realization of the metallic behaviour in high mobility Si-MOSFETs. In this paper the density (n) dependence of the conductivity of two-dimensional electron gas in aluminum arsenide was analyzed in the metallic side ($n \geq 0.59?1011cm-2$) at very low temperature. Our study reveals an inhomogeneity driven percolation type transition to an insulating state due to the breakdown of screening in the random charged impurities disorder background. The critical density found under this assumption is lower than that assumed by observing the sign of the temperature coefficient of conductivity.

8811-72, Session PWed

Spin polarization in two-dimensional hole gas in GaAs

Abdelhamid El Kaaouachi, Said Dlimi, Abdelghani Sybous, Lhoussine Limouny, Abdelfattah Narjis, Univ. Ibn Zohr (Morocco); Gerard Biskupski, Univ. des Sciences et Technologies de Lille (France); Mohamed Errai, Univ. Ibn Zohr (Morocco); Hassan El Idrissi, Hassan II Univ. (Morocco); El Fatmi Daoudi, Univ. Ibn Zohr (Morocco)

In the ballistic regime where $kBT\tau 0/ \hbar > = 1$, the temperature dependence of the metallic conductivity in a two-dimensional holes system in gallium arsenide, is found to change in a non-monotonically with the degree of spin polarization. In particular, its fades away just before the onset of complete spin polarization, but reappears again in the fully spin-polarized state, being, however, suppressed relative to the zero magnetic field case. The analysis of the degree of suppression can distinguish between screening and theories based on interaction. We show that in a fully polarized spin state, the effects of disorder are dominant approach to strong localization regime, which is contrary to the behavior of 2D electron systems in weakly unpolarized disordered state. It was found that the relaxation time correction elastic, depending on the temperature has changed significantly with the degree of spin polarization, to reach a minimum just below the start of the spin-polarized integer, where the conductivity is practically independent temperature.

8812-1, Session 1

Ionic contrast terahertz near field imaging *(Invited Paper)*

Guilhem Gallot, Ecole Polytechnique (France)

We demonstrated the direct and noninvasive imaging of functional neurons by Ionic Contrast Terahertz (ICT) near-field microscopy. This technique provides quantitative measurements of ionic concentrations in both the intracellular and extracellular compartments and opens the way to direct noninvasive imaging of neurons during electrical, toxin, or thermal stresses. Furthermore, neuronal activity results from both a precise control of transient variations in ionic conductances and a much less studied water exchange between the extracellular matrix and the intraaxonal compartment. The developed ICT technique associated with a full threedimensional simulation of the axon-aperture near-field system allows a precise measurement of the axon geometry and therefore the direct visualization of neuron swelling induced by temperature change or neurotoxin poisoning.

8812-2, Session 1

Carbazole-based cyanine probes for selective cellular imaging in nonlinear optical microscopy

Mei-Ling Zheng, Technical Institute of Physics and Chemistry (China); Katsumasa Fujita, Osaka Univ. (Japan); Xuan-Ming Duan, Technical Institute of Physics and Chemistry (China); Satoshi Kawata, Osaka Univ. (Japan)

Optical microscopy has been a truly enabling visualization technique in biological and biomedical sciences. Nonlinear optical (NLO) microscopy techniques enable us to reduce photodamage and increase the penetration depth. Additionally, the nonlinear excitation is confined to a focused volume, decreasing phototoxicity and out-of-focus photobleaching. NLO microscopy typically includes two-photon excited fluorescence (TPEF) and second-harmonic generation (SHG). TPEF is a third-order NLO effect that results in an optically confined fluorescence emission. SHG is a second-order NLO effect only observed in non-centrosymmetric structures. While chromophores in general can be excited through TPEF, non-centrosymmetrical arrangements of chromophores are needed for observing an efficient SHG signal. Design strategies towards chromophores for NLO microscopy should combine function and form requirements.

A series of chromophores with enhanced second- and third-order NLO properties was engineered for use in combined SHG and TPEF microscopy. The electron-rich carbazole core serves as a template towards one-dimensional or two-dimensional chromophores. More efficient acceptor groups on the carbazole donor core resulted in the improved second- and third-order NLO properties. A selection of these chromophores was tested in a cellular environment with a multimodal multiphoton microscope. The structural differences of the chromophores resulted in high selectivity for mitochondria or the nucleus in TPEF and ranging from non- to high selectivity for mitochondria in the SHG channel. This study provides prospective applications in tissue, as well as in live animal bioimaging.

8812-3, Session 1

Spectroscopy of site specific DNA assembled plasmonic networks on cell surfaces

Vladimir P. Drachev, Univ. of North Texas (United States); Kyuwan Lee, Joseph M. Irudayaraj, Purdue Univ. (United States)

A new approach has been developed based on DNA- gold nanoparticle network structures as a multiplex probe for both localized surface plasmon resonance (LSPR) and surface-enhanced Raman scattering (SERS) detection [1]. The network structures are well controlled and synthesized by DNA hybridization at specific cell surface sites. The designed network structure improves the sensitivity of the conventional cell surface marker probes to the level of single molecule detection at the membrane of a living cell.

In this paper we discuss optical properties of gold nanoparticle networks for multiplex profiling of human breast epithelial cells to identify the membrane surface markers. The SERS signal of label molecules increases with the number of particles in the network and saturates above 200 particles in the aggregate. The scattering signal detected with the dark field microscopy is also increased for the network relative to a nanorod or nanoparticle of other shape. The peak position is shown to be reproducible for different DNA lengths and number of particles in aggregates and can be extrapolated with a simple equation. The structure can be reversibly controlled by varying the temperature near DNA hybridization melting point. Photothermal effect results in the selective dissociation of nanoparticle structures. The concept of network formation was tested first using antigens and antibody binding reaction on a substrate and then implementing for CD24 and CD44 receptors of three breast cancer cell lines (MCF-7, MDA-MB-231, and MDA-MB-468).

Highly fluorescent semiconducting polymer dots for single-molecule imaging and biosensing *(Invited Paper)*

Daniel T Chiu, Wei Sun, Jiangbo Yu, Fangmao Ye, Yu Rong, Univ. of Washington (United States)

This presentation describes the development and application of fluorescent polymeric nanoparticles that we have carried out in our lab in the past several years. I will highlight their photophysical properties and their use in sinlge-molecule microscopy and cellular imaging. We have constructed a number of biosensing systems using these nanoparticles and I will highlight these developments and offer an outlook of their future developments.

8812-5, Session 1

Single plasmonic nanoparticle biosensors for single-molecule and super-resolution imaging of single live cells *(Invited Paper)*

X. Nancy Xu, Old Dominion Univ. (United States)

Noble metal nanoparticles, such as silver nanoparticles (Ag NPs), show distinctive plasmonic optical properties that highly depend upon their sizes, shapes and surrounding environments. These intrinsic plasmonic optical properties enable us to selectively detect and sense single molecules of interest that are specifically recognized by functional molecules attached on the surface of the NPs. Unlike fluorophors and QDs, Ag NPs resist photo- decomposition and blinking, and possess exceptionally high quantum yield of Rayleigh scattering that are orders of magnitude higher than any fluorophors. We have used these intrinsic plasmonic properties of single NPs to develop several new ultrasensitive nanobiotechnologies, including photostable single-molecule-nanoparticle-optical-biosensors (SMNOBS), single nanoparticle plasmonic spectroscopy, and far-field photostable-optical-nanoscopy (PHOTON). We have used these new tools to quantitatively image single protein molecules and study their functions in single live cells with superior temporal and spatial resolutions. We have demonstrated that these powerful new sensing and imaging tools can be used to map

dynamic cascades of membrane transport and signaling transduction pathways of single live cells in real time at single molecule (SM) and nanometer (nm) resolutions. The detailed experimental design and the updated results will be discussed in this presentation. The work is supported in part by NSF (CBET 0507036) and NIH (R01 GM0764401; 3R01 GM076440-04S1).

8812-6, Session 1

Electron-transfer rate in proteins using optical impedance spectroscopy at single-mode waveguides

Xue Han, Sergio B. Mendes, Univ. of Louisville (United States)

An electro-active platform based on a single-mode integrated optical waveguide over coated with a 13-nm indium tin oxide film was developed for highly sensitive investigations on the kinetics of redox reaction of the protein cytochrome-c sub-monolayer under alternating current (AC) potential modulation. 10-mV AC amplitude based on different DC bias with a series of frequencies was applied on spectroelectrochemical cell. 550-nm was selected to probe cytochrome-c absorbance shifting between reduced and oxidized states. Potential and optical signals were recorded by an oscilloscope simultaneously. AC, DC, and phase delay of optical output were analyzed.

Equivalent electrical elements for cytochrome-c redox reaction are an electron transfer resistor Rct in series with a pseudo capacitor Ca. Standard rate constant Ks is expressed in equation 1. After factoring out effects due to optical changes in the working electrode, usually neglected in literature, resonance angular frequency ωr was identified from the reconstructed faradaic current iF in the frequency domain from the modulated optical absorbance signal. iF from different DC bias had the same frequency dependency profile. At -0.08-V DC bias, which had strongest response signal from cytochrome-c, 2.255*10^(-13)-mole/cm^2 AC active surface coverage and 8.697*10^(-7)-A/cm^2 faradaic current density at resonance frequency were observed. A time rate constant of 24.96/s was determined through purely optical signal from the changes in the redox couple.

This high sensitive, accurate, and simple strategy of spectroelectrochemistry is expected to have more potential applications, especially in small electron transfer signal cases.

Ks=1/[(2*Rct *Ca)]=ωr/2 Equation 1

Addressing biomedicine throughput needs through chip-scale microscopy *(Invited Paper)*

Changhuei Yang, California Institute of Technology (United States)

The pace of microscopy throughput requirement growth in biomedicine is a fast one for which conventional microscopy is ill-suited to address. My group's focus on developing chip-scale microscopy technologies is aimed at addressing this issue by redesigning microscopy from the ground up. In this talk, I will discuss our recent work on 1) the optofluidic microscopy, 2) the ePetri system - a self-imaging petri dish technology that is capable of streaming microscopy images out of an incubator, 3) Talbot microscopy, and 4) Fourier Ptychographic Microscopy. I will discuss the challenges of building a truly compact fluorescence chip--scale microscope and report on the novel strategies we are developing to tackle these challenges.

8812-8, Session 2

Novel optical strategies for biodetection *(Invited Paper)*

Harshini Mukundan, Los Alamos National Lab. (United States)

The biosensor group at the los alamos national laboratory is an interdisciplinary resource of scientists focused on developing solutions to global diagnostic challenges. This presentation will outline some recent advancements of the group, especially towards diagnosis of tuberculosis in patients and detection of E.coli in spinach and beef, using a waveguide based optical biosensor developed by our team. A recent siderophore-based approach to 'fish' for live bacteria will also be discussed. Bringing together synthetic chemistry with optical strategies, novel transduction approaches and nanotechnology to achieve diagnostic success is the focus of this talk.

8812-10, Session 2

Discussion on transmembrane proteins using electrochemically fabricated nanopores

Muhammad S. Khan, Noura S. Dosoky, Debra Moriarity, John D. Williams, The Univ. of Alabama in Huntsville (United States)

Membranes are vital structures found everywhere in the biological system and since last decade nanotechnology has been contributing significant role in many biomedical applications. To probe the chemical and physical properties of transmembrane proteins incorporated with lipid bilayer membrane (LBM), different porous structures (PS) have been used at nanoscale. In this research, we are using porous silicon device to discuss the transmembrane proteins due to its higher surface area to volume ratio. Electrochemical fabrication process will be discussed in detail to fabricate the Nanopores on silicon device. To regulate the flow of ion channels across LBM, two conductive electrodes are used. The Langmuir- Blodgett and Langmuir- Schaefer techniques are used to form the LBM. Scanning Electron Microscopy (SEM) will show images of transmembrane protein on porous structure. Finally, we will present the discussion on using porous silicon membrane to probe the cellular wall of the E. coli bacteria by incorporating different transmembrane proteins on both sides of the porous structure. Advantage of using this methodology is to provide the mechanical stability for the cholesterol free membrane. Future work involves the possibility of integrating the membrane structure with electronic circuitry at nanoscale. Due to the high compatibility of silicon with electronic devices, it can easily be used for many medical and electronic applications. This research will conclude the importance of porous silicon structures which keep the transmembrane proteins in an environment as close as possible to the in-vivo one.

8812-12, Session 2

Hybrid optofluidic integration *(Invited Paper)*

Holger Schmidt, J. W. Parks, H. Cai, D. Ozcelik, S. Liu, Univ. of California, Santa Cruz (United States); L. Zempoaltecatl, Aaron R. Hawkins, Brigham Young Univ. (United States)

We will discuss the hybrid integration of silicon-based optofluidic waveguide devices with additional structures and layers in order to enhance optical detection and manipulation on the single particle level. Specifically, we describe the vertical integration of a microfluidic layer that performs dedicated microfluidic sample handling functions such as analyte mixing, distribution, and filtering. We will also discuss the incorporation of a nanopore-based electrical sensor with the optical detection platform. This combination enables multimodal, correlated detection, discrimination, and analysis of individual nanoparticles.

8812-13, Session 2

Viscoelastic property of the cell membrane influenced by the adhesion of macrophages on the matrix extracellular

Samuel T. Souza, Lais C. Agra, Emiliano Barreto, Jandir M. Hickmann, Eduardo J. da Silva Fonseca, Univ. Federal de Alagoas (Brazil)

Macrophages have important roles in the immune response and tissue homeostasis. Its capacity for phagocytosis renders them effective at patrolling through a variety of tissues. In addition, the hallmarks of activation of macrophages can be verified by cell adhesion and spreading on extracellular matrix (ECM). Among the ECM components, fibronectin has been recognized as the key element in promoting cell adhesion and various functions of macrophages. However, yet is not fully understood if the deformation capacity of the membrane plasmatic is influenced by cell adhesion on the ECM.

In this work we studied viscoelastic properties of the macrophages membrane adhered on a film of fibronectin using the Atomic Force Microscopy (AFM) aiming to identify possible interference of extracellular matrix on the biomechanical characteristics of cells. To this study, J774 macrophages were incubated for 1h and 48h on glass coverslips and on glass coverslips recovered with EMC. After 1h or 48h of incubation, cells were fixed and analyzed with the AFM nanoindentation technique.

Ours results have revealed that no significant variation in Young's modulus of cells incubated just on glass coverslips for 1h and 48h. However, they showed the increase in the Young's modulus of about 36% and 50% for cells incubated on glass coverslips recovered with EMC, respectively, as compared with cells incubated just on glass coverslip for 1 and 48h.

In summary, ours results indicate that cell adhesion on fibronectin induce a significant alterations on viscoelastic properties of the cell membrane, suggesting involvement of the intracellular components, such as cytoskeleton, triggered by interaction between cell and ECM.

8812-14, Session 2

Nano-engineered titanium for enhanced bone therapy

Karan Gulati, Gerald Atkins, David Findlay, Dusan Losic, The Univ. of Adelaide (Australia)

Natural bone is a perfect example of nanoengineering, which often requires support in the form of therapies, implants or corrections for conditions that are beyond the scope of normal repair. Bone cancer, severe fractures, osteoarthritis, and bone infection requires special assistance: chemo/radiotherapy, grafting/correction, protein/hormone administration and antibiotic therapy respectively. These often affect the healthy tissues while the dose at the target site remains ineffective; ultimately leading to exacerbated effects: bone loss, re-surgery and need to amputate. The possible solution to treating such bone conditions is local drug delivery i.e. delivery of therapeutics directly at the site where it is desired.

To achieve effective bone therapy we propose fabrication of titanium implants capable of releasing the loaded drug/protein for extended durations following favorable kinetics. Titanium substrates were modified using electrochemical anodisation to fabricate array of self-ordered hollow titania ($TiO2$) nanotubes (TNTs). In-vitro drug release studies depicted substantial loading amounts and delayed release patterns for anti-bacterial, anti-inflammatory and anti-cancer drugs. To further delay the release of therapeutics to over 30 days a thin layer of biopolymer was coated onto the drug loaded TNTs. Biocompatibility studies with osteoblast cells demonstrated enhanced cell adhesion and proliferation; which directly relates to bone forming ability.

Results demonstrated ability to load wide variety of therapeutics inside these implants with delayed release patterns. Also the dimensions of the TNTs and the biopolymer coating thickness could be tailored to accommodate more drug amount and control the release behavior. The proposed technology can easily be applied for bone therapies/fixation for the infected/fractured bone for mechanical support, with 3D release of drug inside the bone micro-environment and enhanced bone cell functions; making the proposed system suitable to target hard-to-reach bone conditions like: infection and cancer.

8812-15, Session 2

Acute toxicity of rattle-type silica nanorattles coated gold nanoparticles in intravenously exposed mice

Tianlong Liu, Longfei Tan, Technical Institute of Physics and Chemistry (China); Dong Chen, Beijing Creative Nanophase Hi-Tech Co., Ltd. (China); Huiyu Liu, Linlin Li, Changhui Fu, Tianlong Tang, Technical Institute of Physics and Chemistry (China)

Gold nanoparticles is a promising nanomaterials used in the field of biological imaging, cancer diagnosis and treatment. With the rapid increase of nanomaterials applications, the concerns on the health impacts caused by nanomaterials are also increasing [1-3]. In this paper, we synthesized a novel nanostructure in which 13 nm gold nanoparticles exist in the cavity of the core-shell silica structure (SN@GN) and the single dose toxicity, and biodistribution of SN@GN in vivo were demonstrated after intravenous injection in mice. Silica nanorattle are emerging as one of the new and promising nanomaterials for biomedical applications, and our previous study suggest low lethal toxicity of MHSNs when intravenous injection at single dose or repeated administrations [4-5]. For single dose toxicity, lethal dose 50 (LD50) of SN@GN was higher than 500 mg/kg. ALT and AST were elevated in SN@GN treated mice over 160 mg/kg dose, however, levels in vehicle and 80 mg/kg were comparably low. Histological analysis revealed lymphocytic infiltration in liver and lung of high-dose SN@GN treated mice. ICP-OES, TEM and dark field imaging results show that the SN@GN mainly accumulates in mononuclear phagocytic cells in lung, liver and spleen. These findings would be useful for future development of nanotechnology-based drug delivery system and other biomedical applications.

8812-16, Session 2

Magnetic particles and cyanoacrylate-based glue for intraluminal bowel retraction

Pascal André, Univ. of St. Andrews (United Kingdom); Zhigang Wang, Univ. of Dundee (United Kingdom); Ipek Birced, Univ. of St Andrews (United Kingdom); Andrew Brown, Stuart I. Brown, Univ. of Dundee (United Kingdom); Gordon J. Florence, Univ. of St Andrews (United Kingdom); Alfred Cuschieri, Univ. of Dundee (United Kingdom)

Reducing tissue trauma is needed for surgery applications when physical retraction is completed with graspers.[1-2] In this medical field, small magnets have been used for magnetic tissue retraction[3-5], however magnetic particles offers further advantages.[6-7] In this presentation, we will describe a novel method of magnetisation of bowel segments by intraluminal injection of magnetic glue.

Following materials' characterisation studies, micro-particles of stainless steel and iron oxide nanoparticles could be mixed with medical grade cyanoacrylate glues to design an injectable magnetic media suitable for surgery applications. During intra-luminal injection of the magnetic glue using ex-vivo porcine colonic segments, a magnetic probe placed at the injected site ensured that the particles dispersed in the glue as it polymerized to form an intra-luminal mucosally-adherent coagulum. This report will show how the magnetized porcine colonic segments can be retracted by magnetic probes placed external to the bowel wall. A tensiometer was used to record the retraction force and distance.

The results of this study indicate that the formation of an intra-luminal coagulum produces sufficient magnetic retraction for bowel retraction. This ex-vivo study requires confirmation by in-vivo animal studies before clinical translation to Minimal Access Surgery.

8812-17, Session 2

Single nanoparticle sensing using whispering-gallery microresonators and microlasers

(Invited Paper)

Lan Yang, Jiangang Zhu, Sahin K. Ozdemir, Lina He, Woosung Kim, Huzeyfe Yilmaz, Faraz Monifi, Steven H. Huang, Washington Univ. in St. Louis (United States)

Microsystems for detecting biomolecules will play important roles in biomedical research, clinical diagnosis, food safety, pharmaceutical testing, and environmental monitoring. Optical sensors based on Whispering-Gallery-Mode (WGM) resonators have emerged as front-runners for label-free, ultra-sensitive detection of nanomaterials and nanoscale phenomena due to their superior capability to significantly enhance the interactions of light with the sensing targets by confining light photons in small volumes for long periods of time. A WGM resonator traps light in circular orbits in a way similar to a whisper, i.e., a sound wave, traveling along a circular wall, an effect found in the whispering gallery of St. Paul's Cathedral in London. This talk will introduce ultra-high-quality (Q) optical WGM microresonators and their fabrication process. The basis for resonator sensors is that the physical associations and interactions of nanomaterials on the surface of a high-Q optical WGM resonator alter the trajectory and lifetime of photons in a way that can be measured and quantified. I will present a recent discovery of using ultra-high-Q microresonators and microlasers for ultra-sensitive self-referencing detection and sizing of single virion, dielectric and metallic nanoparticles. I will discuss using optical gains in a microlaser to improve the detection limit beyond the reach of a passive microresonator. These recent advancements in WGM microresonators will enable a new class of ultra-sensitive and low-power sensors for investigating the properties and kinetic behaviors of nanomaterials, nanostructures, and nanoscale phenomena.

8812-18, Session 2

Single-beam optical biosensing using laser nanopolymerization and enzyme reactions

Hiroyuki Yoshikawa, Shuhei Imura, Eiichi Tamiya, Osaka Univ. (Japan)

We found a characteristic modulation of the backreflected laser intensity induced by focusing a laser beam on an o-PD solution, and we applied this phenomenon to glucose detection. Because enzyme reactions using peroxidase are widely used for biosensing applications, particularly in enzyme-linked immunosorbent assays (ELISAs), this technique should also be applicable to various biosensors. A reliable optical quantification of glucose can be performed in a short time (~2 min including incubation) with a small sample volume (<20 μL). In addition, the sensing system can be constructed by using simple components without requiring any complex optics and expensive spectroscopic detectors. Furthermore, laser focusing and backreflection detection are simple techniques that are even performed by the read/write heads, known as an optical (or laser) pickup, of optical storage drives. This suggests that this biosensing technique is promising for developing compact and inexpensive optical biosensors for widespread applications to point-of-care monitoring.

8812-19, Session 2

Silica nanorattle and gold nanoshell on silica nanorattle for cancer therapy

Fangqiong Tang, Huiyu Liu, Linlin Li, Tianlong Liu, Technical Institute of Physics and Chemistry (China); Dong Chen, Beijing Creative Nanophase Hi-Tech Co., Ltd. (China)

For decades, nanomedicine has brought new opportunities for cancer therapy. Drug delivery systems based on nanomaterials have been proved to improve inherent limitations of classical pharmacotherapy. Recently, mesoporous silica nanomaterials (MSNs) have attracted more and more attentions for biomedical application especially for drug delivery. As nanocarriers, mes¬oporous silica nanoparticles with unique mesoporous structure have been explored as effective drug delivery systems for a variety of therapeutic agents to fight against various kinds of diseases including bone/tendon tissue engineering, dia¬betes, inflammation, and cancer. Furthermore, it provides unique opportunities for simultaneous diagnosis and therapy with the MSN-based multifunctional nanocomposites not only as drug delivery system but also as an imaging modality. Recently, near-infrared (NIR) resonant nanomaterials, such as gold nanoshells, gold nanorods and carbon nanotubes, have been used for hyperthermia under photothermal treatment (650-900nm). Multifunctional nanocomposites that integrate these special nanomaterials into one system have attracted much attention for their potentials in simultaneous disease diagnosis and therapy. However, it's great challenges to successfully fabricate the nanocomposites and optimize their performance. In this paper, our researches demenstrate that the silica nanorattles and the multifunctional counterparts can to be developed as versatile nanoformulations promising for clinical applications in cancer diagnosis and therapy. It may provide useful information for the development of novel drug delivery system based on mesoporous silica nanomaterials.

8812-20, Session 2

Use of novel silver nanoparticles with hyaluronan as potential biological labels for determine the quality of embryos development

Vasyl J. Syrvatka, Yurij I. Slyvchuk, Institute of Animal Biology NAAS (Ukraine); Oleksandr I. Bilyi, Ivan Franko National Univ. of L'viv (Ukraine); Ivan I. Rozgoni, Ivan I. Hevkan, Institute of Animal Biology NAAS (Ukraine)

In reproductive medicine it is important to determine the quality of embryo development without interference in their function and viability. Unique plasmon-resonant optical properties of silver nanoparticles make them promising candidates for use in nanomedicine as signal enhancers, optical sensors and biomarkers. The main aim of the study was to investigate the physicochemical properties and biological activities of novel functional silver nanoparticles with prospect of their use in embryo transfer techniques as diagnostic and sensing tools.

For this purpose, we synthesized new silver nanoparticles with hyaluronan by chemical reduction method. The physical and biological properties of novel silver nanoparticles were compared with silver nanoparticles identical in size and shapes but with different chemical surfaces modifications by polyvinylpyrrolidone and bovine serum albumin. We used transmission electron microscopy and ultraviolet-

visible spectroscopy techniques for structural characterizations of nanoparticles. The antimicrobial activities of the composite nanoparticles were determined by measurement of their minimum inhibitory concentrations. In addition, we studied the influence of different concentration of composite silver nanoparticles on rabbit's embryo development in vitro.

Our results show that novel silver nanoparticles have distinct physicochemical properties and level of degradation in culture medium versus to nanoparticles with polyvinylpyrrolidone and bovine serum albumin. Furthermore, biological activity on Gram positive and Gram negative bacteria and toxicity on rabbit's embryos was different in nanoparticles with different surface modification. Therefore, the novel silver nanoparticles with hyaluronan have unique physicochemical properties and biological activity and can be applied in reproductive medicine as diagnostic and sensing tools.

8812-23, Session 2

Silica nanorattle as drug carrier for cancer targeting therapy

Linlin Li, Tianlong Liu, Technical Institute of Physics and Chemistry (China); Dong Chen, Beijing Creative Nanophase Hi-Tech Co., Ltd. (China); Huiyu Liu, Longfei Tan, Changhui Fu, Fangqiong Tang, Technical Institute of Physics and Chemistry (China)

Mesoporous silica nanomaterials (MSNs) have attracted more and more attention for bioapplication especially for drug delivery.[1] We have synthesized a novel kind of mesoporous and hollow nanomaterials: slilica nanorattles (SN).[2] It have good monodispersion, controllable size, mesoporous and hollow structure and high specific surface area. The silica nanorattles with suitable size and structure were developed as drug delivery systems for anticancer drug of decetaxel for in vitro and in vivo liver cancer therapy. The results prove that the silica nanorattles have potentials to enhance the therapy efficacy and reduce the systemetic toxicity of the drugs.[3] For better tumour targeting, targeting ligand of folic acid[4] and luteinizing hormone-releasing hormone-Pseudomonas aeruginosa exotoxin 40 (LHRH-PE40) was bioconjugated onto the silica nanorattle for targeted imaging and therapy of ovarian carcinoma and lung cancer, respectively. In addition, we designed a more active targeting strategy. Mesenchymal stem cells (MSC), which have a tropism for brain tumor, were used for acting as delivery vehicles of drug loaded silica nanorattle for targeting therapy of glioma.[4] The combination of "stem cell targeting" and "controlled drug delivery" has promising to target and kill all the tumor cells including the primary and metastasis satellites. These results may provide useful information for the development of new strategies for the design of efficient drug delivery nanocarriers and therapeutic system.

8812-21, Session 3

Plasmonic engineering in nanomedicine *(Invited Paper)*

Srikanth Singamaneni, Washington Univ. in St. Louis (United States)

High refractive index sensitivity of localized surface plasmon resonance (LSPR) of metal nanostructures renders them as attractive nanotransducers for point-of-care biodiagnostics. However, most of the current plasmonic biosensors rely on natural antibodies for biorecognition and rigid substrates for device fabrication. These conventional methods are not ideal for translation of plasmonic biosensors to resource-limited and point-of-care settings. We demonstrate that a common a filter paper loaded with biofunctionalized metal nanoparticles enables the detection of target disease biomarkers in complex physiological fluids. Apart from significantly lowering the cost, such bioplasmonic paper is ideal for translating bioplasmonic paper to resource-limited settings. Furthermore, we also demonstrate that natural antibodies, which suffer from numerous shortcomings such as limited environmental and chemical stability can be replaced with artificial antibodies by molecularly imprinting the plasmonic nanostructures. In the second part of this talk, we present a novel class of ultrabright surface enhanced Raman scattering (SERS) probes, which we call Bi-layered Raman-intense Gold nanostructures with Hidden Tags (BRIGHTs). These novel SERS probes are nearly 20 times brighter compared to the conventional SERS probes and enable rapid molecular bioimaging of breast cancer cells.

8812-22, Session 3

Optical methods for wireless implantable sensing platforms

Muhammad Mujeeb-U-Rahman, Chieh-Feng Chang, Axel Scherer, California Institute of Technology (United States)

Fully Wireless Implantable platforms for sensing and actuation have gained importance for many applications recently. These systems can be used for both corrective health care and biological applications. To be able to work as long-term devices, these need to be designed on very small size scales and need to be fully wireless to avoid foreign body reaction and the risk of infection due to wires. Optical methods are very attractive for such systems due to the small footprint of optical devices and due to inherent decoupling between optics and signal processing circuits used in such systems. Here we present techniques to remotely power such systems using Photovoltaic power supply. We will show designs optimized for such applications which require high voltages (higher than the built-in potentials of the substrate materials) and designs optimized for high current requirements. We will provide theoretical and experimental results of such power harvesting systems and how these can be tuned for different applications. We will show examples of integrated designs in standard CMOS processes and see how these compare to theoretical results for Silicon based Photovoltaic devices. We will also show results from small-scale compound semiconductor Photovoltaic devices and their integration with the Silicon based sensing systems. We will also include design of Silicon-on-Insulator based Photovoltaic systems and methods to increase optical path lengths in such devices to increase their efficiency. Finally, we will show experimental results using Photovoltaic devices embedded in biological media and discuss the effect of optical methods on their surrounding media.

8812-24, Session 3

Size-dependent nanoparticle delivery by biodegradable microsphere-mediated perforation using femtosecond laser

Tatsuki Mitsuhashi, Mitsuhiro Terakawa, Keio Univ. (Japan)

A combination of nano/microparticles and laser irradiation is promising for drug delivery and theranostics. However, nano/microspheres have concerns with regards to the potential cell toxicity which is mainly dependent on their material and size. We have been studying cell membrane perforation using an enhanced optical field around a biodegradable sphere excited by a near-infrared femtosecond laser. In this study, with the purpose of achieving a size selective drug delivery using biodegradable polymer, we investigated the size of the particles that can be delivered into cells and discussed the governing mechanism. FITC-labeled silicon nanoparticles of different sizes were used in this study and obtained that the efficiency of cellular delivery decreased with increasing the particles' diameter. However, particles up to 100 nm in diameter were able to be delivered. By observing the emission spectra, we elucidated that the breakdown of water is necessary to obtain a high efficiency. The effect of a charge of the silicon particles on the efficiency will also be presented. This study contributes to developing a safe high throughput size selective drug delivery using biodegradable polymer spheres.

8812-25, Session 3

Nanoimprinted optical biosensor for diagnostics and biomimetic lung-on-a-chip for drug studies *(Invited Paper)*

Sonia Grego, RTI International (United States)

(Invited) Engineered devices leveraging micro- and nano-technology enable novel solutions for significant diagnostic and therapeutic applications such as point-of-care detection of infectious diseases and biomimetic cellular models of human organs for drug studies.

Optical biosensors represent rapid and compact analytical tools. Field-deployable platforms are high desirable for applications such as diagnosis of infection from a clinical specimen yet many of the recently developed optical biosensors are limited to laboratory use due to the large size and complexity of the read-out system. The Tunable Wavelength Interrogated Sensor Technology (TWIST) relies on a device and system designed for a compact and rugged biosensor platform. The sensing device is a grating-integrated optical waveguide obtained by nanoimprint lithography with an inexpensive stamp. The TWIST configuration and performance, including on-chip reference, will be described, and its application to infection disease diagnostics will be discussed.

The development of new therapeutics is poised to greatly benefit from microfluidic devices enabling biomimetic cell cultures. Engineered cell-cultures reconstitute physiological organ functions and, therefore, more closely emulate tissue response to drugs and insults. The lung is a primary site of exposure to pathogens as well as an attractive drug delivery route. This talk will describe a sophisticated microfluidic lung model which recapitulates key features of the function and morphology of airway epithelium. This lung cellular construct relies on the use of highly differentiated human primary cells and it is enabled by a multilayer device designed to ensure optimal cell differentiation and to reproduce physiological interfaces between cell types.

8812-26, Session 3

Smart integrated optical sensor patch dedicated to wireless real-time brain-machine interface and body area networks

Ehsan Kamrani, Seok Hyun A. Yun, Wellman Ctr. for Photomedicine (United States)

REMOTE control of ambient tools using thought has been a dream falsified in several science fiction stories. Available human-machine interfaces (HMIs) use bulky systems and invasively implanted electrodes to monitor and transfer brain signals. Portable and real-time non-invasive brain imaging using functional near-infra-red spectroscopy (fNIRS) provide ability of translating brain commands appears in the form of hemodynamic and neural dynamics to the electric signals. Some recent works have applied fNIRS and its combination with electro encephalogram (EEG) in HMIs and human brain studies, however they suffers from bulky, wired, difficult to setup, and low signal-to-nose ratio (SNR) photodetector front-end, in additional to their infeasibility to be applied for continues and real-time monitoring due to the power and speed limitations they are suffering. These drawbacks also have impeded attaching optical monitoring tools such as pulse-oximetry and fNIRS to be used in the body area networks (BANs).

Here we introduce an ultra-miniaturized (~5 g weight and ~1 [cm]^2 housing) wireless patch for real-time monitoring, processing and transponding of brain signals. It records and decodes the electro-optical brain signals using a small optical sensor patch without implanting electrodes. It includes two LEDs and a driver, silicon avalanche photodiode (SiAPD), photodetector front-end, analog-to-digital converter (ADC), signal processing unit and an ultra-low power RF transceiver, on-chip and wirelessly powered. The low power consumption (less than 5mW) makes this miniature patch a proper candidate to be applied in BAN. The wireless link can afford up to 5 m distances with high data-rate (10 MHz) and low noise. This patch provides also an optional wireless communication with cell-phone. One can control the patch function and also monitor the signals on any ordinary smart cell-phone. In contrast to the available monitoring tools providing vital information only from specific regions of human body, this new plug-and play device can monitor and delivers signals from different locations of the whole human body. It can be placed as a brain-computer interface (BCI) in patients with spinal cord injuries to make them possible to control external devices, such as a computer cursor or a prosthetic limb, assistive devices, etc. with their thoughts. The neural activity picked up by the BCI will be translated using on-chip processing unit, allowing the patient to learn to control computer interfaces (cursors, monitor,…) and assistive devices such as a prosthetic hand or a wheelchair.

The prototype of the photo-transceiver is implemented and the work is ongoing on wireless control and transmission implementation and its clinical demonstration and assessment.

8812-27, Session 3

Nano-cone optical fiber array sensors for miRNA profiling

Yunshan Wang, Hsueh-Chia Chang, Satyajyoti Senapati, Univ. of Notre Dame (United States); Paul R. Stoddart, Swinburne Univ. of Technology (Australia); Scott S. Howard, Univ. of Notre Dame (United States)

Up/down regulation of microRNA panels has been correlated to cardiovascular diseases and cancer. Frequent miRNA profiling at home can hence allow early cancer diagnosis and close chronic disease monitoring, thus reducing both mortality rate and healthcare cost. However, lifetime of miRNAs is less than 1 hour without preservation and their concentrations range from pM to mM. Despite rapid progress in the last decade, modern nucleic acid analysis methods still do not allow personalized miRNA profiling. Real-time PCR and DNA micro-array both require elaborate miRNA preservation steps –and expensive equipment.

We report a novel and low-cost optical fiber sensing platform, which has the potential to profile a panel of miRNA with simple LED light sources and detectors. The individual tips of an optical imaging fiber bundle (mm in diameter with 7000 fiber cores) were etched into cones with 10 nm radius of curvature and coated with Au. FRET (Forster Resonant Energy Transfer) hairpin oligo probes, with the loop complementary to a specific miRNA that can release the hairpin, were functionalized onto the conic tips. Exciting light in the optical fiber waveguide is optimally coupled to surface plasmonics on the gold surface, which then converges to the conic tips with two orders of magnitude enhancement in intensity. Unlike nanoparticle plasmonics, tip plasmonics can be excited over a large band width and hence the plasmonic enhanced fluorescence signal of the FRET reporter is also focused towards the tip--- and is further enhanced with the periodic resonant grid of the fiber array which gives rise to pronounced standing wave interference patterns. Multiplexing is realized by functionalizing different probes onto one fiber bundle using a photoactivation process. The net result is a plasmonic sensor for miRNA profiling with a dynamic range from one to one thousand miRNA molecules per tip (up to one million over 1000 tips) with more than 5 miRNA targets per fiber bundle.

8812-29, Session 3

Nanoplasmonics approaches to biosensing *(Invited Paper)*

Reuven Gordon, Univ. of Victoria (Canada)

This talk will overview our recent advances towards ultrasensitive nanohole array SPR, directivity enhanced Raman scattering (DERS) for reliable single molecule level detection, and optical manipulation of single proteins. Applications to immunoassays and the early detection of cancers will be presented.

8812-30, Session 3

Focused cylindrical vector beam assisted microscopic phase-sensitive surface plasmon resonance biosensor

Chonglei Zhang, Rong Wang, Xiaocong Yuan, Nankai Univ. (China)

We designed and proposed a microscopic configuration of wide-dynamic-range phase-sensitive surface Plasmon resonance biosensor based on differential interferometry between focused radially polarized and azimuthally polarized cylindrical vector beams recently. This system not only with a sensitivity of 7.385E-7refractive index unit (RIU)/0.1,but also verified that the dynamic range of this system could be as large as 0.35 RIU. Due to the system is based on the microscopic configuration, could be used to imaging by scanning, the resolution is about 200nm, less than diffraction limit because of the tight-focus characteristic of cylindrical vector beam. We use the system to detect the cytoskeletal, antigen-antibody reaction and so on.

8812-31, Session 3

Hybrid waveguide based long range surface plasmon biosensor

Youqiao Ma, Dublin Institute of Technology (Ireland)

In this paper, an integrated biosensor based on a hybrid coupler consisting of a dielectric waveguide and a long range surface plasmon polaritons (LRSPPs) waveguide is proposed. The influence of the structural parameters of the biosensor is investigated using a finite element method (FEM). By appropriately selecting the waveguide parameters, the propagation constants between LRSPPs and waveguide (WG) modes can be matched, along with the light coupling between WG and LRSPPs modes, which in turn allows the sensitivity to be optimized. The resonant coupling wavelength between WG and LRSPPs modes is very sensitive to surrounding refractive index changes in the vicinity of the metal surface, with an estimated sensitivity of 4180 nm/RIU (refractive index unit). This is marginally higher than the value of 3750 nm/RIU in the same RI range from 1.33 to 1.34 reported in reference [1] for optical biosensing applications. However compared to [1] our proposed structure has the advantage that it is inherently easier to introduce an analyte into our structure.

8812-11, Session PWed

Design and fabrication of silicon-based optofluidic waveguide platforms *(Invited Paper)*

Aaron R. Hawkins, Brigham Young Univ. (United States)

Using silicon-based microfabrication and materials we have developed a photonic platform capable of single bioparticle analysis. This platform combines liquid and hollow core waveguides on the micron-scale (5x12 μm) to isolate femtoliter sized sample volumes. Fluorescence excitation and emission signals in the visible range are directed into and out of the sample volume at orthogonal angles to maximize signal-to-noise. This paper reveals the development path of these structures over several device generations including innovations in material, geometries, and fabrication techniques to increase detection sensitivity.

8812-33, Session PWed

Encapsulating gold nanoparticles in silica hollow nanospheres for in vitro and in vivo dark field imaging

Longfei Tan, Dong Chen, Fangqiong Tang, Technical Institute of Physics and Chemistry (China)

Nanostructures with interstitial hollow space and mesoporous shell have low density, high specific area and permeable porous shell for the penetrating of guest species, which are ideal for drug carriers.[1] Due to their biocompatibility, low toxicity, high chemical and mechanical stabilities, silica hollow nanospheres have show great potential in drug delivery application[2]. Recently, rattle-type nanostructures, a kind of hollow nanostructures with metal core, were attracted more attention because of their potential to integrate optical, magnetic and electronic properties in one. Gold nanoparticles is a promising nanomaterials used in the field of biological imaging, cancer diagnosis and treatment.[3,4] Encapsulating gold nanoparticles in silica hollow nanospheres will offer fascinating tuned surface plasmon resonance (SPR) properties, which make them ideal materials for drug delivery and bio-imaging.[5] In this work, we synthesized a novel nanostructure in which 13 nm gold nanoparticles encapsulated in the cavity of the silica hollow nanospheres (Au@SiO2). The presence of silica shell protects gold cores in complex biological environments, ensures their dark field imaging characteristics both in vitro and in vivo. These Au@SiO2 nanospheres also exhibit higher drug loading capacity and desired release rates due to their hollow cavity and mesoporous shell. Cytotoxicity experiments show good biocompatibility of Au@SiO2 in vitro. Acute toxicity in mice showed that the maximum tolerated dose of Au@SiO2 greater than 200 mg/kg, significantly improve the biocompatibility of gold nanoparticles. Encapsulating gold Nanoparticles in silica hollow nanospheres is expected to have great potential in medical imaging and therapy application.

Molecular detection for multiple cancer biomarkers using multi-tasking localized surface plasmon resonance sensor

Yoochan Hong, Yonsei Univ. (Korea, Republic of); Jin-Suck Suh, Yong-Min Huh, Yonsei Univ. College of Medicine (Korea, Republic of); Dae-Sung Yoon, Yonsei Univ. (Korea, Republic of); Jaemoon Yang, Yonsei Univ. College of Medicine (Korea, Republic of)

The noble metal nanoparticles, such as gold or silver, are used as sensing substrate because of the collective oscillations of their conduction band electrons. This phenomenon is called as localized surface plasmon resonance (LSPR). The basic LSPR effect has been long understood, the field has experienced significant growth recent 10 years due to advances in the nanotechnology. More recently, LSPR-based nanobiosensors were developed as tools for highly sensitive, label-free, and flexible sensing techniques for the detection of biomolecular interaction. Herein, we describe that development of LSPR nanobiosensor, which can detect adsorption of protein onto sensor substrate and cleavage of enzyme specific targetable peptide from the sensor substrate simultaneously. When the protein extracted from cancer cells adsorbed onto sensing substrate, the LSPR signal was red-shifted, and in the case of the enzyme, as enzyme specific targetable peptide was cleaved, we observed that LSPR signal was blue-shifted. First of all, we prepared sensing substrate that composed of different nanoparticles which have significantly distinct plasmonic band gaps. Subsequently, for specific detection of biomarker, CD44, a receptor expressed on cancer cell surface, we used specific targeting antibody, and we also conjugated for detection of another biomarker, MT1-MMP, the enzyme expressed on invasive cancer cells.

The interactions of the carbon-based nanoparticles with HeLa cell's plasma membrane

Marta Overchuk, Tanya Dumych, Institute of Cell Biology (Ukraine); Svitlana Prylutska, Yuriy Prylutsky, National Taras Shevchenko Univ. of Kyiv (Ukraine); Rostyslav O. Bilyy, Institute of Cell Biology (Ukraine)

The study of carbon-based nanostructures is a highly topical branch of bionanotechnology because of their potential application in biomedicine. Carbon-based nanotubes (CNT) are known for their ability to kill tumor cells causing hyperthermia shock. Fullerens are regarded as valuable nanocarriers for antitumor drug delivery, as they possess strong antioxidant properties. Chemically modified CNT also can be used for drug delivery. The needle-like shape of CNT lets them penetrate the cell's plasma membrane without killing the cell.

In the current work the interactions of pristine C60 fullerens and multi-walled carbon nanotubes filed with (MWCNT-Fe) iron with cell's plasma membrane were studied. The interactions were analyzed in the cell-nanopartice system. It was shown, that both MWCNT-Fe and C60 fullerens tend to form pores, channels or other types of local defects in the plasma membrane, that are wide enough to let the passage of water into the cell. The application of high resolution DIC and fluorescent microscopy demonstrated the externalization of phosphatidylserine (PS) from the inner to outer layer of the cell membrane in small local patches (points of contact), while other parts of plasma membrane being PS-negative. The externalization of PS was visualized with a use of Annexin-V staining, a fluorescent dye, that binds specifically to PS.

8812-36, Session PWed

Azimuthally-invariant Mueller-matrix mapping of biological tissue in differential diagnosis of mechanisms protein molecules networks anisotropy

Volodimir G. Ushenko, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

At present, the biological and medical research using many practical techniques based on the measurement and analysis of the Mueller matrices of the samples. Not all elements of the Mueller matrix are convenient to characterize the sample of biological tissue - generally, 12 of the 16 elements is change when the sample is rotated around the axis sensing. This paper shows that the azimuthally stable, independent of the angle ( ) rotation of the sample, the following are the elements of of Mueller matrix.

Set a maximum sensitivity of higher order statistical moments that characterize Muller - matrix invariants by linear and circular birefringence, the morphological features of the molecular structure of biological tissues protein networks.

Laser polarization fluorescence of optically anisotropic crystals molecular imaging in the differentiation of biological benign and malignant tumors

Alexander V. Dubolazov, Yuriy A. Ushenko, Artem O. Karachevtsev, Artem V. Motrich, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

In the current scientific literature is almost no data on the effects of fluorescence polarization forms in tissues. Therefore, the actual problem is in combining diagnostic capabilities of laser polarimetry and laser fluorescence. In this paper we propose a model of laser polarization of biological tissues fluorescence molecular imaging with the mechanisms of the optically anisotropic absorption, - linear and circular dichroism in protein networks.

Effectiveness of the method azimuthally - invariant Mueller - matrix mapping laser polarization of fluorescence molecular imaging of protein networks in the problem of differentiation of benign and malignant tumors of the uterine wall was demonstrated.

Detection of saccharides with a fluorescent sensing device based on a gold film modified with 4-mercaptophenylboronic acid monolayer

Shu-Jen Chen, Jui-Feng Chang, Nai-Jen Cheng, Jeng-Nan Yih, National Kaohsiung Univ. of Applied Sciences (Taiwan); Kuo-Chi Chiu, Industrial Technology Research Institute (Taiwan)

An extremely sensitive fluorescent sensor based on a phenylboronic acid monolayer was developed for detecting saccharide molecules. The fluorescent sensor was prepared by assembling a monolayer of 4-mercaptophenylboronic acid (4-MPBA) onto a gold-coated compact disk. The change in the fluorescence of the 4-MPBA monolayer was extremely obvious in basic methanolic buffer containing monosaccharides down to the picomolar level. The fluorescence spectra demonstrated that the 4-MPBA monolayer was sensitive to monosaccharides and disaccharides, and the affinity of the monolayer toward saccharides was in the order of glucose > fructose > mannose > galactose > maltose > lactose > sucrose. Additionally, the fluorescence intensity of 4-MPBA monolayer was restorable after cleaning with weak acid, indicating that the reported fluorescent sensor with the detection limit of glucose down to the picomolar level is reusable for sensing saccharides.

Photothermal ablation of metastatic cancer cells using magnetic polyaniline nanocomposite guided by MR imaging

Seungyeon Hwang, Dan Heo, Yoochan Hong, Minhee Ku, Eugene Lee, Seungjoo Haam, Jin-Suck Suh, Jaemoon Yang, Yonsei Univ. (Korea, Republic of)

For effective treatment of invasive cancer, photothermal therapy based on nanoparticles has been reported as representative method. In recent, polyaniline has been used as a photothermal agent in our research group, because it can absorb the light of near-infrared (NIR) region, then generates a substantial amount of heat energy that can be used for cancer cell ablation. To diagnose cancer cell, on the other hand, magnetic nanoparticles have used in magnetic resonance (MR) imaging agents. From these facts, we synthesized a magnetic polyaniline nanocomposite (MPNC) for photothermal therapy guided by MR imaging. MPNC was synthesized using iron-acetylacetonate and polyaniline by thermal-decomposition method without any additive ligands. To detect membrane type 1 metalloproteinase (MT1-MMP), subsequently, the surface of MPNC was PEGylated and modified with MT1-MMP-specific targetable peptide. To confirm fundamental characteristics of MPNC, colloidal size using dynamic light scattering, NIR absorption using spectrometer, morphology using transmission electron microscope, and magnetic property using vibrating sample magnetometer were evaluated. To estimate MR imaging potential and photothermal ablation capability of MPNC for target cancer cell, MPNC was intravenously injected into the tumor-bearing mice. The invasive cancer cells, treated with MT1-MMP-specific MPNC, were detected by MRI and broken down and damaged after irradiation of NIR light.

Metalorganic magnetic nanoparticles as a targeted drug delivery system of Gd3+ for neutron-capture therapy against cancer

Olga V. Kondrashina, Voronezh State Univ. (Russian Federation)

The challenge in successful neutron-capture therapy against cancer depends has been the ability keep proper

concentration of Gd in tumor tissues during the irradiation. We developed a new method of producing nanoparticles based on cholesteric liquid crystal DNA-dispersion complexed with Gd in very high local concentration of gadolinium ions (up to 400 mg/ml inside particles). Their magnetic properties lead to active diffusion of Gd in tissue with the help of a strong magnetic field and keep those nanoparticles there for the desired amount of time. Due to the high local concentration of gadolinium the impact of irradiation of the neutron-capture therapy occurs very locally (radius of influence is around 100 microns from particle) but highly effectively and that preserves the healthy tissues from unwilling damage. One more potential way was found to active targeted delivery of gadolinium ions in tumors. That is immobilization of nanoparticles by adsorption on macrophages. This way may help irradiate malignant cells within ascite tumors. The composition can be stored in the laboratory for 200 days without any change in physical properties. These nanoparticles have a great affinity to gadolinium ions so have low toxic effect on living cells without irradiation.

Towards an on-chip integrated NIRS photodetector front-end for real-time brain imaging

Ehsan Kamrani, Polytechnique Montréal (Canada); Frédéric Lesage, Mohamad Sawan, Ecole Polytechnique de Montréal (Canada)

Near infrared spectroreflectometry (NIRS) is a noninvasive, safe, minimally intrusive, and high temporal resolution technique with potential to be used as a portable system for real-time and long-term brain imaging, intensive care units (ICUs) and brain-computer interface (BCI) applications. This novel neuroimaging technique can non-invasively monitor the rapid changes in both fast neuronal (with ms temporal-resolution) and slow hemodynamic signals (regional cerebral blood volume and hemoglobin oxygenation). So it has potential to be applied for monitoring, evaluation and treatment of neurological diseases such as stroke and epilepsy.

However, to date the realization of this potential has not materialized with current commercial devices due to high energy consumption and size issues.

We propose in this research project a miniaturized, reconfigurable and low-noise NIRS Photodetector front-end towards an ultra-lightweight, ultra low-power wireless multichannel NIRS system for long-term monitoring applications. It includes low-voltage, low-noise, highlysensitive, and high-gain silicon avalanche photodiodes (SiAPDs), integrated with front-end circuitries for Linear and Geiger modes of operation. This fully integrated system is implemented on-chip using submicron complementary metal-oxide-semiconductor (CMOS) technology to achieve a smart-imaging sensor for several applications. Proposed SiAPDs exhibit high-avalanche gain, low-breakdown voltage and high-photon detection efficiency accompanying with low-dark count rates. The linear-mode circuitry includes three new Transimpedance amplifier (TIA) frontends with high-gain bandwidth product (GBW), low-power consumption, and ultra-low noise characteristics to be applied in continuous-wave NIRS. The TIA front-end has been designed using distributed-gain concept combined with resistive-feedback and common-gate topology. In order to operate the SiAPDs in Geiger-mode for photon-counting application, an ultra-fast Quench-Reset front-end is also implemented on-chip using standard CMOS technology. It introduces an integrated hold-off time control and on-chip counter in a small area with low-power consumption and low-noise characteristics.

Low-power, high-speed, miniaturized, and controllable single-photon counting circuit dedicated to biomedical imaging applications

Ehsan Kamrani, Frédéric Lesage, Mohamad Sawan, Ecole Polytechnique de Montréal (Canada)

Single-photon detectors support a broad range of applications such as light detection and ranging (LIDAR), telecommunication systems, quantum cryptography and quantum information processing, molecular imaging and brain imaging using time correlated single-photon counting (TCSPC) and near infra-red spectroscopy (NIRS). Single-photon avalanche photodiodes (SPAD) operating at Geiger-mode, has shown the greatest potential for high-sensitivity and ultra-low intensity light detection applications due to their internal gain characteristics. An infinite selfsustaining avalanche current flows through SPAD with impact of a single photon into its surface which can be counted as a pulse at the SPAD output. In order to count the number of consequently incident photons, an external circuit called Quench-Reset is required to quench the avalanche current and then reset the SPAD bias to its initial condition after a hold-off time.

Commercially available Quench-Reset circuits suffer from high-power consumption, large-size, relatively low-speed, and high-noise which impeding developing a portable, miniaturized and low-power photon-counting system for different applications.

We have proposed and designed a miniaturized photon-counting system including a highspeed and low-power photon-counting circuit integrated with silicon CMOS avalanche photodiode (SiAPD). Integrating the SiAPD and photon-counting circuitry has reduced the afterpulsing and increased the sensitivity accompanying with significantly lower-power consumption.

Minimized controllable dead-time of the proposed system reduces the excess noise and increases the detection speed. The controllable hold-off time implemented in this circuit reduces the afterpulses and makes the system adaptable with different applications. This circuit is implemented using sub-micron standard CMOS technology and offers low-power consumption, small/controllable hold-off and quench-rest times.

Plasmonic nanoantennas for monitoring single cancer cells attachment using LSPR and SERS

Alejandro Portela, Horacio Cabral, Kazunori Kataoka, Hitoshi Tabata, The Univ. of Tokyo (Japan)

This work present a biosensing method using an array of optical plasmonic nanoantennas for the analysis of cell-surface interaction through localized surface plasmon resonance (LSPR) and surface enhanced Raman spectroscopy. Calculations using different antenna length and gap size were conducted showing the tunability of the resonance peak position and the possibility to detect the changes in the refractive index produced by a single cell. The different sets of antennas with length from 40 to 100nm, gap size of 20 to 40nm were characterized by scanning electron microscopy (SEM) and their optical response registered for an array of 10 by 10 antennas separated by 1?m and for each of them individually. A bioconjugation of the gold nanoantennas was achieved using an RGD peptide that specifically bind cells containing ?v?3 receptors which are expressed on several cancer cells. The surface functionalization and cell trapping ability was verified by means of fluorescent confocal microscopy, using first a different pair of dyes for the RGD and the cell respectively. A second experiment without fluorescent dyes was conducted registering the shift on Rayleigh scattering on the arrays of nanoantennas where the cells were found. The shift on the resonance peak position was not detected in all the arrays and it showed a highest shift of 5 nm. For the single antennas analysis the shift registered reached 10 nm that is in good agreement with the numerical simulations. SERS analysis allowed verifies the binding events but also monitoring the cell attachment to the surface.

8813-1, Session 1

Theory of spin Seebeck effect in a variety of magnetic systems *(Invited Paper)*

Sadamichi Maekawa, Japan Atomic Energy Agency (Japan)

When metals and semiconductors are placed in a temperature gradient, the electric voltage is generated. This mechanism to convert heat into electricity, the so-called Seebeck effect, has attracted much attention as the mechanism for utilizing wasted heat energy [1].

Ferromagnetic insulators are good conductors of spin current, i.e., the flow of electron spins [2]. When they are placed in a temperature gradient, generated are spin current and the spin voltage [3], i.e., spin accumulation. Once the spin voltage is converted into the electric voltage by the inverse spin Hall effect in attached metal films, the electric voltage is obtained from heat energy [4-5]. This is called the spin Seebeck effect (SSE).

Here, we present the basic concept of SSE [6] and discuss about SSE in a variety of magnetic systems.

Spin Seebeck effect: fundamentals and applications *(Invited Paper)*

Ken-ichi Uchida, Tohoku Univ. (Japan) and Japan Science and Technology Agency (Japan)

The spin Seebeck effect (SSE) refers to the generation of a spin voltage as a result of a temperature gradient in magnetic materials [1-5]. The SSE is of crucial importance in spintronics and spin caloritronics since it enables simple and versatile generation of a spin current from heat.

The simplest and most straightforward setup of the SSE is the longitudinal configuration [3], in which a spin current flowing parallel to a temperature gradient is measured via the inverse spin Hall effect (ISHE). The longitudinal SSE device consists of a ferromagnetic insulator (FI) covered with a paramagnetic metal (PM) film. When a temperature gradient is applied perpendicular to the FI/PM interface, an ISHE-induced voltage is generated in the PM layer.

In this talk, we report the observation of the longitudinal SSE in various FI/PM systems and provide evidence that the SSE is free from thermoelectric artifacts [5], i.e., the anomalous Nernst effect caused by extrinsic magnetic proximity [6]. Then, we discuss the SSE from an application point of view [4].

Diffusion thermopower of (Ga,Mn)As/GaAs tunnel junctions *(Invited Paper)*

Charles Gould, Julius-Maximilians-Univ. Würzburg (Germany)

The issues of power consumption and heat dissipation are at the forefront of present day information technology concerns. As such, a fundamental understanding of the relationship between electrical and thermal effects is crucial to device design and operation.

One needs only consider the injection of spin polarized current into a non-magnetic semiconductor to appreciate the potential importance of these thermoelectric contributions to device behavior. Such spin injection is often detected using a four contact non-local technique, passing current between two adjacent contacts, and measuring the chemical potential difference resulting from spin accumulation at two other contacts situated at a distance from the current path. Such a measurement should yield a voltage signal which is equal but of opposite sign depending on the relative orientations of the contacts. Experimentally, this is rarely the case and the results typically include a voltage offset, which is often simply discarded as an uninteresting constant background.

This background voltage is a thermoelectric contribution. In most cases it is isotropic and adds a constant offset. As I will show in this talk, when the magnetic materials involved are crystalline with strong spin-orbit coupling, the linking of the magnetic properties to the density of states yields a spin caloritronic effect; Tunneling Anisotropic MagnetoTermopower. The thermal contribution is then far from isotropic, having a rich magnetic response. This observation may not only have interesting implications for device applications, but can also lead to misinterpretations if one fails to take it into consideration.

8813-4, Session 1

Heat transport by magnons *(Invited Paper)*

Burkard Hillebrands, Technische Univ. Kaiserslautern (Germany)

Spintronics is concerned with the development of devices which exceed the performance and energy efficiency of charge-based electronics by exploiting the electron's spin degree of freedom. Spin angular momentum, which is the information carrier in spintronics, can be transferred not only by the flow of electrons, but also by magnons: the quanta of spin waves (collective excitations of the spin lattice of a magnetic material). Magnon-based data operations have a great advantage since they are not based on the motion of any real particles like electrons in electronics - magnons are subject to dissipation to a much lesser degree than electrons. Magnon spintronics can be implemented in an electric-isolator environment (yttrium iron garnet, YIG) fully avoiding Ohmic losses. I will concentrate on the main constructing blocks of smart magnon spintronics devices: converters between the spin and charge of electrons and magnons, magnon conduits, and physical phenomena allowing information processing by magnons. The most promising convertors for the magnon spintronics are based on the spin pumping effect (which transforms spin waves into pure spin currents) and the inverse spin Hall effect (which converts spin currents into charge currents). Our study is concentrated on magnetic insulator YIG-nonmagnetic Pt structures. Magnon conduits will be discussed on the example of meso-sized YIG-based and micro-sized Permalloy-based magnonic crystals (MCs).

8813-108, Session 1

The role of phonons in the Spin Seebeck Effect *(Invited Paper)*

Joseph P. Heremans, The Ohio State Univ. (United States)

Our current understanding of the spin-Seebeck effect requires magnons in the ferromagnet to be out of thermal equilibrium, which can be done by either phonon-magnon drag or by magnon thermal conductivity itself. Our earlier experimental work on the transverse spin-Seebeck effect in GaMnAs indicated the dependence of the amplitude of the Spin Seebeck signal on the phonon mean free path, and also on phonon-electron drag. This was an indication for the presence of phonon-magnon drag. Subsequently we reported a strong spin-Seebeck-like signal in InSb in the ultraquantum regime, where the free electrons are spin polarized and where there are no magnons: here phonon-electron drag is very important. To create contrast, we will present not only these data, but also preliminary data on the spin-Seebeck effect in amorphous ferromagnets, Metglass, in which the phonons are much more localized than in the large single-crystals studied previously.

8813-5, Session 2

Stabilization and dynamics of skyrmions in nanostructures for information applications *(Invited Paper)*

Joao Sampaio, Vincent Cros, Unité Mixte de Physique CNRS/Thales (France); Stanislas Rohart, Andre Thiaville, Univ. Paris-Sud 11 (France); Albert Fert, Unité Mixte de Physique CNRS/Thales (France)

The magnetic skyrmion is a topologically stable magnetic configuration that shows many interesting particle-like behaviors, such as strong localization, attractive and repulsive interactions, and self-organization into crystalline lattices. So far observed in non-centrosymmetric bulk crystals, skyrmion lattices were recently observed in magnetic thin films, stabilized by the interfacial Dzyaloshinskii–Moriya interaction (DMI) induced by a substrate with strong spin-orbit coupling [X. Yu, PNAS, 109 8856, 2012]. Its small size, and the recently shown propagation of skyrmion lattices using small current densities [A.N. Bogdanov et al., Phys. Rev. Lett. 87 037203, 2001; S. Heinze et al., Nat. Phys. 7 713, 2011], makes it a promising basis for information-processing devices. Any practical application, however, will likely require the manipulation of isolated skyrmions in magnetic thin film nanometric structures, still to be demonstrated. We will present a comprehensive micromagnetic simulation study of isolated skyrmions in nanostructures of typical structure Pt/Co/AlOx with perpendicular magnetic anisotropy. We show that DMI stabilizes isolated hedgehog-like skyrmions in nanostructures for a large range of the DMI strength (of the order of the experimentally measured values). Furthermore, we show that several isolated skyrmions can be reliably moved along nanostripes by low current densities without changing their relative positions, even with important pinning defects, which enables encoding and transfer of information. To conclude, we have demonstrated that isolated magnetic skyrmions can be easily stabilized in magnetic 2D nanostructures as a balance between exchange, DM and magnetostatic interactions, and are promising structures for various future skyrmion-based devices.

Atomic-scale magnetic skyrmion lattices in ultra-thin films *(Invited Paper)*

Bertrand Dupe, Markus Hoffmann, Stefan Heinze, Christian-Albrechts-Univ. zu Kiel (Germany)

Skyrmions are topologically protected field configurations with particle-like properties that play an important role in various fields of science. They have been predicted to exist also in bulk magnets and in recent experiments it was shown that they can be induced by a magnetic field. A key ingredient for their occurrence is the Dzyaloshinskii-Moriya interaction (DMI) which was found to be strong also for magnetic nanostructures on substrates with large spin-orbit coupling [1]. In these systems the DMI stabilizes spin-spirals with a unique rotational sense propagating along one direction of the surface as observed for ultrathin films [1-3] and atomic chains [4]. Here, we go a step beyond and present an atomic-scale skyrmion lattice as the magnetic ground state of a hexagonal Fe monolayer on Ir(111) [5]. We develop a spin-model based on density functional theory that explains the interplay of Heisenberg exchange, DMI and the four-spin exchange as the microscopic origin of this intriguing magnetic state. Experiments using spin-polarized scanning tunneling microscopy confirm the skyrmion lattice which is incommensurate with the underlying atomic lattice. By growing atomic overlayers on Fe/Ir(111), e.g. Pd, Rh, or Ir, the magnetic properties of the system can be tuned which allows the observation and manipulation of individual skyrmions [6]. This work is a collaboration with G. Bihlmayer, S. Blügel, K. von Bergmann, M. Menzel, N. Romming, Ch. Hanneken, A. Kubetzka, J. Brede, and R. Wiesendanger.

8813-8, Session 3

Entanglements in spin Seebeck effect *(Invited Paper)*

Chia-Ling Chien, Johns Hopkins Univ. (United States)

In spin Seebeck effect (SSE) [1], a metal with strong spin-orbit coupling, such as Pt, detects the pure spin current generated by a temperature gradient. SSE in transverse geometry with in-plane (ΔxT) and longitudinal geometry with out-of-plane (ΔzT) temperature gradient using Pt in contact with a ferromagnet (metal, semiconductor, or insulator) has been reported.

However, in the transverse geometry, in addition to the intended ΔxT, there exists also ΔzT in a thin magnetic film on substrate, which gives rise to the anomalous Nernst effect (ANE).

The voltages of SSE due to ΔxT and ANE due to ΔzT are additive and entangled [2]. In the longitudinal geometry with exclusive ΔzT, one encounters magnetic proximity effects in Pt that also contributes [3]. These complications prevent unequivocal establishment of SSE.

We have recently observed intrinsic SSE using longitudinal geometry in Au/YIG without magnetic proximity effects, but the signal in Au/YIG is 50 times smaller than that in Pt/YIG [4].

8813-9, Session 3

Thermal creation of a spin current by Seebeck spin tunneling *(Invited Paper)*

Ron Jansen, National Institute of Advanced Industrial Science and Technology (Japan); J.C. Le Breton, Netherlands Foundation for Fundamental Research on Matter (FOM) (Netherlands); A.M. Deac, Helmholtz-Zentrum Dresden-Rossendorf (Germany); H. Saito, S. Yuasa, National Institute of Advanced Industrial Science and Technology (Japan)

The combination of thermoelectrics and spintronics offers unique possibilities. On the one hand, it provides a new, spin-based approach to thermoelectric power generation and cooling. On the other hand, it provides a thermal route to create and control pure spin currents without charge flow in spintronic devices that make functional use of heat. Here we describe Seebeck spin tunneling — a thermally-driven spin flow, of purely interfacial nature — generated in a tunnel contact between electrodes of different temperatures. Seebeck spin tunneling arises from the spin-dependent Seebeck coefficient of a tunnel junction and is thus the thermoelectric analog of spin-polarized tunneling.

By exploiting this in ferromagnet–oxide–silicon tunnel junctions, we observe a thermal flow of spin-angular momentum from the ferromagnet to the silicon without a charge tunnel current. This thermal spin current can be used by itself, or in combination with electrical spin injection. We describe the role of the energy-dependent tunnel spin polarization and the impedance mismatch, and compare the efficiency of electrical and thermal creation of spin. The results highlight the engineering of heat transport in spintronic devices and enable the (re-)use of heat.

8813-10, Session 3

Planar Nernst effects and the search for thermal spin currents with in-plane thermal gradients *(Invited Paper)*

Barry L. Zink, Univ. of Denver (United States)

The generation of pure spin currents is an important requirement for future spintronic circuits. Recently some groups have reported that such a spin current can be produced simply by applying a thermal gradient to a ferromagnetic material. This effect, called the spin Seebeck effect (SSE), has generated tremendous interest

in the interaction of heat, charge and spin in ferromagnetic systems. In this talk we will present our own recent measurements of thermoelectric and thermomagnetic effects in thin film metallic ferromagnets. These are enabled by a micromachined thermal isolation platform that removes potentially confounding effects introduced by the presence of a highly thermally conductive bulk substrate. We are able to measure the thermopower (traditional Seebeck effect), thermal and electrical conductivity, and Peltier effects in addition to a variety of less widely known thermoelectric and thermomagnetic effects. One of the most interesting is the planar Nernst effect (PNE), a transverse thermopower caused by spin-dependent scattering. This PNE should therefore be present in any measurement where a thermal gradient is aligned in the plane of a magnetic metal film. Furthermore, our “zero substrate” experiment shows no signal with the symmetry of the spin Seebeck effect. This suggests that the presence of the bulk substrate is required to produce such a signal, and calls the role of a pure spin current in the effect into question. This work was performed in collaboration with A. D. Avery, D. Wesenberg, J. Underwood, and M. R. Pufall, and supported by the NSF CAREER award (DMR-0847796)

8813-11, Session 3

Spin-dependent transport of energy and heat in ferromagnetic insulators *(Invited Paper)*

Jean-Eric Wegrowe, Henri-Jean Drouhin, Ecole Polytechnique (France)

A phenomenological derivation of the transport equations for ferromagnetic energy and associated heat in ferromagnetic devices is proposed. A reduction method applied to the ferromagnetic degrees of freedom allows a two spin-channel model to be defined. The typical spintronics and spin caloritronics approach can then be generalized to ferromagnetic insulators. The coupled transport equations for non-uniform ferromagnetic excitations and heat are derived. The effect of thermal spin-injection from an insulating ferromagnet into an initially non-ferromagnetic electrode is described and discussed in terms of anomalous or planar Seebeck and Nernst effects.

8813-12, Session 4

Unconventional magnetic ordering in quantum dots *(Invited Paper)*

Igor Zutic, James Pientka, Rafal Oszwaldowski, Karel Vyborny, Jeongsu Lee, Jong Han, Univ. at Buffalo (United States); Peter Stano, Institute of Experimental Physics (Slovakia); Andre Petukhov, South Dakota School of Mines and Technology (United States)

The formation of a magnetic polaron (MP) can be viewed as a cloud of localized magnetic ion spins, aligned through an exchange interaction with a confined carrier spin and is typically considered a low-temperature phenomenon in semiconductors. However, recent experimental advances in colloidal nanocrystals and epitaxially grown quantum dots show robust signatures of MPs that can persist up to room temperature and lead to effective internal fields up to 100 tesla [1]. These highly tunable semiconductor nanostructures, allowing versatile control of the number of carriers, their spin, and the effects of quantum confinement, offer intriguing possibilities for magnetism. We suggest how magnetic ordering can be controlled even at a fixed number of carriers [2], enhanced by heating [3], and present in closed-shell systems [4]. We expect that doping quantum dots with magnetic impurities may open unexplored opportunities to study the nanoscale correlations [5]. Through Mn-carrier exchange interaction, molecular-like correlations can be enhanced, imprinted on Mn spins, and thus observed. We propose experiments to verify our predictions.

Optical control of the spin of individual magnetic atoms *(Invited Paper)*

Lucien Besombes, Institut NÉEL (France)

With semiconductor quantum dots (QDs) doped with magnetic atoms, the probing of a single atomic spin in a solid state environment become possible using optical techniques. The state of a photon emitted or absorbed by a II-VI semiconductor QD containing a Mn atom is directly related to the spin state of the Mn (S=5/2). We will demonstrate that a

Mn atom or a pair of Mn atoms embedded in a QD may act as optically addressable spin based memories. We will in particular analyse how an optically induced modification of the Mn fine structure affects its spin dynamics.

Single spins in semiconductor quantum dot microcavities *(Invited Paper)*

Sven Höfling, Julius-Maximilians-Univ. Würzburg (Germany); Kristiaan De Greve, Peter L. McMahon, Leo Yu, David L. Press, Jason S. Pelc, Chandra M. Natarajan, Na Young Kim, Thaddeus Ladd, Eisuke Abe, Stanford Univ. (United States); Sebastian Maier, Dirk Bisping, Julius-Maximilians-Univ. Würzburg (Germany); Christian Schneider, Stanford Univ. (United States); Martin Kamp, Julius-Maximilians-Univ. Würzburg (Germany); Robert H. Hadfield, Heriot-Watt Univ. (United Kingdom); Alfred Forchel, Julius-Maximilians-Univ. Würzburg (Germany); Yoshihisa Yamamoto, Stanford Univ. (United States)

Semiconductor quantum dots can be utilized to capture single electron or hole spins and have therewith promise for various applications in fields like spintronics, spin based quantum information processing and chiral photonics. We integrate InGaAs quantum dots into semiconductor microcavities to enhance light-matter interaction for ultrafast optical manipulation and read-out. Single electron and single hole spins can be statistically or deterministically loaded into the quantum dots and coherently controlled. By applying spin echo techniques, coherence times of both spin carrier types in the microsecond-range are obtained. Within this time about 10^5 complete single qubit rotations can be performed with ultrafast optical pulses. Utilizing the type system of a single quantum-dot electron spin in a magnetic field and ultrafast non-linear frequency conversion, quantum-dot spin-photon entanglement is observed.

8813-15, Session 4

Disentangling the electron and hole g-factors of InAs/InP quantum dots *(Invited Paper)*

Joost van Bree, Andrei Y. Silov, Technische Univ. Eindhoven (Netherlands); Craig E. Pryor, Michael E. Flatté, The Univ. of Iowa (United States); Paul M. Koenraad, Technische Univ. Eindhoven (Netherlands)

A single spin in a quantum dot provides a model system for the observation and manipulation of an individual quantum system, and has been proposed as a qubit for usage in quantum information technology. The magnetic moment and Zeeman energy splitting of such a single spin are controlled by the g-tensor, whose value in the solid state differs from the bare electron g-factor of ~2 due to strong spin-orbit interaction. Therefore control over the g-tensor provides an effective spin-manipulation method, and a thorough understanding of the nature of the g-tensor is desired.

We will present a detailed magneto-optical study on self-assembled InAs/InP quantum dots. By applying a magnetic field in various directions, we have been able to separate the electron and hole g-factors of a single quantum dot in different spatial directions. We observe a strong size dependence of the g-factor, which can be explained in terms of quenching of the envelope orbital momentum by spatial confinement. This size dependence of the g-factors is confirmed by k.p-calculations. Interestingly, by tuning the height of the quantum dot it is possible to change the sign of either the electron or the hole g-factor or choose it to be close to zero. Moreover, we observe that the g-factor is sensitive to its electrostatic environment. This opens up a route to actively control the spin state: one can flip the spin of a quantum dot having a g-factor close to zero, by applying an electric field across the quantum dot which changes its sign.

8813-16, Session 4

Magnetism of magnetic ion doped semiconductor nanocrystals *(Invited Paper)*

Shou-Jyun Zou, National Chiao Tung University (Taiwan); Shun-Jen Cheng, National Chiao Tung Univ. (Taiwan)

Magnetic ion-doped semiconductor nanocrystals (NCs) have recently drawn a great deal of interest because of the intriguing physical properties and the potential application in spintronics and magneto-electronics. Rich physical phenomena, such as giant Zeeman splitting [1], spontaneous magnetization [2], complex excitonic fine structures [3] and quantum-size induced paramagnetism[4,5], have been observed in self-assembled quantum dots or colloidal nanocrystals doped with magnetic ions, typically Mn2+.

We report on our recent theoretical studies of magnetic CdSe NCs and the comparison with existing experiments. [5-7] The exact diagonalization (ED) technique is emplyed to compute the electronic and magnetic properties of the spherical NCs with controlled number of magnetic ions Mn2+ and electrons. The ED approach, beyond the widely used mean field theory for magnetic semiconductor bulks and thin films, takes fully into account the electron-electron, ferromagnetic (FM) electron-Mn and antiferromagnetic (AFM) Mn-Mn interactions. For more physical analysis, a spin theory based on a constant interaction model is developed for dealing with magnetic semiconductor NCs with arbitrary number of magnetic ions. The numerical results are physically elucidated by formailsms yielded by analysis whenever it is possible.

As main results, ferromagnetic magnetic polarons (MPs) with fully polarized Mn spins are shown to be stably formed in small magnetic NCs due to the strong dot confinements. For large NCs, the magnetic polarons might exhibit various magnetic phases, from ferromagnetism (FM) to anti-ferromagnetism (AF), depending on the spatial distribution of Mn ion impurities. Another remarkable revealed feature is the predicted existence of magnetic anisotropies (MAs) in symmetric magnetic NCs. The physical origins of the MAs are associated with the scatterings of electron carriers to magnetic ions and the resulting quenching of orbital magnetic moments. Experimentally, pronounced paramagnetism of Mn-doped CdSe NCs was observed in the presence of magnetic fields. Surprisingly the paramagnetism lasts over a wide range of magnetic field B up to 6 Tesla, far above the B-range given by Curie's law. The uncommon paramagnetic feature is regarded as a direct signature of anti-ferromagnetic interaction between Mn ions according to our theoretical studies. In summary, our ED studies provide a theoretical description for the electronic and magnetic properties of magnetic ion doped NCs and suggest the controllability of magnetism in the magnetic semiconductor nanostructures.

Generation and manipulation of spin wave by spatially shaped light spot *(Invited Paper)*

Takuya Satoh, The Univ. of Tokyo (Japan)

In a magnetically ordered material, the interaction of spins leads to a propagating wave of spin precessional motion. This 'spin wave' shows promise as a new kind of information carrier even in an insulator. This

phenomenon has attracted much attention in the field of 'magnonics,' that is, using the spin wave that is generated, controlled, and detected as an information carrier. One critical challenge, however, is to establish a suitable control technology for the propagation of spin waves. Here we propose a promising technique that uses a spatially shaped light pulse with circular polarization. Focusing this light pulse on a magnet generates spin waves within the light spot via the inverse Faraday effect. Moreover, the wave number distribution of the spin waves is determined by the spatial intensity distribution of the light spot. We demonstrated the principle of this technique experimentally and numerically. We successfully controlled the direction of the energy flow by shaping the light spot into an ellipse with its major axis parallel or perpendicular to the magnetic field. Our findings will open up the possibility of fast and arbitrary synthesis of spin wave patterns by using a more sophisticated light shaping technique, such as use of a computer-generated hologram.

8813-18, Session 5

Thermal effects in the planar approximation for spin torque dynamics *(Invited Paper)*

Yaroslaw Bazaliy, Univ. of South Carolina (United States)

Thermal effects play an important role in the current-induced magnetization dynamics experiments performed at room temperature. Temperature fluctuations can be described by a two-dimensional diffusion equation for the magnetization direction. It is also known that a deterministic description of spin torque devices with strong easy plane magnet can be reduced to a simplified one-dimensional effective equation that only takes into account small deviations of magnetization from the easy plane. Here we study thermal effects in such strong easy plane devices and develop a one-dimensional probabilistic description of their behavior.

8813-19, Session 6

Topological insulators from the view point of chemistry *(Invited Paper)*

Claudia Felser, Max-Planck-Institut für Chemische Physik Fester Stoffe (Germany)

Topological insulators are a hot topic in condensed matter physics. The excitement in the physics community is comparable with the excitement when a new superconductor is discovered. Many Heusler compounds with C1b structure are ternary semiconductors that are structurally and electronically related to the binary semiconductors. The diversity of Heusler materials opens wide possibilities for tuning the bandgap and setting the desired band inversion by choosing compounds with appropriate hybridization strength (by the lattice parameter) and magnitude of spin-orbit coupling (SOC, by the atomic charge). Based on first-principle calculations we demonstrate that around 50 Heusler compounds show band inversion similar to that of HgTe [1]. The topological state in these zero-gap semiconductors can be created by applying strain or by designing an appropriate quantum well structure, similar to the case of HgTe. Many of these ternary zero-gap semiconductors (LnAuPb, LnPdBi, LnPtSb and LnPtBi) contain the rare-earth element Ln, which can realize additional properties ranging from superconductivity (for example LaPtBi) to magnetism (for example GdPtBi) and heavy fermion behaviour (for example YbPtBi). These properties can open new research directions in realizing the quantized anomalous Hall effect and topological superconductors. C1b Heusler compounds have been grown as single crystals and as thin films. The control of the defects, the charge carriers and mobilties will be optimized and quantum well structures will be grown. The combination of a piezoelectric Heusler compounds and compounds at the borderline between trivial and topological insulators offers the possibility of a switchable device. It is also possible to design new topological insulators with strong correlations. In AmN and PuTe a band gap is opened by correlation effects. In a family of semiconductors with the simple NaCl structure band gaps up to 0.4 eV were found [2]. This is not so surprising since the SOC should be large in Actinides. Heusler compounds are similar to a stuffed diamond, correspondingly, it should be possible to find the "high Z"' equivalent of graphene in a graphite-like structure or in other related structure types with 18 valence electrons and with inverted bands [3]. Indeed the ternary compounds, such as LiAuSe and KHgSb with a honeycomb structure of their Au-Se and Hg-Sb layers feature band inversion very similar to HgTe which is a strong precondition for existence of the topological surface states [4,5]. LiAuSe is a strong TI, whereas KHgSb a weak TI. We will discuss the necessary and sufficient conditions for new TI materials, based in symmetry and bonding arguments [3].

Magnetospectroscopy of HgTe-based topological insulators *(Invited Paper)*

Frédéric Teppe, Univ. Montpellier 2 (France); Wojciech Knap, Univ. Montpellier 2 (France) and Ctr. National de la Recherche Scientifique (France); Maksim Zholudev, Christophe Consejo, Nina Diakonova, Dominique Coquillat, Dmitro B. But, Univ. Montpellier 2 (France)

Recently, a new class of topological insulators was experimentally demonstrated in materials with band inversion due to strong spin-orbit coupling [B. Andrei Bernevig, et al., Science 314, 1757 (2006); M.Z. Hasan and C.L. Kane, Rev. of Modern Physics 82, 3045 (2010)]. Indeed, HgTe/CdxHg1-xTe quantum wells can change to topological insulator phase from conventional insulator phase when the thickness of the quantum well is varied to the critical thickness dc = 6.3 nm. In this work, we study a set of four samples of different quantum well width by magnetospectroscopy from below to above the critical thickness dc. In quantizing magnetic fields up to 16 T, both intraband and interband transitions have been observed. For the widest QW we confirm the observation of the crossing of the zero-mode Landau due to the breaking of time-reversal symmetry. In both non-inverted quantum wells close to the critical thickness, we report unambiguously on the square root dependence of the transition energy on the magnetic field, as expected in the single-particle model of massless Dirac fermions.

Ambipolar Rashba effect in the semiconductor compounds BiTeX *(Invited Paper)*

Luca Moreschini, Lawrence Berkeley National Lab. (United States); Alberto Crepaldi, Gabriel Autes, Helmut Berger, Ecole Polytechnique Fédérale de Lausanne (Switzerland); Aaron Bostwick, Eli Rotenberg, Lawrence Berkeley National Lab. (United States); Oleg Yazyez, Marco Grioni, Ecole Polytechnique

Fédérale de Lausanne (Switzerland)

The relativistic spin-orbit interaction can lift the usual electron spin degeneracy only when space inversion symmetry is broken. Such symmetry breaking can be provided either by the non-centrosymmetric structure of the bulk crystal, or at surfaces and interfaces. Both cases have attracted the attention of condensed matter physicists in the last years because of obvious implications for spin-dependent transport. In the former category, the case of the semiconductor BiTeI has very recently been object of special interest. With its polar stacking of atomic layers, it present a similar structure to the class of Bi-based topological insulators, and has been shown to present clear spin-split bands both in the valence and conduction electronic states. We have studied by angle-resolved photoemission (ARPES) the band structure of the BiTeX (X=I, Br, Cl) class of compounds, and we have shown that acting on the surface termination the chemical potential can be controllably placed in either of the bands. Therefore, the BiTeX materials present two key ingredients for spin-based electronics: a large spin-orbit splitting of the transport electrons and ambipolar conduction.

Fine structure of band-edge excitons in PbSe nanocrystals and nanorods *(Invited Paper)*

Joseph G. Tischler, Evan R. Glaser, Edward E. Foos, Diogenes Placencia, Woojun Yoon, Janice E. Boercker, Alexander L. Efros, U.S. Naval Research Lab. (United States)

Lead chalcogenides are unusual semiconductors with a direct gap at the L points of the Brillouin zone. The 4-fold degeneracy of the L points implies 4-fold degeneracy of the 1S ground states of electrons and holes. In nanocrystals (NCs) this degeneracy leads to fine structure in the spectrum of band-edge excitons that are controversial.

The fine structure of these states is a complicated function of the intervalley interaction, the electron-hole exchange interaction, and deviations of the NC shape from spherical symmetry such as in NRs. The high degree of degeneracy of the exciton states in these NCs makes fluorescence line-narrowing experiments inefficient for studying their fine structure and highlights the need for alternative approaches.

Here we study the fine structure of band-edge excitons in PbSe nanocrystals and nanorods using two magneto-optical methods: circularly polarized magneto-photoluminescence and optically detected magnetic resonance. Our data are well described by the standard singlet-triplet model of exciton photoluminescence from non-degenerate electrons and holes. This suggests that intervalley splitting is much larger than electron-hole exchange in PbSe NCs. Our magneto-optical data directly give the electron and hole g-factors as well as the electron-hole exchange interaction. We find that the electron and hole g-factors are both positive, with ge slightly larger than gh. We also find that at low temperature the emission comes from the triplet dark state (phosphorescence), because of the large exchange energy (several tens to hundreds of meV). Finally, we show that the exchange energy is inversely proportional to the NC volume.

8813-23, Session 7

A new twist on organic spintronics: controlling transport and electroluminescence in organic sandwich devices using fringe fields from ferromagnetic films *(Invited Paper)*

Markus Wohlgenannt, The Univ. of Iowa (United States)

Organic spintronics is concerned with the study of spin-injection and magnetic-field dependent transport phenomena in organic semiconductors. In addition to spin-valve effects, there exists a large room-temperature magnetoresistive effect in organic devices made entirely from non-magnetic materials, the so-called organic magnetoresistive (OMAR) effect, which has no analogue in inorganic spintronics. OMAR is known to be caused by the variation from hopping site to hopping site of the nuclear hyperfine field, and this can dramatically affect the electronic hopping transport in organics. We demonstrate a third, new method of controlling the electrical conductivity and electroluminescence of an organic film at room temperature, using the spatially-varying magnetic fringe fields of a magnetically-unsaturated ferromagnet. Surprisingly these inhomogeneous fringe fields vary over length scales roughly two orders of magnitude larger than the hopping length in the organic materials, and the theoretical explanation of the effect is more challenging than hyperfine-related models of magnetotransport. We explain the experimental magnetoresistance traces using a model based on differential electron spin precession in magnetic field gradients. Our devices, which do not rely on spin injection, tunneling anisotropic magnetoresistance or spin-valve behavior, may provide a simple approach to integrating magnetic metals and organics for hybrid spintronic devices. These devices may find application as high-voltage readouts of the magnetic state of low-impedance ferromagnetic films.

8813-24, Session 7

Exchange interaction of transition metal spin centers in diamond *(Invited Paper)*

Victoria R. Kortan, Cuneyt Sahin, Michael E. Flatté, The Univ. of Iowa (United States)

Advances in single-ion implantation as well as electronic and optical spectroscopy have permitted direct observation of the exchange interaction between two dopant spins in a semiconductor[1,2], which is accurately described by tight-binding models of the semiconducting host[2,3]. These advances suggest controllable fabrication and utilization of few-dopant structures to explore fundamental properties and for applications[4]. Transition metal substitutional dopants in tetrahedrally-bonded semiconductors are good candidates for controllable spin manipulation and spin-spin interaction because they offer both highly-localized and more extended spin-polarized states. For example, both the Ni and Cr dopants have spin-1 ground states in diamond, but the extent of wavefunction localization is very different[5]. We calculate the exchange interaction between pairs of transition metal spin centers and between two NV centers in diamond as a function of pair separation using the technique of Ref. 3, but with an spds* tight-binding model. We find strong exchange interactions between pairs of transition metal dopants as well as between two NV centers. This work was supported by an AFOSR MURI. 8813-25, Session 7

Quantum dynamics and control of spins in diamond *(Invited Paper)*

Viatcheslav Dobrovitski, Ames Lab. (United States)

Understanding and controlling quantum spins in solids is an exciting scientific endeavor. Besides fundamental interest in non-equilibrium quantum many-spin dynamics, this research is important for applications ranging from nanosciences and spintronics, to advanced sensing and quantum information science.

The nitrogen-vacancy (NV) centers in diamond have emerged as a promising platform for prospective solid-state quantum spin technologies. I will present our recent work on investigating and controlling the quantum spin dynamics of individual and coupled electronic and nuclear spins in diamond. Advanced approaches for quantum spin control, based on the pulse dynamical decoupling, enable protection of quantum coherence of the NV center's spin [1] from its solid-state environment [2]. Furthermore, the decoherence-protected quantum spin dynamics can be extended to the case of coupled spins, thus enabling high-fidelity quantum gates on two spin qubits in diamond, and the resulting first implementation of the quantum search algorithm with solid-state spins [3]. Further extending this approach to the few-spin case, we have demonstrated an extremely sensitive nanoscale tomography with nanometer resolution and sensitivity to a single nuclear spin [4]. Finally, I will discuss how these advances can make possible multi-qubit quantum registers for the small-scale quantum information processing in diamond.

Nonlocal, local, and extraction spin valves based on ferromagnet/semiconductor hybrid structures consisting of the Heusler alloy Co2FeSi on GaAs *(Invited Paper)*

Manfred Ramsteiner, Yori Manzke, Pawel Bruski, Rouin Farshchi, Jens Herfort, Paul-Drude-Institut für Festkörperelektronik (Germany)

Lateral transport structures which take advantage of a shared interface of the semiconductor (SC) with a ferromagnetic metal (FM) are important building blocks for spintronic applications. From the materials point of view the hybrid system Co2FeSi on GaAs has been proven to be very promising particularly because of the high efficiency of electrical spin-injection.

We demonstrate nonlocal, local and extraction spin-valve structures consisting of Co2FeSi stripes on an n-type GaAs transport channel. In extraction spin valves (ESV), we utilize the accumulation of spin-polarized electrons in the SC that results from spin reflection of electrons drifting towards an SC/FM interface. In this presentation we compare the operation of nonlocal, local and extraction spin valves and explain the observed peculiarities with the specific bandstructure of fully and partially ordered Co2FeSi.

Finally, we elucidate the extension of the ESV concept to a functional spintronic circuit that comprises multiple extraction events. Such a multiple extraction spin valve (MESV) acts as a configurable current divider in which the accumulation of spin-polarized electrons in the SC channel drifts toward consecutive ferromagnetic stripes. As a result, a single electrical output corresponds to a particular magnetization configuration of the entire stripe array. We discuss potential implementations of this concept for spintronic memory and magneto-logic circuits and for sources of highly spin-polarized drift currents.

8813-27, Session 7

Light-matter-spin interactions in colloidal quantum structures *(Invited Paper)*

Min Ouyang, Univ. of Maryland, College Park (United States)

Semiconductor based colloidal quantum structures represent attractive systems to study various fundamental physics and applications at the nanoscale, including scalable solid-state implementations of quantum information pro- cessing by using spins of electrons and excitons as qubits. In this talk I will discuss a few recent progresses from my group on the topic of spin dynamics and spin manipulation in colloidal nanostructures. I will start with general spin coherence dynamics in pure semiconductor quantum dots probed by ultrafast laser spectroscopy, followed by its hydrostatic pressure effect and novel plasmon enhanced spin manipulation and spin echo enabled by a unique metal-semiconductor colloidal hybrid quantum structures.

8813-28, Session 8

Andreev nanoprobe of half metals and topological insulators using d-wave superconductors *(Invited Paper)*

John Y. T. Wei, Univ. of Toronto (Canada)

Andreev reflection (AR) spectroscopy is a powerful technique for probing the electron spin polarization of ferromagnetic materials [1]. This technique exploits the fundamental spin correlation of the AR process, and has been implemented using various contact geometries and s-wave superconductors as counterlectrode. In this talk, I will survey recent developments in this field, particularly the use of high-Tc cuprate tips as d-wave superconducting counterelectrode. I will discuss the inherent advantages of d-wave AR spectroscopy, namely high junction impedance which eliminates Joule heating, and small junction size which enables sub-domain resolution. These concepts have been realized using YBa2Cu3O7 tips on CrO2 films in a point contact geometry, demonstrating spin-polarized measurement at ~ 10nm length scales [2]. Finally, I will preview the extension of d-wave AR spectroscopy to probing the spin correlations of topological insulators, as well as the realization of spin-sensitive Andreev nanoprobe above 77K.

8813-29, Session 8

First principles modeling of electron scattering in topological insulators *(Invited Paper)*

Hong Guo, McGill Univ. (Canada); Jian Wang, Lei Zhang, The Univ. of Hong Kong (China); Xuefeng Wang, Suzhou Univ. (China); Yibin Hu, Mcgill Univ. (Canada); Leo Liu, Nanoacademic Technologies Inc. (Canada); Yonghong Zhao, Sichuan Normal Univ. (China)

Topological insulators (TI) are materials having an energy band gap in the bulk and conducting helical electronic states on the surface which have the peculiar property that the direction of the electron spin is locked to its momentum. The helical states are protected by time reversal symmetry hence robust against static disorder scattering, a property that can be exploited for spintronics. The physics of TI is induced by strong spin-orbit interaction. We have analyzed the quantum transport properties of TI device structures from atomistic first principles. On the technical side, we have carried out density functional theory (DFT) analysis within the Keldysh nonequilibrium Green's function (NEGF) formalism where the device Hamiltonian and quantum transport properties of the open two-probe transport junction structures were calculated self-consistently including the spin-orbit contributions. In the NEGF-DFT formalism, the density matrix is calculated by NEGF under external bias voltage, and the nonequilibrium density matrix is used to construct the self-consistent field (SCF) that determines the Hamiltonian of the system. At equilibrium, the SCF reduces to the DFT potential. To deal with the spin-orbit physics in TI accurately, triple-zeta double-polarization atomic orbital basis functions are used to expand the physical quantities. In this talk, I will present NEGF-DFT first principles calculations of the helical state induced by spin-orbit interactions on TI surfaces, the spin-texture, the spatial distribution of the spin states, and the electron scattering by static potential perturbations. We establish a quantitative picture on how strong a bulk perturbation could derail the helical surface spin states. Three dimensional TI material Bi2Se3 will be focused. I will also briefly report a mesoscopic phenomenon in TI nanowires having a finite cross section, where a stripe state appears to form on the surfaces due to a strong anisotropy of the material. It was found numerically that in the diffusive regime the average conductance of stripe states is quantized with fractional values.

8813-30, Session 8

Spin-orbit interaction at surfaces: Rashba-type spin structures in the unoccupied bands *(Invited Paper)*

Markus Donath, Sebastian D. Stolwijk, Sune N. Wissing, Anna Zumbülte, Anke B. Schmidt, Peter Krüger, Westfälische Wilhelms-Univ. Münster (Germany); Kazuyuki Sakamoto, Chiba Univ. (Japan)

Spin-orbit-induced spin splittings in the surface electronic structure of heavy elements and topological insulators are a hot topic of today's research in condensed matter physics. The interest is guided by possible applications of these materials in spintronic devices, in which the electron spin is used as an information carrier. While the occupied bands are thoroughly investigated by spin- and angle-resolved photoemission, there is basically a blank area on the E(k||) map beyond the Fermi level.

We present spin- and angle-resolved inverse-photoemission results on the unoccupied surface bands of selected Rashba systems. A home-made rotatable spin-polarized electron source allows the investigation of k-dependent spin structures.

(i) The Au(111) surface with its sp-derived surface state serves as a prototype system for probing Rashba-type spin splittings with inverse photoemission. (ii) Tl/Si(111)-(1x1) is an outstanding example for a system having surface states with peculiar spin-orbit-induced spin structures. We observe an unoccupied surface state with k-dependent rotation of the spin polarization from in-plane to out-of-plane upon approaching the K point. Here, the two spin components are split in energy by more than 0.5 eV, which leads to almost complete spin polarization at the Fermi level. (iii) Among the surface alloys with heavy elements on noble metals, the √3x√3R30° Bi/Ag(111) ordered surface alloy stands out as the system with the largest Rashba parameters. Our study unveils the E(k||) dispersion of several unoccupied surface bands with distinct spin polarization.

8813-31, Session 8

Splitting electrons with dirt: Majorana fermions from scattering *(Invited Paper)*

Inanc Adagideli, Sabanci Univ. (Turkey)

We focus on inducing topological state from regular, or irregular scattering in (i) p-wave superconducting and (ii) proximity coupled Rashba wires [1]. We find that while disorder is detrimental to topological state in p-wave wires, we find that it can induce topological state in Rashba wires contrary to common expectations. We find that the total phase space area of the topological state is conserved for long disordered wires, and can be even increased in an appropriately engineered superlattice potential. Finally we relate the topological charge to normal state conductance and spin conductance. [1] I. Adagideli, M. Wimmer, and A. Teker, arXiv:1302.2612

8813-32, Session 8

A fundamental view on spintronics: from Rashba-type spin-splitting to topological insulators *(Invited Paper)*

Christian R. Ast, Max-Planck-Institut für Festkörperforschung (Germany)

The Rashba-Bychkov (RB) model has been remarkably successful in describing the spin splitting of two-dimensional (2D) electron systems with a structural inversion asymmetry (SIA), which makes it one of the key mechanisms in the emerging field of spintronics for manipulating the electron spin without the use of magnetic fields. Using angular resolved photoemission spectroscopy as well as scanning tunneling microscopy/spectroscopy, we were able to show that the Bi/Ag(111) surface alloy is a representative of a new class of materials, which exhibits a particularly large Rashba-type spin-splitting. The fact that only a fraction of the atoms in a surface alloy exhibit a large atomic spin-orbit interaction question the dominant role of the atomic spin-orbit coupling and point towards a strong structural influence in the spin-splitting mechanism. We have transferred this concept onto a semiconducting surface, where we also identified a large spin-splitting in Bi/Si(111). The recently discovered topological insulators (TI) can be regarded as the topologically non-trivial counterpart of the Rashba-type spin-splitting. Here as well, 3D TIs exhibit a robust surface state with unique properties, such as forbidden back scattering. Using Bi2Se3 as a model system, we discuss the effects of exposure to ambient conditions and the environmental robustness; an issue that needs to be clarified if 3D TIs are to be used in spintronics devices.

Expanded horizons for generating and exploring optical angular momentum in vortex structures *(Keynote Presentation)*

David L. Andrews, Univ. of East Anglia Norwich (United Kingdom)

It is well known that spin offers a useful extension to the information capacity of nanometer-scale electronic devices, and that it is possible for spin transfer to effect high fidelity communication between component units such as quantum dots. In the field of spin optics, standard methods provide for two independent degrees of freedom to be communicated by photon polarization: circular states of opposing handedness are the most obvious candidates, although any two states that correspond to diametrically opposite positions on the Poincaré sphere provide a suitable basis. However, various forms of complex light with structured wave-fronts or vector polarization now offer additional degrees of freedom, enabling individual photons to convey a far greater information content than was previously thought possible. There is particular interest in Laguerre-Gaussian modes, whose helically twisted wave-front is associated with orbital angular momentum, in addition to any spin due to polarization. Experiments demonstrate that single photons carry the entire spatial helical-mode information. Moreover, twisted optical modes provide for the generation of surface plasmon optical vortices. As the field continues to grow and the technical difficulties are overcome, it has now been recognized that electron beams have a similar capacity for vortex propagation, suggesting new possibilities to resolve high density information from suitable structures.

8813-34, Session 9

Spin-orbit interaction in optical singularimetry *(Invited Paper)*

Joerg B. Goette, Max-Planck-Institut für Physik komplexer Systeme (Germany)

Singularimetry is a new and elegant optical measurement technique which utilises the position of vortices in the spin and orbital currents to gather information about material properties or dynamic processes on an interface [1]. It is based on the fact that a vortex beam [2] upon reflection from or transmission through an interface experiences a change in its topology - a higher charge vortex breaks up into a constellation of unit vortices. The position of these vortices within the light beam depend on higher order terms of the optical spin-orbit coupling. A measurement of the vortex position can therefore reveal information about topological aberrations and the structure of interface.

The scheme makes use of a pre- and postselection of the polarization (or spin) of the light, and is analogous to a quantum weak measurement [3]. Varying the input and output spin of the light changes the observable vortex constellation, and probes all elements of the a scattering matrix, which mediates the light-matter interaction. Increasing the vortex charge probes higher order terms in systematic expansion of the scattering matrix in terms of a spin-orbit coupling parameter. As the scheme is based on the topology of wave fields it is not just restricted to optical beams.

Quantum information processing with spin-orbit laser modes *(Invited Paper)*

Antonio Z. Khoury, Carlos Eduardo R. Souza, Allan R. Vieira, Univ. Federal Fluminense (Brazil); Malena O. Hor-Meyll, UFRJ (Brazil)

Optical beams carrying orbital angular momentum have attracted considerable interest both in quantum optics and quantum information. These beams are optical vortices produced by holographic techniques and astigmatic mode converters. Their application to quantum information tasks ranges from implementation of conditional quantum gates to quantum criptography. Combination of orbital and spin angular momenta allows one to encode and operate a pair of independent qubits on a single photon. These degrees of freedom can be entangled to each other (internal entanglement) as well as to those of other photons (hybrid entanglement), giving rise to new implementations of quantum communication protocols.

While the photon spin can be easily operated with polarization devices (wave plates and polarizing beam splitters), the orbital degree of freedom requires a more involved approach. We shall discuss some simple setups used to operate and select paraxial modes carrying orbital angular momentum. We developed a single lens design for an astigmatic mode converter and implemented a controlled-not gate based on a Michelson interferometer. We also used a modified Sagnac interferometer to sort the spin-orbit modes according to their parity. The Sagnac geometry benefits from phase stability and allows for independent manipulation of the interfering beams.

8813-36, Session 10

Beaming and steering of photons with spin and orbital angular momentum using spiral plasmonic antenna *(Invited Paper)*

Qiwen Zhan, Univ. of Dayton (United States)

In this talk, I will present some of our latest works on the beaming and steering of photons with angular momentum using spiral plasmonic antennas. Through coupling quantum dot nano-emitters to a spiral plasmonic antenna, highly directive nano-scale photon sources that emit photons with spin and orbital angular momentum can be realized. Both analytical and numerical models indicate that the beamed photons can be imprinted with desired photonic spin angular momentum and orbital angular momentum information simultaneously via the interactions between the nano-emitters and the plasmonic spiral antenna. These theoretical predictions are confirmed by results obtained from carefully designed experiments. Furthermore, the feasibility of controlling the emission direction of the nano-scale spin photon source is demonstrated by both numerical simulation and experimental results. The beaming direction can be steered through introducing a displacement to the emitters away from the geometrical center of the spiral antenna. A steerable nanoscale spin photon source may find important applications in single molecule sensing, quantum optical information processing and integrated photonic circuits.

8813-37, Session 10

Structured light in nanostructures *(Invited Paper)*

Natalia M. Litchinitser, Jingbo Sun, Mikhail I. Shalaev, Jinwei Zeng, Alexander N. Cartwright, Univ. at Buffalo (United States)

We discuss fundamental optical phenomena at the interface of singular optics and nanostructured optical materials, including theoretical and experimental studies of linear and nonlinear light-matter interactions of vector and singular optical beams in optical metamaterials. Understanding the physics of the interaction of complex beams with nanostructured “engineered” media is likely to bring new dimensions to the science and applications of complex light, including novel regimes of spin-orbit interaction, extraordinary possibilities for dispersion engineering, and novel possibilities for nonlinear singular optics.

We report theoretical and experimental studies of linear and nonlinear interactions of complex light beams with orbital angular momentum with fiber-based magnetic and negative-index metamaterials. In particular, our studies show that magnetic metamaterials can be used to manipulate complex polarization states, while negative index metamaterials can be used to manipulate the phase front of singular beams. We also predict that backward phase-matched process in negative index metamaterials with quadratic nonlinearity results in generation of backward propagating vortex beam with simultaneously doubled frequency and orbital angular momentum and reversed rotation direction of the wavefront. Finally, we discuss structured light propagation in indefinite optical metamaterials and propose several novel functionalities enabled by these strongly anisotropic structures, including beam intensity and wavefront shaping as well as transformations of orbital angular momentum.

These studies could find applications for multidimensional information encoding, secure communications, and quantum cryptography as both spin and orbital angular momentum could be used to encode information; dispersion engineering for spontaneous parametric down-conversion; and on-chip optoelectronic signal processing.

8813-38, Session 10

The Lorentz force law and its connections to hidden momentum, the Einstein-Laub force, and the Aharonov-Casher effect *(Invited Paper)*

Masud Mansuripur, College of Optical Sciences, The Univ. of Arizona (United States)

The Lorentz force of classical electrodynamics, when applied to magnetic materials, gives rise to hidden energy and hidden momentum. Removing the contributions of hidden entities from the Poynting vector, from the electromagnetic momentum density, and from the Lorentz force and torque densities simplifies the equations of the classical theory. In particular, the reduced expression of the electromagnetic force-density becomes very similar (but not identical) to the Einstein-Laub expression for the force exerted by electric and magnetic fields on a distribution of charge, current, polarization and magnetization. Examples reveal the similarities and differences among various equations that describe the force and torque exerted by electromagnetic fields on material media. An example of the simplifications afforded by the Einstein-Laub formula is provided by a magnetic dipole moving in a static electric field and exhibiting the Aharonov-Casher effect.

8813-39, Session 10

Spinoptical metamaterials: spin-controlled photonics based on symmetry violation *(Invited Paper)*

Nir Shitrit, Igor Yulevich, Elhanan Maguid, Dror Ozeri, Dekel

Veksler, Vladimir Kleiner, Erez Hasman, Technion-Israel Institute of Technology (Israel)

Metamaterials are artificial matter structured on a size scale smaller than the wavelength of external stimuli enabling a custom-tailored electromagnetic response of the medium and thus leading to state-of-the-art functionalities. Alongside, spinoptics provides an alternative route to control light, whereby the photon spin – circular polarization helicity – is utilized as an additional degree of freedom in nano-optics, and consequently, paving the way for optical spin degeneracy removal phenomena owing to a geometric gradient in a structured matter. Specifically, spinoptics enables one to engineer a metamaterial dispersion in a spin-dependent manner as in the Rashba effect in spintronics, which is a manifestation of the spin-orbit interaction under broken inversion symmetry, i.e., the inversion transformation does not preserve the structure.

Here, we report on a spinoptical metamaterial manifested by a spin-controlled dispersion owing to the optical Rashba effect. The observed spin-split dispersion of spontaneous emission is attributed to the optical spin-orbit interaction under spatial inversion asymmetry in anisotropic inhomogeneous structured matter. We obtain an inversion asymmetric metasurface by modeling the uniform and the staggered chirality spin-folding modes of the frustrated kagomé antiferromagnet in artificial structures with anisotropic antenna configurations. The spin-dependent dispersion of a spinoptical metamaterial is governed by a momentum selection rule, generated by the representation theory considering the structure symmetry restrictions, highlighting the combined contributions of the structural and orientational lattices. This new type of metamaterial is a starting point for integrated spintronic-spinoptical applications based on design of the metasurface symmetry properties via anisotropic nanoantennas with space-variant orientation.

Electrical detection of three-terminal Hanle-effect signals in Si across Schottky tunnel barriers *(Invited Paper)*

Kohei Hamaya, Kyushu Univ. (Japan); Yuichiro Ando, Osaka Univ. (Japan)

Here we show some interesting phenomena in spin accumulation signals, detected by the three-terminal Hanle-effect measurements, in Si-based lateral devices. Using a delta-doping approach, we fabricated Schottky tunnel barriers between CoFe and Si. Thus, our devices have no insulating tunnel barriers at the contacts. Across the Schottky tunnel barriers, we can detect spin accumulation in nondegenerated Si channels [1-3]. First, the electrical detection of the spin-accumulation signals at room temperature was achieved in a Si-MOSFET structure [1]. Interestingly, the magnitude of the spin signals was able to be modulated by the application of gate voltage. Next, the influences of the presence of the localized states at the CoFe/Si interface and of magnetic domain structures in the CoFe contact on the spin-accumulation signals will be discussed [2,3]. Finally, the effect of the replacement of the CoFe contact with Heusler-alloy contacts on the spin signals will be discussed [4].

We wish to thank K. Sawano, A. Sakai, and M. Miyao for their experimental supports and useful discussions. This work was partly supported by SCOPE from MIC, Japan.

Electrical spin injection into silicon and the role of Schottky barrier *(Invited Paper)*

Saroj P. Dash, Chalmers Univ. of Technology (Sweden)

Electrical creation of spin polarization in semiconductors and understanding the process of spin injection and detection are the main challenges in spintronics.

Electrical spin injection and detection has been demonstrated in silicon at room temperature for the first time by Dash et al. [1, 2]. Several control experiments also have proven unambiguously that the large room temperature spin signal originates from spin-polarized tunneling and spin accumulation in the Si bands [3]. The Schottky barrier profile at the interface mainly controls the spin transport process. Here we will present the role of Schottky barrier on the spin injection and detection in silicon. Using a very narrow Schottky barrier and SiO2 tunnel barrier, we demonstrate a giant spin accumulation in highly doped silicon at room temperature. With an increase in Schottky barrier width we observe a sign-reversal of the Hanle spin signal at low bias voltages. This demonstrates that an increase in Schottky barrier resistance decouples the spins in the localized states from the bulk band of silicon, and causes a transition from direct tunneling to a thermionic and localized state assisted tunneling. Our findings provide new insights about the role of Schottky barrier for spin injection, accumulation and detection in silicon.

How reliable are Hanle measurements in metals in a three-terminal geometry? *(Invited Paper)*

Oihana Txoperena, Marco Gobbi, Amilcar Bedoya-Pinto, Federico Golmar, Xiangnan Sun, CIC nanoGUNE Consolider (Spain); Luis E. Hueso, CIC nanoGUNE Consolider (Spain) and IKERBASQUE, Basque Foundation for Science (Spain); Felix Casanova, CIC nanoGUNE Consolider (Spain)

Spintronics is a rapidly growing research area that aims to use and manipulate the spin of the electron. There is special interest in purely electrical spin injection and detection in semiconducting devices, to integrate the spin functionality into conventional electronics. A simple device to study spin injection and transport in semiconductors uses a three-terminal (3T) geometry, in which spin accumulation is induced and probed via Hanle effect by a single magnetic tunnel contact. Since the 3T geometry does not require submicron-sized fabrication processes, this type of devices have become very popular. However, many results associated to this method are still controversial, including spin accumulation values well above the theoretical ones, an anomalous bias dependence of the Hanle signal or the unclear origin of the inverted Hanle effect.

We test the validity of Hanle measurements in 3T devices by using aluminum (Al) and gold (Au). The obtained Hanle and inverted Hanle curves show an anomalous behavior. First, we measure signals 8 orders of magnitude larger than those predicted by standard theory. Second, the temperature and voltage dependences of the signal do not match with the tunneling spin polarization of the ferromagnetic contact. Finally, the spin relaxation times obtained with this method are independent of the choice of the metallic channel. These results are not compatible with spin accumulation in the metal. Furthermore, a scaling of the Hanle signal with the interface resistance of the devices suggests that the measured signal is originated in the tunnel junction.

8813-43, Session 11

Spin injection, transport, and relaxation in spin light-emitting diodes: magnetic field effects *(Invited Paper)*

Nils C. Gerhardt, Henning Höpfner, Carola Fritsche, Arne Ludwig, Astrid Ludwig, Ruhr-Univ. Bochum (Germany); Frank Stromberg, Heiko Wende, Werner Keune, Univ. Duisburg-Essen (Germany); Dirk Reuter, Univ. Paderborn (Germany); Andreas D. Wieck, Martin R. Hofmann, Ruhr-Univ. Bochum (Germany)

Efficient electrical spin injection into semiconductor based devices at room temperature is one of the most important requirements for the development of applicable spintronic devices in the near future and is thus an important and very active research field. Here we report experimental results for the electrical spin injection in spin light-emitting diodes (spin-LEDs) without external magnetic fields at room temperature. Our devices consist of a Fe/Tb multilayer spin injector with remanent out-of-plane magnetization, an MgO tunnel barrier for efficient spin injection and an InAs quantum dot light-emitting diode. Using a series of samples with different injection path lengths allows us to experimentally determine the spin relaxation during vertical transport from the spin injector to the active region at room temperature. In combination with our concept for remanent spin injection, we are additionally able to investigate the influence of an external magnetic field on the spin relaxation process during transport. While the spin relaxation length at room temperature without external magnetic field is determined to be 27 nm, this value almost doubles if an external magnetic field of 2 Tesla is applied in Faraday geometry. This demonstrates that the results for spin injection and spin relaxation obtained with or without magnetic field can hardly be compared. The efficiency of spin-induced effects is overestimated as long as magnetic fields are involved. Since strong magnetic fields are not acceptable in application settings, this may lead to wrong conclusions and potentially impairs proper device development.

8813-44, Session 12

Electrical spin injection in semiconductors probed by magnetoresistance and spin pumping experiments: the exact role of localized states and related hyperfine interactions *(Invited Paper)*

Henri Jaffrès, Jean-Marie George, Julian Pereiro, Sankara Ruttala, Unité Mixte de Physique CNRS/Thales (France); Matthieu Jamet, Commissariat à l'Énergie Atomique (France)

In this talk review, I will present our latest experiments obtained on electrical spin injection at MgO/Ge interfaces and (Ga,Mn)(As,P)/n+-GaAs Ezaki diodes and probed by magnetoresistance and spin pumping experiments. Our experiments concern the electrical detection of spin accumulation by respective Hanle and Inverted Hanle effects giving specific magnetoresistance associtated to voltage drop or increase and related to the change in the level of spin accumulation. I will discuss the origin of the spin signal enhancement observed at low temperature and related to a preferential spin injection in localized states of semiconductor nearby the ferromagnet/semiconductor interfaces.

In the III-V (Ga,Mn)(As,P)/GaAs Ezaki devices, we interprete the full Hanle curves by the existence of the hyperfine interactions between the spin of carriers injected and the nuclear spins of the Ga and As atomic species within the localized states.

8813-45, Session 12

Non-local versus three-terminal detection of spin accumulation in (Ga,Mn)As/GaAs spin Esaki diode devices *(Invited Paper)*

Mariusz Ciorga, Univ. Regensburg (Germany); Junichi Shiogai, Tohoku Univ. (Japan); Martin Utz, Dieter Schuh, Univ. Regensburg (Germany); Makoto Kohda, Tohoku Univ. (Japan); Dominique Bougeard, Univ. Regensburg (Germany); Tsutomu Nojima, Junsaku Nitta, Tohoku Univ. (Japan); Dieter Weiss, Univ. Regensburg (Germany)

Over the last couple of years there has been a real progress in understanding and realization of electrical spin injection and detection in semiconductors. Detection of spin accumulation is typically realized by means of four-terminal (4T) measurements in non-local (NL) configuration, i.e., with injector and detector circuits separated from each other. The alternative method of spin detection involves three-terminal (3T) measurement where an injector electrode is used also for spin detection. This method has been used especially in cases when non-local signals could not be observed, e.g., in most of the experiments on Si. There have been however many controversies related to the latter method, as measured 3T signals often exceed by orders of magnitude the value expected from a standard model of spin injection.

In the presentation we will discuss the similarities and differences between 3T and 4TNL spin signals observed in spin injection devices based on (Ga,Mn)As/GaAs Esaki diodes. In particular we will discuss in details a dependence of the signal on bias voltage/current applied to the injector. The non-local spin signal decreases with bias as a result of a drop in spin injection efficiency. The 3T signal, on the other hand, shows a very strong enhancement for positive voltages – by two orders of magnitude at the voltage corresponding to the Esaki dip in current-voltage characteristic. We will discuss the observed enhancement in connection to the model involving spin accumulation generated in localized states as well as to the effect of electric field on spin detection sensitivity.

The work was supported by German Science Foundation (DFG) through the project SFB689.

8813-46, Session 12

Dynamical spin injection and spin transport in Si and Ge at room temperature *(Invited Paper)*

Masashi Shiraishi, Osaka Univ. (Japan)

Electrical spin injection methods have been widely used in order to investigate spin transport and relaxation properties in nonmagnetic metals, inorganic semiconductors and organic molecules. Recent establishment of dynamical spin injection, yielding pure spin current in condensed matters, paved a new pass way to spin injection into various materials [1,2], where ferromagnets play a role of “spin battery”. We firstly succeeded in generating pure spin current (not spin-wave spin current) and detecting spin transport in p-Si [3], single layer graphene [4] and Al [5] by using the dynamical method. Furthermore, dynamical spin injection in p-Ge was also succeeded [6]. In this talk, I focus on our recent success on spin pumping in Si and Ge by introducing the detail of spin transport and spin relaxation, especially temperature dependence and doping concentration dependence.

Spin currents in Ge-based heterostructures *(Invited Paper)*

Federico Bottegoni, Alberto Ferrari, Stefano C. Cecchi, Marco Finazzi, Giovanni Isella, Franco Ciccacci, Politecnico di Milano (Italy)

Germanium has recently become an appealing candidate for spintronics applications, due to the large spin-orbit interaction, long electron spin lifetimes at the L point of the Brillouin zone and the easy integrability with Si-based electronics. In this context, we studied the properties of spin currents optically injected in Ge-based heterostructures and detected using inverse spin Hall effect (ISHE). We characterized the ISHE signal in diffusive regime, as a function of the initial electron spin polarization, generation depth, doping of the structures and externally applied electric fields.

8813-48, Session 13

Fundamental aspects of spin and charge transport in nanoscale systems and ultra-cold atoms *(Keynote Presentation)*

Massimiliano Di Ventra, Univ. of California, San Diego (United States)

I will discuss some of the most basic questions in fermionic and bosonic transport, such as the conditions for the existence of a steady-state current, its uniqueness, the role of interactions and spin statistics, its entanglement entropy, etc. This will lead me to introduce an alternative viewpoint to conduction - the micro-canonical formalism of transport - which is ideal to study the above issues [1]. I will point out the similarities and differences with the widely used Landauer formalism, and advance a series of predictions that can be verified by loading ultra-cold atoms into artificial optical lattices.

8813-50, Session 13

Engineering Dirac points with ultracold fermions in optical lattices *(Invited Paper)*

Leticia Tarruell, Institut d'Optique Graduate School (France); Daniel Greif, Thomas Uehlinger, Gregor Jotzu, Tilman Esslinger, ETH Zurich (Switzerland)

Dirac points are central to many phenomena in condensed-matter physics, from massless electrons in graphene to the emergence of conducting edge states in topological insulators. At a Dirac point, two energy bands intersect linearly and the electrons behave as relativistic Dirac fermions. In solids, the rigid structure of the material determines the mass and velocity of the electrons, as well as their interactions. A different, highly flexible means of studying condensed-matter phenomena is to create model systems using ultracold atoms trapped in the periodic potential of interfering laser beams. Here we report the creation of Dirac points with adjustable properties in a tunable honeycomb optical lattice. Using momentum-resolved interband transitions, we observe a minimum bandgap inside the Brillouin zone at the positions of the two Dirac points. We exploit the unique tunability of our lattice potential to adjust the effective mass of the Dirac fermions by breaking inversion symmetry. Moreover, changing the lattice anisotropy allows us to change the positions of the Dirac points inside the Brillouin zone. When the anisotropy exceeds a critical limit, the two Dirac points merge and annihilate each other--a situation that has recently attracted considerable theoretical interest but that is extremely challenging to observe in solids. We map out this topological transition in lattice parameter space and find excellent agreement with ab initio calculations. Our results not only pave the way to model materials in which the topology of the band structure is crucial, but also provide an avenue to exploring many-body phases resulting from the interplay of complex lattice geometries with interactions.

8813-51, Session 14

Chiral spin torque at magnetic domain walls *(Keynote Presentation)*

Stuart S. P. Parkin, IBM Almaden Research Ctr. (United States)

Electronic spin currents provide a powerful means of manipulating magnetization in magnetic memory and logic nano-devices. In particular, the transfer of spin angular momentum derived from currents spin-polarized by volume electron scattering gives rise to a spin transfer torque (STT) that can drive magnetic domain walls (DWs) along nanowires. This bulk-derived STT mechanism, however, weakens as the volume to surface ratio of the nanowire is reduced in ultra-thin magnetic layers: in this case the DWs are found to move in the opposite direction to that expected from bulk STT and, moreover, at much higher speeds. These properties are most pronounced in structures containing interfaces between atomically thin cobalt layers and platinum. Here we show that these properties are due to two intertwined phenomena both derived from spin-orbit interactions at the Co/Pt interfaces. By measuring the influence of magnetic field on current driven DW motion in perpendicularly magnetized Co/Ni/Co trilayers we find that there exists an internal effective magnetic field that operates on each DW. This field, localized at the DWs is oriented along the nanowire but has a direction that alternates between successive DWs, such that, acting in concert with spin Hall currents, the DWs are driven in lock-step along the nanowire. We propose that this chiral effective field arises from a Dzyaloshinskii-Moriya interaction (DMI) at the Co/Pt interfaces. By revealing the origin of this remarkable phenomenon that allows for the highly efficient manipulation of DWs in ultrathin magnetic films, new families of spintronic devices can be anticipated.

8813-52, Session 14

A time-domain method for mapping stochastic dynamics in spin torque oscillators *(Invited Paper)*

Graham E. Rowlands, Cornell Univ. (United States); Jian Zhu, Headway Technologies, Inc. (United States); Jordan A. Katine, HGST (United States); Juergen Langer, SINGULUS TECHNOLOGIES AG (Germany); Ilya N. Krivorotov, Univ. of California, Irvine (United States)

Spin torque from a spin-polarized current can excite magnetization auto-oscillations in the free layers of spin-valves, thereby generating microwave voltages at frequencies tunable by the applied current. These spin-torque oscillators (STOs) may find applications as microwave sources or magnetic field sensors for computer hard drives. Because of the STOs' small sizes, their magnetization dynamics are strongly influenced by ambient thermal fluctuations. For this reason, the microwave signals emitted by STOs typically possess large generation linewidths, a characteristic that is perhaps the primary barrier to industrial applications.

We demonstrate a new method of using time-resolved measurements of STO voltage oscillations to extract new information about these stochastic dynamics. Frequency domain techniques are often used as indirect probes of the coherence properties of the dynamics, while our method allows for direct observation of the time evolution of the magnetization vector. By first performing a careful analysis of the DC electrical properties of a particular STO, we can reconstruct the distributions of angles at which the magnetization trajectories intersect the sample plane. We show that these distributions are accurately

reproduced by the effective energy Fokker-Planck formalism [1,2], and that we may readily extract the bias-dependent strength of the field-like component of spin-torque. Finally we show how the spectra of these devices can be accurately predicted without the need for complicated analytical machinery.

Spin-motive force in solid-state systems *(Invited Paper)*

Stewart E. Barnes, Univ. of Miami (United States)

In MRAM magnetic tunnel junctions (MTJs) spin-motive forces (SMF) [1] are the Newtonian reciprocal of the spin-torque transfer (STT) effect and more generally are associated with ``drag" effects, i.e., the transfer of linear momentum between, e.g., electrons and phonons degrees of freedom. For a MTJ, from the free layer FMR frequency, typically 2-10GHz the basic SMF ~10muV and apparently negligible compared with an applied voltage ~ 1V. However this is multiplied [2] by a large magnification factor M the ratio of R the barrier resistance to r, that of the metallic free layer. As a result the SMF plays a pivotal role in such devices. It explains the observed magneto-resistance and results , e.g., in negative resistances.

Efficient current induced domain wall motion in CoFeB/MgO nanowires with perpendicular magnetic anisotropy *(Invited Paper)*

Su Jung Noh, Tomek Schulz, Tim Zacke, Johannes Gutenberg Univ. Mainz (Germany); Capucine Burrowes, Guillaume Agnus, Dafiné Ravelosona, Univ. Paris-Sud 11 (France); Berthold Ocker, SINGULUS TECHNOLOGIES AG (Germany); Mathias Kläui, Johannes Gutenberg Univ. Mainz (Germany)

A recently investigated material with a perpendicular magnetic anisotropy is CoFeB/MgO [1], which is shown to yield high TMR ratios.[2] High TMR, which requires MgO barriers is suitable for the electrical read-out of a non-volatile shift register device.

In here, we study the domain-wall (DW) writing, shifting and read-out for DW based devices. We fabricate Ta(5nm)/Co20Fe60B20(1nm)/MgO(2nm)/Ta(5nm) nanowire with Hall crosses for DW read-out using the extraordinary Hall effect (EHE). For DW writing, Au bars have been placed across the nanowires for the DW nucleation using local Oersted field generated by a pulse current.

Single DWs can be nucleated at pulse current densities through the Au nanowires of j = 5.64 x 1011 A/ without applying any external fields. We determine the DW nucleation statistics that depends on the pulse length, which can be modelled as a thermally activated process with 100 % nucleation for j = 6.3 x 1011 A/m2.

After the DW preparation at the entrance of the Hall cross, we inject current pulses into the CoFeB/MgO nanowire to shift the DW. The DW can be pushed into the Hall cross at a current density of j = 9.5 x 1010A/m2 with 13 mT of supporting external field. By varying the current and applied fields, we determine the non-adiabaticity from the field-current equivalence [3].

Magnetic resonances driven by an ac current *(Invited Paper)*

Maxim Tsoi, The Univ. of Texas at Austin (United States)

Excitation of ferromagnetic resonance (FMR) by an ac current has been observed in macroscopic ferromagnetic films for decades and typically relies on the ac Oersted field of the current to drive magnetic moments into precession and classical rectification of ac signals to detect the resonance. Recently, current-driven resonances have attracted renewed attention with the discovery of spin-transfer torque (STT) effect [1-3] due to its potential applications in magnetic memory and microwave technologies. Here STT associated with the ac current is used to drive magnetodynamics on the nanoscale that enables FMR studies in sample volumes smaller by a factor of 1000 compared to conventional resonance techniques.

In our experiments we use nanoscale point contacts to produce extremely high-density ac (microwave frequency) currents and study their influence on magnetodynamics in magnetic thin films and multilayers. Here a time-dependent STT associated with the microwave current drives magnetization into resonance and enables STT-FMR [4] studies on the nanoscale. In our experiments we detect both rectified signals and absorption of microwaves that allows for a direct comparison of STT-FMR technique with conventional FMR schemes. At double the FMR frequency we observe the STT-driven parametric resonance [5] which is different from a regular forced resonance (FMR) since the action appears as a time varying modification on the system's parameter – STT produces a time-dependent modulation of the effective damping parameter.
Due to its nonlinear nature, parametric excitation grows significantly faster than the forced excitation and may result in a faster switching of magnetization and, therefore, an increased speed (and reduced power) of logic and memory devices based on STT (e.g. STT-MRAM). This work was supported in part by NSF grant DMR-1207577.

Spin-orbit enhanced electric-field control of magnetism in multiferroic BiFeO3 *(Invited Paper)*

Rogerio de Sousa, Univ. of Victoria (Canada)

The ability to control magnetism using electric fields is of great fundamental and practical interest. It may allow the development of ideal magnetic memories with electric write and magnetic read capabilities, as well as logic devices based on spin waves that dissipate much less energy [1]. Multiferroic materials with coexisting magnetic and ferroelectric phases have emerged as the prototypical physical system to search for E-field control of magnetism. Previous demonstrations are based on poling the ferroelectric polarization into another direction in order to force the spins to move into a different easy plane.

Here I will present a microscopic theory [2] that shows that E-field control of magnetism can actually be much more striking, provided the material has strong spin-orbit interaction. I will show that in bismuth ferrite (BiFeO3 or BFO) spin-orbit coupling at the bismuth ion sites results in a special kind of magnetic anisotropy that is linear in the applied E-field, and that this interaction explains the origin of the giant E-field effect on magnons observed in [1]. This interaction can convert the cycloid ground state into a homogeneous antiferromagnet, with a weak ferromagnetic moment whose orientation can be controlled by the external E-field direction. Remarkably, the E-field control of magnetism occurs without changing the ferroelectric state, reducing the energy dissipation in spin-based devices.

Large tunnel electroresistance controlled by ferroelectric domain switching in BaTiO3 and BiFeO3- based ferroelectric tunnel junctions *(Invited Paper)*

Vincent Garcia, Unité Mixte de Physique CNRS/Thales (France)

After being conceptualized in the early 1970's, ferroelectric tunnel junctions (FTJs), where an ultrathin ferroelectric film is sandwiched between two electrodes, have remained elusive for more than 30 years. At room temperature, we use piezoresponse force microscopy (PFM) to show robust ferroelectricity in BaTiO3 ultrathin films, and conductive-tip atomic force microscopy to demonstrate the non-destructive resistive readout of the polarization state via its influence on the tunnel current [Nature 460 (2009) 81-84]. Solid-state devices were fabricated out of these ferroelectric tunnel barriers. These FTJs show OFF/ON ratio >100 with fast and low energy resistive switching correlated to ferroelectric switching [Nature Nanotech. (2012) 101-104]. By varying the voltage pulse amplitude, intermediate resistance states are reachable and PFM imaging reveals a direct correlation between resistance and ferroelectric domains configuration. The FTJs behave as memristors where quasi-continuous resistance variations with cumulated voltage pulses in the ns range can be interpreted with standard models of ferroelectric domains dynamics [Nature Mater. 11, 860-864 (2012)]. More recently, we observed giant tunnel electroresistance (OFF/ON ratio >10,000) in solid-state FTJs based on ultrathin films of BiFeO3. Using PFM imaging, we demonstrated that the changes in resistance scale with the nucleation and growth of ferroelectric domains in the ultrathin BiFeO3. These devices emerge as an alternative to other resistive binary or analog memories with the advantage of not being based on voltage-induced migration of matter at the nanoscale, but on a purely electronic mechanism.

Exploring symmetry effects in low dimensional transport in SrTiO3-based heterostructures *(Invited Paper)*

Christopher Bell, SLAC National Accelerator Lab. (United States)

At low temperatures bulk SrTiO3 is on the border of ferroelectricity, and can be doped to create a low density superconductor with high electron mobility. These fascinating properties have motivated the recent interest in low dimensional SrTiO3 heterostructures. The conductivity at the asymmetrically confined LaAlO3/SrTiO3 interface [1], and in particular its control with a field effect gate [2, 3], is one example where we can explore novel low dimensional physics. At the same time, studies of symmetrically confined 2D superconductivity and 2D quantum oscillations in Nb:SrTiO3 [4, 5] offer additional control and insights into this fascinating quantum material. This talk will compare and contrast these two different ways of constraining the electrons, noting especially the emergent magnetism in the former system [6], opening the door to intriguing spin transport properties.

Magnetic complex oxide devices: from a diode to a transistor *(Invited Paper)*

Yasuyuki Hikita, SLAC National Accelerator Lab. (United States)

The recent advances in the ability to control interface structures on the atomic scale has allowed new spin devices to be explored using complex oxide materials [1]. One of the major approaches in making devices is the active use of the strong internal electric field at interfaces as in bipolar transistors. Since the operation of such devices is dominated by carrier transport perpendicular to the interface, it is essential to understand and control the interface energy band alignments.

In this talk, I will introduce three studies on heterojunction devices using La0.7Sr0.3MnO3 (LSMO) and Nb-doped SrTiO3 (NSTO). First is the direct observation of Schottky barrier height (SBH) variation with magnetic field using internal photoemission spectroscopy, reflecting strong magneto-orbital coupling in LSMO [2, 3]. Second is the application of interface dipole engineering in controlling the SBH without affecting the properties of the two materials [4]. A change in SBH of 0.5 V was achieved by modifying the interface termination and hence the interface dipole arising from screening of the polarity mismatch at the interface. Finally, I will present successful operation of an "all-oxide" hot-electron transistor which can be a promising platform for future spin-valve transistors given their epitaxial interface structures [5].

Optically-induced magnetism in strontium titanate *(Invited Paper)*

Scott A. Crooker, William D. Rice, Los Alamos National Lab. (United States); Chris Leighton, Palak Ambwani, Univ. of Minnesota (United States)

Strontium titanate (SrTiO_3), a nominally diamagnetic semiconducting perovskite, is one of the most extensively investigated complex oxides and is considered a fundamental building block in the emerging field of "oxide electronics". In recent years a variety of fascinating and unexpected phenomena have been discovered in SrTiO_3, both in bulk and at interfaces. Examples include superconductivity at the lowest known electron densities, coexisting quantum oscillations and superconductivity, two-dimensional electron gas formation at interfaces, and even suggestion of local moment formation and magnetic order [1]. These discoveries have motivated a renewed interest in the electronic, magnetic, and optical properties of such complex oxide materials.

Here we demonstrate that a long-lived and persistent magnetization can be optically induced (and optically detected) in bulk doped single crystals of strontium titanate [2]. In analogy with the phenomenon of optical spin orientation that is widely exploited in III-V semiconductors, we find that magnetic circular dichroism studies reveal clear evidence of induced magnetization in SrTiO_3 at zero applied field. These signals are confirmed with SQUID magnetometry. Interestingly, and in contrast to III-V semiconductors, the optically-induced magnetism in SrTiO_3 is extremely long-lived. We discuss relevant mechanisms that lead to the observed phenomena.

Tailoring 'materials on the verge' in magnetic oxide heterostructures *(Invited Paper)*

Anand Bhattacharya, Argonne National Lab. (United States)

The complex oxides have many electronic and structural phases, which arise as a result of electron-electron and electron-lattice interactions. These phases often compete, and we can usually tune between them by doping charge carriers. An alternative to this approach is to carry this out in a reversible manner by applying an external field. The key to achieving this tunability is to tailor materials that are on the verge of a phase transition where they have a strong susceptibility to external fields. In our work with manganite superlattices, we have shown that it is possible to create quasi two-dimensional regions of a ferromagnetic (FM) metal within an antiferromagnetic (AF) host by exploiting the competition between double-exchange ferromagnetism and AF superexchange. We created this delta-doped material by adding a single atomic layer of dopant cations to the host AF material. The doped electrons cause the AF spins in the vicinity of the dopant cations to cant in a manner that was first predicted by de Gennes but has remained elusive experimentally. This material could be a candidate for electric field-effect and ferroelastic strain tuning between FM and AF phases. We demonstrate our approach with a study of another double-exchange ferromagnet, Fe3O4, where we use ferroelastic strain to carry out non-volatile resistive switching over a broad range of temperatures, including in the vicinity of the Verwey metal-insulator transition where we observe the largest susceptibility of resistance to ferroelastic strain.

Fast strain driven dynamics: magnetization rotation of Co/Pt and antiferromagnetic ordering in Cr2O3 *(Invited Paper)*

Shireen Adenwalla, Univ. of Nebraska-Lincoln (United States) and Nebraska Ctr. for Materials and Nanoscience (United States); Uday Singh, William Echtenkamp, Christian Binek, Univ. of Nebraska-Lincoln (United States)

We are able to generate large (1%), fast (GHz) dynamics strains by patterning piezoelectric substrates with appropriately curved electrodes. The electrode curvature focuses the strain energy into a focal spot. We use this large strain to drive two technologically important materials, perpendicular magnetic anisotropy Co/Pt and the antiferromagnet Cr2)3, which has been shown to allow for electrical control of exchange bias. In the first set of experiments, thin films of Co/Pt are patterned at the focal spot and by using the large strain and the magnetoelastic coupling, we attempt to overcome the strong perpendicular anisotropy of these thin films, rotating the magnetization into and out of the plane at GHz frequencies. The 2nd set of experiments involves thin films of the antiferromagnetic magento-electric Cr2O3. Strain coupling alters the ordering temperature and we drive the material back and forth across the transition temperature using fast dynamic strain. In both cases, we use the magneto-optical Kerr effect (MOKE) to monitor the transitions. We present both dc time averaged data and preliminary data at the high driving frequencies of the curved transducers.

Engineering magnetism and transport at perovskite cobaltite interfaces via oxygen vacancy ordering *(Invited Paper)*

Shameek Bose, Manish Sharma, Maria Torija, Univ. of Minnesota, Twin Cities (United States); Jaume Gazquez, Oak Ridge National Lab. (United States) and Univ. Complutense de Madrid (Spain); Maria Varela, Oak Ridge National Lab. (United States); Josh Schmitt, Chunyong He, Univ. of Minnesota, Twin Cities (United States); Julie Borchers, Mark Laver, National Institute of Standards and Technology (United States); Sami El-Khatib, Univ. of Minnesota, Twin Cities (United States) and American Univ. of Sharjah (United Arab Emirates); Valeria Lauter, Haile Ambaye, Rick Goyette, Oak Ridge National Lab. (United States); Chris Leighton, Univ. of Minnesota, Twin Cities (United States)

Thin films and heterostructures of perovskite cobaltites are of significant interest both for fundamental issues in magnetism (e.g. spin-state crossovers, magnetic phase separation), and for applications in oxide devices (e.g. solid oxide fuel cells, oxide spintronics). In our recent work on the prototypical SrTiO3(001)/La1-xSrxCoO3 system we demonstrated that interface-induced magneto-electronic phase separation dominates the properties of such systems, driven by accumulation of oxygen vacancies at the interface [1]. This results from a novel mechanism for accommodation of lattice mismatch with the substrate based on formation and long-range ordering of oxygen vacancies [2], thus providing a fundamental link between strain state and oxygen vacancy density. With this link understood, in this work we demonstrate how interfacial magnetic and electronic properties can be fine-tuned by controlling oxygen vacancy ordering via heteroepitaxial strain and crystallographic orientation [3]. In particular, we show that manipulation of the ordering vector of the oxygen defect superstructure can induce dramatic improvements in strain relaxation and thus magnetic and transport properties.

Giant spin Hall effect induced by skew scattering from large SO impurities in copper *(Invited Paper)*

Yasuhiro Niimi, Yohei Kawanishi, Dahai Wei, Univ. of Tokyo (Japan); Cyrile Deranlot, Unité Mixte de Physique CNRS/Thales (France); Hongxing Yang, CEA (France); Mairbek Chshiev, CEA-LETI (France); Thierry Valet, In Silicio (France); Albert Fert, Unité Mixte de Physique CNRS/Thales (France) and Univ. Paris-Sud 11 (France); Yoshichika Otani, The Univ. of Tokyo (Japan) and RIKEN (Japan)

The spin Hall effect (SHE) is a key ingredient for future spintronic devices since it enables to convert charge currents into spin currents or vice-versa without ferromagnets and magnetic fields. Platinum is generally accepted to be the best SHE material exhibiting a spin Hall (SH) angle of a few percent. However it is a costly metal, unsuitable for the practical application. In this work, we have studied extrinsic SHEs in Cu-based

alloys such as CuIr and CuBi alloys, as alternative SHE materials.

To estimate the SH angle we have used two models; a purely 1D model and 3D spin transport model based on the Valet-Fert formalism. We found that for Pt and CuIr alloys whose spin diffusion lengths are smaller than the thickness, the SH angles obtained from the 1D and 3D models do not differ significantly (about 0.02). For CuBi alloys, on the other hand, the SH angle we obtain is much larger than that of Pt and CuIr, which is consistent with a recent ab-initio calculation. However the analysis in the 3D model gives a larger SH angle (-0.24 for 3D compared to -0.12 for 1D). The difference between the 1D and 3D models comes from the correction by the 3D model of the spreading of the spin accumulation over the sides of the contact when the spin diffusion length is relatively long. CuBi appears to be a very promising SHE material for spintronics.

8813-66, Session 17

Magnetic damping in nanometer-thick yttrium iron garnet films *(Invited Paper)*

Yiyan Sun, Young-Yeal Song, Zihui Wang, Houcheng Chang, Michael Kabatek, William Schneider, Mingzhong Wu, Colorado State Univ. (United States); Eric Montoya, Bartek Kardasz, Bret Heinrich, Simon Fraser Univ. (Canada); Helmut Schultheiss, Suzanne G. te Velthuis, John E. Pearson, Axel Hoffmann, Argonne National Lab. (United States)

Spin waves have garnered increased attention lately due to their potential use for low-power information processing. Towards this end, ferromagnetic insulators, such as yttrium iron garnet (YIG), are of high interest, since they offer very low damping for magnetization dynamics, and hence, long spin-wave life times and propagation distances. For practical applications, as well as for fundamental science studies there is high demand of very thin YIG films, which still preserve the advantageous properties of the bulk materials. Here we present the growth and characterization of nanometer-thick YIG films prepared by pulsed laser deposition (PLD), which were optimized to have magnetic damping that is only a factor of ten above intrinsic bulk values [1]. Combining these films with thin layers of Pt allows modulation of the damping via electric charge currents [2]. In this case the spin Hall effects in Pt [3] give rise to a net spin accumulation at the Pt/YIG interface, which then through interfacial spin scattering can exert a torque on the magnetization in the YIG layer, so that the damping is decreased or increased, depending on the charge current direction. Furthermore, the presence of Pt gives rise to an unexpected additional magnetic damping, which may be correlated with induced magnetic moments in the Pt layer.

Dynamic measurement of spin Hall effects in nonmagnetic/ferromagnetic bilayer films *(Invited Paper)*

Kouta Kondou, RIKEN (Japan); Hiroaki Sukegawa, Seiji Mitani, National Institute for Materials Science (Japan); Shinya Kasai, National Institute for Materials Science (Japan) and RIKEN (Japan); Yoshichika Otani, RIKEN (Japan) and The Univ. of Tokyo (Japan)

Spin Hall effect (SHE) is well known as an effective method for generating pure spin currents without using ferromagnetic materials. The ratio between input charge current density Jc and output spin current density Js is defined as spin Hall angle Js/Jc. Until now, several groups have reported different spin Hall angles for Pt using different measurement techniques. For example, L. Q. Liu et. al. have recently demonstrated the spin Hall angle determined by dynamic measurements based on spin torque ferromagnetic resonance (ST-FMR) in nonmagnetic/ferromagnetic bilayer films. However systematic experiments for quantitative evaluation of spin Hall angle is lacking. Therefore, we have systematically studied the film thickness dependence of Js/Jc in ST-FMR spectrum to estimate the exact value of spin Hall angles for Pt, Pd, Ta, Mo and Ru.

A theory of quantum dynamics of a nanomagnet under excitation *(Keynote Presentation)*

Lu Jeu Sham, Univ. of California, San Diego (United States)

A quantum treatment of magnetization dynamics of a nanomagnet between a thousand and a million spins may be needed as the magnet interacts with quantum control. The advantage of the all-quantum approach over the classical treatment of magnetization is the accounting for the correlation between the magnet and the control agent and the first-principles source of noise. This talk will concentrate on an overview of the theory with a presentation of the basic ideas which could have wide applications and illustrations with some results. Details of applications to specific models are or will be published elsewhere. A clear concept of the structure of the ground and excited macrospin states as magnetization rotation states and magnons in the Bloch/Dyson sense gives rise to a consistent theory of the magnetization dynamics of a ferromagnet modeled by the Heisenberg Hamiltonian. An example of quantum control is the spin torque transfer, treated here as a sequence of scatterings of each current electron with the localized electrons of the ferromagnet, yields in each encounter a probability distribution of the magnetization recoil state correlated with each outgoing state of the electron. This picture provides a natural Monte Carlo process for simulation of the dynamics in which the probability is determined by quantum mechanics. The computed results of mean motion, noise and damping of the magnetization will be shown.

Pulsed optical excitation of ordered spin systems in the weak excitation regime *(Invited Paper)*

Hiro Munekata, Kosuke Yamamoto, Takashi Mastuda, Kazuhiro Nishibayashi, Yoshitaka Kitamoto, Nozomi Nishizawa, Tokyo Institute of Technology (Japan)

Investigation of optical excitation of ordered-spin systems has given us the opportunity of pursuing fundamental limit for manipulation of magnetization as well as developing novel devices in optoelectronics and photonics, such as optical buffer memory and latchets. Photo-induced precession of magnetization is an interesting phenomenon in the sense that the energy of ultra-short laser pulses is stored in part for relatively long duration in a spin system in the form of precession. This phenomenon has been studied in various magnetic materials, including metals, semiconductors, and insulators. In this presentation, we are concerned with photo-induced precession of magnetization in ferromagnetic, ultra-thin Co/Pd multi-layer films at excitation fluence as low as 0.25 microJ/cm^2 per a laser pulse of 150 fs, the regime of low energy excitation. This has been achieved with the sample whose Co and Pd layer thicknesses are, respectively, 0.78 nm and 0.81 nm, in which magnetic property of meta-stable fcc Co layers is affected through the magnetic proximity effect in Pd layers. A model which connects precession amplitude and parameters associated with spin dynamics has been developed, through which efficiency of energy transfer between electron and spin sub-systems has been examined quantitatively. Thermal and non-thermal contributions in the weak excitation regime have also been examined in the time domain shorter than 10ps for both Co/Pd multi-layers and (Ga,Mn)As epitaxial layers, from which we point out that the thermal influence appears in the form of a tiny ultrafast demagnetization in the former whereas it is often absent in the later.

8813-70, Session 18

Reversal of magnetization of small magnetic particles by the ac field *(Invited Paper)*

Dmitry A. Garanin, Liufei Cai, Eugene M. Chudnovsky, Lehman College (United States)

Numerical and analytical studies of the magnetization reversal of a single-domain magnetic particle by a circularly polarized ac field of time-dependent frequency are performed. An advantage of the circular polarization is that magnetic field is precessing in sync with the magnetization thus providing a sustained reversal torque. For the time-linear frequency sweep, the phase diagrams are computed that illustrate the dependence of the reversal on the frequency sweep rate v, the amplitude of the ac field h, the magnetic anisotropy field d, and the damping parameter α. The necessary condition of the reversal is $h > \alpha d$. The maximal energy efficience is reached in the middle of this interval. Further, if the frequency sweep is too fast, the magnetization cannot follow and does not reverse. If the frequency sweep is too slow, an instability develops in the middle of reversal and reversal becomes uncontrolled. In the optimal case the spin is adiabatically following the frequency sweep so that it remains on resonance during the whole reversal. The most efficient magnetization reversal requires a nonlinear time dependence of the frequency, $\omega(t)$, for which an exact analytical formula is derived with account of damping. Implementation of a small-scale magnetization reversal is proposed in which a nanomagnet is electromagnetically coupled to two weak superconducting links controlled by the voltage. The dynamics of such a system is analyzed with account of the back effect of the magnet on the superconducting links that is shown to be detrimental for the reversal.

8813-110, Session 18

Current-induced spin polarization and the spin Hall effect in a clean bilayer system

Felix G. G. Hernandez, Leonardo M. Nunes, Gennady M. Gusev, Univ. de São Paulo (Brazil); Askhat K. Bakarov, A.V. Rzhanov Institute of Semiconductor Physics (Russian Federation)

The experimental demonstration of the spin Hall effect in a two-subband system is reported. The sample consist of a high mobility two-dimensional electron gas in a symmetric wide quantum well. The spatial dependence is studied by Kerr rotation as function of the external magnetic field using the applied electric field amplitude and direction as control parameters. We observe that the effect is robust in the bilayer structure leading to opposite spin accumulation near the edges of a Hall bar. We found an electrically controllable internal magnetic field (nonzero Rashba coefficient), a large spin Hall conductivity, and a mobility-enhanced spin diffusion constant in the Fermi liquid regime. The data was analyzed following both phenomenological and microscopic theoretical approaches and compared with experimental references of bulk samples in the single layer configuration.

8813-106, Session PWed

Multiferroic nanomagnetic logic: ultra low-power hybrid spintronics-straintronics

Mohammad Salehi Fashami, Noel D'Souza, Virginia Commonwealth Univ. (United States); Kamaram Munira, The Univ. of Alabama (United States); Avik Ghosh, Univ. of Virginia (United States); Supriyo Bandyopadhyay, Jayasimha Atulasimha, Virginia Commonwealth Univ. (United States)

It has been recently shown by the authors that multiferroic nanomagnets (consisting of a piezoelectric and a magnetostrictive layer) can serve as excellent bistable switches for digital information processing since they dissipate a mere ~100 KT per switching event at clock rates of ~1 GHz at room temperature. This is 3-4 orders of magnitude more energy efficient than CMOS. Such multiferroic nanomagnets can function as memory elements in isolation or be laid out in specific geometric shapes and patterns to implement logic gates through dipole coupling. Furthermore, they can implement associative memory elements and multi-state logic . This talk will focus on(i) the magnetization dynamics of such dipole-coupled multiferroic nanomagnets clocked by mechanical stress, modeled by solving the Landau-Lifshitz (LL) equations,(ii) We will theoretically demonstrate operation of a universal logic gate with fan-out and unidirectional logic flow in the gate,(iii) A preliminary study of the reliability of such gates, determined by solving the stochastic LL equations will also be presented , and (iiii) Finally, experimental progress on logic propagation in chains of stress clocked nanomagnets will be discussed.

Optical generation of spin imbalance in Si nanowires

Paulo E. Faria Jr., Univ. de São Paulo (Brazil); Guilherme M. Sipahi, Igor Zutic, Univ. de São Paulo (Brazil) and Univ. at Buffalo (United States)

In addition to its central role in conventional electronics, silicon has spin-dependent properties (such as long spin relaxation and decoherence times) that could be particularly useful in spin-based quantum-information processing and spintronics [1]. Unfortunately, its indirect band gap precludes using the standard optical methods of spin injection and detection in semiconductors. However, this obstacle can be removed in Si nanowires which display direct band gap and could also serve as

spin interconnects by modulating spin polarization [2]. Using the k.p method we study the feasibility of optical spin injection in Si nanowires and quantify the degree of spin polarization, given in terms of carriers and spin injection rates [3]. Supported by FAPESP and CNPq, US ONR, NSF-ECCS, DOE-BES, and NSF-NRI.

Crossed persistent spin helices *(Invited Paper)*

Carlos Egues, Univ. de São Paulo (Brazil)

In Rashba-Dresselhaus quantum wells with tuned couplings spin-density-wave patterns that are not susceptible to any type of spin-independent and/or electron-electron scatterings are possible. These long-lived persistent spin helices arise from the partial cancellation of the equal-strength Rashba and Dresselhaus spin-orbit terms which gives rise to a fixed spin quantization axis [1]. These robust excitations have been recently realized [2]. Two-subband quantum wells offer the possibility to obtain two distinctively gate-tunable Rashba couplings – including their signs – within a single system [3]. We have investigated the possibility for crossed persistent spin helices in realistic two-subband wells with orthogonal spin quantization axes for the first and second subband [4]. We find unique two-dimensional spin textures resulting from the coherent interference between the two crossed spin helices. We have performed a detailed self-consistent calculation of all relevant spin-orbit coupling parameters of our wells: i. e., the Rashba and Dresselhaus couplings within each subband and the corresponding intersubband couplings. We have also investigated the spin lifetime of the crossed spin helices. Interestingly, we find that for some parameter range the intersubband spin-orbit contributions can enhance the spin lifetimes. Transient spin grating spectroscopy [5] can, in principle, be used to probe these novel spin-density excitations. My collaborators in this work are J. Fu, P. H. Penteado, M. O. Hachiya, and D. Loss. This work has been supported by: CNPq, FAPESP and PRP/USP (Q-NANO).

Nonlocal formulation and dimensionality-crossover effects for spin Coulomb drag in low dimensional structures *(Invited Paper)*

Irene D'Amico, The Univ. of York (United Kingdom); Carsten A. Ullrich, Univ. of Missouri (United States)

In spintronic devices some sources of dissipation can be controlled, for example by reducing disorder, whereas others are intrinsic and hence unavoidable. This is the case for the spin Coulomb drag (SCD) effect [PRB-62-4853-2000], which occurs when different spin populations move with different velocities while exchanging momentum via Coulomb scattering: even without spin-flip mechanisms, a spin current will decay due to Coulomb interactions between different spin populations. As a consequence the SCD may significantly reduce spin diffusion [EPL-55-566-2001, Nature-437-1330-2005, Nature-Phys-8-153-2012], and cause intrinsic damping of collective spin-excitations [PRB-74-121303(R)-2006, PRL-109-166401-2012].

Here we focus on SCD as intrinsic damping of intersubband spin plasmons in semiconductor quantum wells. In earlier work [PRB-74-121303(R)-2006], the spin plasmon linewidth was calculated within a linear response formalism where the SCD was treated using a local density approximation (LDA). However recent experiments [PRL-109-166401-2012] show that this formalism, although giving the right order of magnitude, significantly overestimates the actual spin plasmon linewidth. Situations in which LDA breaks down may reveal new insights into the behavior of interacting quantum systems. The description of SCD line broadening of spin plasmons is such a case: as we show, the failure of LDA is related to the crossover between two-dimensional and three-dimensional behaviour of the intersubband dynamics in quantum wells. We derive a new formalism for the spin Coulomb drag which accurately includes both spatial inhomogeneity and quantizations in the growth direction. This new formulation is crucial to accurately and correctly model dissipation in low dimensional structures, where inhomogeneity and dimensionality-crossover effects are important.

Spin-photonic devices based on (110) quantum wells *(Invited Paper)*

Hitoshi Kawaguchi, Nara Institute of Science and Technology (Japan)

We fabricated a (110) VCSEL with GaAs/AlGaAs MQWs, and demonstrated circularly polarized lasing with a high degree of circular polarization at RT that originated from a long electron spin relaxation time (τs) [1]. Lasing was observed in the one circularly polarized mode over a wide wavelength range from 838 to 857nm, in which a degree of circular polarization higher than 0.8 was maintained [2].

We also investigated carrier lifetime (τc) and τs in (110) GaAs/AlGaAs MQW micro-posts and found that the long τs is preserved even when the sidewall boundaries with fast surface recombination are introduced and the τc is drastically shortened [3]. We precisely measured the τs in the microposts using a pump-probe technique. A long τs of 0.74ns was obtained even for 0.5τm posts in which the τc was drastically shortened to 27ps. Such long τs and short τc are suitable for fast switching of lasing circular polarizations in VCSELs [4].

Moreover, we fabricated a (110) p-i-n structure with a GaAs/AlGaAs MQW and demonstrated a tenfold modulation of the τs by an external electric field at RT [5].

Spin-orbit induced magnetoanisotropies in ferromagnet/semiconductor junctions *(Invited Paper)*

Jaroslav Fabian, Martin Gmitra, Alex Matos-Abiague, Univ. Regensburg (Germany); Claudia Draxl, Humboldt-Univ. zu Berlin (Germany)

Spin-orbit fields are phenomenological manifestations of spin-orbit coupling in materials and materials structures lacking space inversion symmetry, which is the majority of technologically important systems: metal surfaces, semiconductor interfaces, ferromagnetic tunnel junctions, graphene on a substrate, surfaces of topological insulators. They all have unique spin-orbit fields that determine spin relaxation, persistence spin helix, spin Hall conductivity, quantum spin Hall protection of the edge states, anisotropic magneto-transport, or magneto-optical phenomena, to name the most important. Each structure has its own spin-orbit field---a sort of spin-orbit DNA. The question is how to determine it for a general electron state and how to control it effectively. In this talk I present a solution for a Fe/GaAs interface which is important for electrical spin injection and magnetotransport tunneling and lateral transport experiments. The spin-orbit fields are extracted from first principles. I will demonstrate how the spin-orbit fields depend on the Fe magnetization orientation, which proves the concept of the magnetic control of spin-orbit coupling in general. I will also discuss related anisotropic magnetotransport experiments. I acknowledge funding from DFG SFB 689.

8813-76, Session 20

Spin transport in single and bilayer graphene *(Invited Paper)*

Gernot Guntherodt, Frank Volmer, Eva Maynicke, Mark Droegeler, Tsung-Yeh Yang, Julia Samm, Syed Rizwan Ali, Mihaita Popinciuc, Bernd Beschoten, RWTH Aachen (Germany); Jayakumar Balakrishnan, Ahmet Avsar, M. Zeng, J. Setiawan, Barbaros Özyilmaz, National Univ. of Singapore (Singapore)

Carrier mobilities over 100.000 cm2/Vs have excited strong interest in graphene for future electronics devices. Moreover, graphene is considered as a promising candidate for spintronics applications. The reason is the weak spin-orbit coupling, the absent hyperfine interaction and the observation of micrometer long spin relaxation lengths [1]. So far most spin transport studies have focused on single layer graphene (SLG). However, bilayer graphene (BLG) has unique electronic properties, which differ greatly from those of SLG by its effective mass of charge carriers, interlayer hopping and electric-field induced band gap. Our studies of spin transport in BLG as a function of mobility, minimum conductivity, charge carrier density and temperature reveal the importance of the D'yakonov - Perel' (DP)-type spin dephasing mechanism [2]. In BLG samples, the spin dephasing time scales inversely with the charge carrier mobility both at room temperature and at low temperatures. Spin dephasing times of up to 2 ns are observed in samples with the lowest mobility. Most remarkably, we observe also a similar inverse scaling of the spin dephasing times and the charge carrier mobility in SLG samples [3]. We demonstrate the role of adatoms and of tunneling vs. transparent Co/MgO/graphene contacts for the manipulation of the spin dephasing times.

A graphene solution to conductivity mismatch: spin injection from ferromagnetic metal/graphene tunnel contacts into silicon *(Invited Paper)*

Olaf M. van 't Erve, Connie H. Li, Adam Friedman, Enrique Cobas, Jeremy T. Robinson, Berend T. Jonker, U.S. Naval Research Lab. (United States)

We will show that a FM metal / monolayer graphene contact serves as a spin-polarized tunnel barrier contact which successfully circumvents the classic metal / semiconductor conductivity mismatch issue for electrical spin injection. We demonstrate electrical injection and detection of spin accumulation in Si above room temperature, and show that the corresponding spin lifetimes correlate with the Si carrier concentration, confirming that the spin accumulation measured occurs in the Si and not in interface trap states.

An ideal tunnel barrier should exhibit several key material characteristics: a uniform and planar habit with well-controlled thickness, minimal defect / trapped charge density, a low resistance-area product for minimal power consumption, and compatibility with both the FM metal and semiconductor, insuring minimal diffusion to/from the surrounding materials at temperatures required for device processing.

Graphene, offers all of the above, while preserving spin injection properties, making it a compelling solution to the conductivity mismatch for spin injection into Si. Although Graphene is very conductive in plane, it exhibits poor conductivity perpendicular to the plane. Its sp2 bonding results in a highly uniform, defect free layer, which is chemically inert, thermally robust, and essentially impervious to diffusion. The use of a single monolayer of graphene at the Si interface provides a much lower RA product than any film of an oxide thick enough to prevent pinholes (~ 1 nm).

Our results identify a new route to low resistance-area product spin-polarized contacts, a crucial requirement enabling future semiconductor spintronic devices which rely upon two-terminal magnetoresistance, including spin-based transistors, logic and memory.

Probing magnetic moment formation in graphene through the scattering of pure spin currents *(Invited Paper)*

Adrian Swartz, Kathleen McCreary, Wei Han, Jen-Ru Chen, Univ. of California, Riverside (United States); Jaroslav Fabian, Univ. Regensburg (Germany); Roland K. Kawakami, Univ. of California, Riverside (United States)

Graphene's two dimensional nature and high surface sensitivity have led to fascinating predictions regarding induced spin-based phenomena through careful control of adsorbates on the graphene surface, including the extrinsic spin Hall effect, band gap opening, and induced magnetism. By taking advantage of atomic scale control provided by MBE, we have investigated submonolayer deposition of adsorbates and their interactions with graphene. Spin transport measurements performed in-situ during systematic introduction of atomic hydrogen demonstrated that hydrogen adsorbed on graphene forms magnetic moments that couple via exchange to the injected spin current. The effects of induced magnetic moments are evident in the non-local magnetoresistance and Hanle spin precession. The observed behavior is quantitatively explained utilizing a phenomenological theory for scattering of pure spin currents by localized magnetic moments. Ar sputtering introduces lattice vacancies and demonstrated similar behavior, indicating that the origin of the induced moments are due to so called pz-orbital defects. On the other hand, experiments with charge impurity scatterers such as Mg, are noticeably absent of features related to magnetic moment formation. Furthermore, we observe effective exchange fields due to the spin-spin coupling between conduction electrons and magnetic moments, which are of interest for novel phenomena and spintronic functionality but have not been seen previously in graphene. The exchange fields cause increased spin precession leading to enhanced effective g-factors, which demonstrate a dependence on the electrostatic back gate voltage, and also leading to new interpretations of Hanle spin precession data and analysis.

Graphene magnetic tunnel junctions *(Invited Paper)*

Enrique Cobas, Adam L. Friedman, Olaf M. van 't Erve, Jeremy T. Robinson, Berend T. Jonker, U.S. Naval Research Lab. (United States)

Graphene has been shown to be an extraordinary material with record-setting room temperature conductivity and carrier mobility and spin diffusion lengths approaching 100um. However, most research has focused on its excellent in-plane transport properties, neglecting its very different out-of-plane properties. Graphene's 2D nature leads to poor inter-layer coupling and transport, highlighted by graphite's conductance anisotropy of 10,000:1. Graphene's discrete monolayer habit, thermal stability and lack of dangling bonds lend themselves to application as an ultra-thin tunnel barrier. It's lack of spin-orbit coupling promises applications in magnetic tunnel junctions. Moreover, recent band structure arguments predict excellent spin filtering across ferromagnet-graphene interfaces.

We will discuss our fabrication and measurements of ferromagnet-graphene-ferromagnet junctions utilizing NiFe, CVD-grown graphene and Co in a fully scalable photolithographic process. The junctions exhibit non-linear I-V transport properties with weak temperature dependence consistent with tunneling-transport devices. Moreover, we observe spin-polarized tunneling with the characteristic parallel-antiparallel switching of magnetic tunnel junctions. The tunneling magnetoresistance reaches two percent at low temperature and low bias but remains observable even at room temperature. The effect exhibits the expected asymmetric bias dependence due to the different materials on either side of the graphene and its temperature dependence is examined and fitted well using a temperature-dependent modification of the Julliere model previously published by Shang et al.

This work demonstrates the application of graphene as a tunnel barrier in the out-of-plane direction both for charge and spin-polarized charge and has implications for electronics and spintronic devices, including tunnel transistors, magnetic tunnel junctions and spin-transfer torque devices.

8813-80, Session 21

Ultrafast spin-polarized vertical-cavity surface-emitting lasers *(Invited Paper)*

Nils C. Gerhardt, Henning Höpfner, Mingyuan Li, Hendrik Jähme, Ruhr-Univ. Bochum (Germany); Thorsten Ackemann, Univ. of Strathclyde (United Kingdom); Martin R. Hofmann, Ruhr-Univ. Bochum (Germany)

Spin-polarized lasers are highly attractive spintronic devices providing characteristics superior to their conventional purely charge-based counterparts. Spin-polarized vertical-cavity surface emitting lasers (spin-VCSELs) promise to offer lower thresholds, enhanced emission intensity, spin amplification, full polarization control, chirp control and ultrafast dynamics. In particular, the ability to control and modulate the polarization state of the laser emission with extraordinarily high frequencies is very attractive for many applications like broadband optical communication and ultrafast optical switches.

After briefly reviewing the state of research in this emerging field of spintronics, we present a novel concept for ultrafast spin-VCSELs which has the potential to overcome the conventional speed limitation for directly modulated lasers and to reach modulation frequencies significantly above 100 GHz. The concept is based on the coupled spin-photon dynamics in birefringent micro-cavity lasers. By injecting spin-polarized carriers in the VCSEL, oscillations of the coupled spin-photon system can by induced which lead to oscillations of the polarization state of the laser emission. These oscillations are decoupled from conventional relaxation oscillations of the carrier-photon system and can be much faster than these. Utilizing these polarization oscillations is thus a very promising approach to develop ultrafast spin-VCSELs for high speed optical data communication in the near future.

Different aspects of the spin and polarization dynamics, its connection to birefringence and bistability in the cavity, and the limitations of this novel approach will be analysed theoretically and experimentally for spin-polarized VCSELs at room temperature.

8813-81, Session 21

Electrical helicity switching with dual-electrode Fe/AlOx/GaAs-based spin-LED *(Invited Paper)*

Nozomi Nishizawa, Hiro Munekata, Tokyo Institute of Technology (Japan)

Spin light emitting diode (spin-LED) would be a device with great possibility in view of a new circular polarized light (CPL) source aiming at future applications such as all-optical magnetic writing, 3-D display, and chiral resolution. For practical application, realization of electrical helicity switching without using an external magnetic field is one of key issues. Reported here is the demonstration of electrical helicity switching using one spin-LED chip having two ferromagnetic Fe electrodes with different coercive force prepared on a GaAs-based double heterostructure (DH) incorporating a 500-nm thick $In_{0.03}Ga_{0.97}As$ active layer. The DH has an AlOx tunneling barrier layer on top of it. Electrical helicity switching has been realized by electrically selecting one of the two Fe electrodes with antiparallel magnetization configuration, as has manifested itself in electroluminescence (EL) extracted from cleaved side-wall of spin-LED. In fact, EL spectra at 5 K have exhibited opposite sign of circular polarization (CP), reflecting antiparallel configuration; the magnitude of circular polarization from one particular device has been P_{circ} = +14 % and -7 %. CP was observed up to around 70 K. When we switched between the two electrodes, a clear helicity switching between right and left polarization was observed, whereas, when passing current simultaneously through two electrodes, P_{circ} ~ 0. This fact can be understood in terms of mixing two opposite circular polarization, yielding linearly polarized light. Tuning the current ratio between two electrodes has yielded smooth conversion between circular and linear polarization.

8813-82, Session 21

Semiconductor optical isolators for integrated optics *(Invited Paper)*

Hiromasa Shimizu, Tokyo Univ. of Agriculture and Technology (Japan)

Optical isolators are one of the indispensable devices to protect semiconductor laser diodes (LDs) from backward reflected light in integrated optics. In order to realize optical isolators, nonreciprocal propagation of light (breaking of time inversion symmetry) is necessary, which can be realized by magnetic materials. Conventional optical isolators are composed of Faraday rotators and two polarizers. Ferrimagnetic garnets are widely used as magneto-optic materials exhibiting Faraday rotation. However, these optical components are not compatible with integrated optics. Therefore, semiconductor optical isolators for integrated optics have been strongly desired. Recently, these integrated optics have been expected on Si as well as III/V waveguides in order to integrate them with electronic driving circuits in optical transmitters and receivers. Semiconductor optical isolators, where semiconductor and ferromagnetic materials are integrated, are one of the most important applications in spin-optics.

We have developed semiconductor optical isolators based on nonreciprocal loss, where the ferromagnetic metals are deposited on semiconductor optical amplifier (SOA) waveguides. Ferromagnetic metals provide the optical isolation owing to the transverse magneto-optic Kerr effect, and the SOA gain compensates the propagation loss by the ferromagnetic metals. We have demonstrated optical isolation of 14.7 dB/mm 1), monolithic integration with LDs 2), and optical isolation with amplifying characteristics 3). These advantages of semiconductor optical isolators are promising for integrated optics.

8813-83, Session 21

Experiment and simulation of spin resolved photoconductivity in mesoscopic devices *(Invited Paper)*

Steven K. Clowes, Juerong Li, Univ. of Surrey (United Kingdom); Adam M. Gilbertson, Imperial College London (United Kingdom); Konstantin L. Litvinenko, Univ. of Surrey (United Kingdom); Lesley F. Cohen, Imperial College London (United Kingdom)

Optical orientation of spins using modulated circularly polarised light provides a highly sensitive technique to study spin dependent transport in mesoscopic semiconductor devices. Recently, we have reported on two studies where this technique was successful in electrically detecting the spin orientation of photo-excited electrons. The mechanics behind these measurements is that in weak magnetic fields the charge carrying electrons exhibit spin sensitive cyclotron motion in the highly spin-orbit coupled materials that are used. This demonstrated a potential route of exploiting spin filtering effects in non-magnetic semiconductors.

In addition to this experimental work, simulations of these spin sensitive signals have been performed using a classical billiard ball model, which included both spin precession and a spin-dependent electron energy. These simulations used an iterative approach to entwine the spin and orbital motion, and as such required a conservation of energy approximation. In this paper, we compare this simple model with the results of a fully entwined semi-classical approach which does not include this energy approximation. We have also incorporated into the model the effects of electrical gates by including a spatially varying Rashba interaction, which would make possible fast control of spin. We will present the results of these new simulations, including a discussion how they compare to experimental measurements and the potential for new device designs.

8813-105, Session 21

High-performance spintronic computing with magnetoresistive semiconductor heterojunctions *(Invited Paper)*

Joseph S. Friedman, Northwestern Univ. (United States)

Manipulation of the spin degree of freedom provides an opportunity for substantial improvements in computing efficiency. While spintronic memory is already making its way into consumer products, spintronic logic faces additional challenges. Unlike memory, in which a device needs to have two stable and distinct states, logic has the additional requirement of cascading: the output of each logic gate must be capable of driving the input of several similar logic gates. This feature has proven difficult to implement and a major impediment to the development of spintronic processors.

Two recently invented logic families, spin-diode logic and emitter-coupled spin-transistor logic, provide an opportunity for high-performance cascaded logic circuits. These logic families make use of magnetoresistive semiconductor heterojunctions, in which the presence of a magnetic field causes a major increase in resistance. The state of the device can be controlled through the magnetic field created by a nearby current to perform logical operations. This phenomenon is exploited by placing two control wires alongside a magnetoresistive heterojunction diode or transistor, permitting these control wires to function as logical inputs. The output currents of these devices are connected to the inputs of similar devices to produce cascaded logic circuits.

Spin-diode logic and emitter-coupled spin-transistor logic produce highly compact circuits with superb speed and power characteristics. In particular, circuits realized in these logic families use three to ten times fewer devices than conventional CMOS. Additionally, there is minimal dynamic power dissipation, presenting a pathway for low power high performance computing beyond 10 GHz.

8813-84, Session 22

Spins and pseudospins in graphene *(Invited Paper)*

Roland Winkler, Northern Illinois Univ. (United States); Ulrich Zuelicke, Victoria Univ. of Wellington (New Zealand)

Recently atomically flat layers of carbon known as graphene have become the rising star in spintronics as their electrons carry not only the ordinary spin degree of freedom, but they also have a pseudospin degree of freedom tied to the electrons' orbital motion which could enable new routes for spintronics.

Here we focus on bilayer graphene (BLG). Using group theory we have established a complete description of how electrons in BLG interact with electric and magnetic fields. We show that electrons in BLG experience an unusual type of matter-field interactions where magnetic and electric fields are virtually equivalent: every coupling of an electron's degrees of freedom to a magnetic field is matched by an analogous coupling of the same degrees of freedom to an electric field. This counter-intuitive duality of matter-field interactions allows novel ways to create and manipulate spin and pseudo-spin polarizations via external fields that are not available in other materials.

8813-85, Session 22

Silicene: from epitaxial growth toward technological applicability *(Invited Paper)*

Patrick Vogt, Technische Univ. Berlin (Germany); Andrea Resta, Aix-Marseille Univ. (France) and CINaM - Ctr. Interdisciplinaire de Nanoscience de Marseille (France); Thomas Bruhn, Aix-Marseille Univ. (France) and CINaM - Ctr. Interdisciplinaire de Nanoscience de Marseille (France) and Technische Univ. Berlin (Germany); Paola De Padova, Istituto per lo Studio dei Materiali Nanostrutturati (Italy); Guy Le Lay, Aix-Marseille Univ. (France) and CINaM - Ctr. Interdisciplinaire de Nanoscience de Marseille (France) and Istituto per lo Studio dei Materiali Nanostrutturati (Italy)

Since the discovery of graphene and the tremendous advancement in this field of research enormous efforts have been invested to search for other similar 2-dimensional materials, especially silicene. Silicene, a 2D structure of Si atoms in a honeycomb-like arrangement, shares essentially the same electronic properties as graphene, namely an electronic linear dispersion resembling that of relativistic Dirac fermions. Despite these similarities to graphene, silicene would not only differ in terms of chemical reactivity but tuning of the electronic band gap or spintronic applications, such as spin-filters, have been suggested for gated silicene layers, opening novel applications for these 2D materials.

We could show recently that monolayer epitaxial silicene can be synthesized a silver (111) templates. In this case the atomic structure turns out to be more complex and is influenced by the substrate surface. Meanwhile, other orientations of silicene on Ag(111) and the formation of silicene on another metallic substrate have been discussed in literature.

Based on these results we have grown silicene multilayer structures which can be explained by stacking of single silicene layers. We will discuss the atomic structure and the electronic properties of this layered system and compare the strong similarities of these silicene stacks to graphite.

The formation of silicene multi-layer structure opens new possibilities to solve one puzzling problem for the technological applicability: the exfoliation of stand-alone silicene layers.

Spin-valley coupling in atomically thin dichalcogenides *(Invited Paper)*

Xiaodong Cui, The Univ. of Hong Kong (Hong Kong, China)

Motivated by the triumph and limitation of graphene for electronic applications, atomically thin layers of group VI transition metal dichalcogenides are attracting extensive interest as a class of graphene-like semiconductors with a desired band-gap in the visible frequency range. The monolayers feature a valence band spin splitting with opposite sign in the two valleys located at corners of 1st Brillouin zone. This spin-valley coupling, particularly pronounced in tungsten dichalcogenides, can benefit potential spintronics and valleytronics with the important consequences of spin-valley interplay and the suppression of spin and valley relaxations.

Here we report the first optical studies of WS2 and WSe2 monolayers and multilayers. The efficiency of second harmonic generation (SHG) shows a dramatic even-odd oscillation consistent with the presence (absence) of inversion symmetry in even (odd) layer. Photoluminescence (PL) measurements show the crossover from an indirect band gap semiconductor at mutilayers to a direct-gap one at monolayers. The PL spectra and first-principle calculations consistently reveal a spin-valley coupling of 0.4 eV which suppresses interlayer hopping and manifests as a thickness independent splitting pattern at valence band edge near K points. This giant spin-valley coupling, together with the valley dependent physical properties, may lead to rich possibilities for manipulating spin and valley degrees of freedom in these atomically thin 2D materials.

8813-87, Session 22

Optical manipulation and electrical control of valley pseudo-spins in atomically thin semiconductors *(Invited Paper)*

Sanfeng Wu, Xiaodong Xu, Univ. of Washington (United States)

Electronic valleys are energy extrema of Bloch bands in momentum space. Analogous to the electron spin degree of freedom, valley indices can be considered as pseudospins for new modes of electronic and photonic device operation. In this talk we will discuss experimental progress on the investigation of these pseudospins using atomically-thin semiconductors (MoS2, WSe2 etc.), which are either monolayer or bilayer group VI transition metal dichalcogenides. Using MoSe2 as an example, we first show that these new 2D semiconductors exhibit remarkable excitonic effects with a large (30meV) trion binding energy. By applying a gate voltage, we demonstrate the electrostatic tunability of charging effects in positively charged, neutral, and negatively charged excitons via photoluminescence. We further show that these excitons are associated with valley pseudospins and can be addressed by specific light helicity. This demonstration of optical preparation of valley-pseudospins arises from the inversion-symmetry breaking in monolayer samples. Using inversion-symmetric bilayer samples, we are able to investigate the feasibility of on/off switching and continuous tuning of the valley pseudo-spins by breaking the inversion symmetry through vertical gate electric fields. We show that the circularly polarized photoluminescence can be tuned from -15% to 15% as a function of gate voltage and can be well explained as resulting from the continuous variation of valley magnetic moments. Therefore, we show that these new 2D semiconductors not only behave as remarkable excitonic systems, but also provide an ideal platform for realizing the optical manipulation and electrical control of valley degrees of freedom.

8813-88, Session 23

Magnetic field controlled reconfigurable logic gates with integrated nanomagnets *(Invited Paper)*

Mark B. Johnson, U.S. Naval Research Lab. (United States); Jin Dong Song, Korea Institute of Science and Technology (Korea, Republic of); Jinki Hong, Korea Univ. (Korea, Republic of); Joonyeon Chang, Korea Institute of Science and Technology (Korea, Republic of)

We describe the development of a magnetic logic device that is uniquely different from spintronic approaches based on magnetoresistive effects that derive from spin dependent transport of carriers. The core of our device is a thin film avalanche diode channel fabricated as a p-n bilayer. Because of the structural asymmetry, the carriers are sensitive to an in-plane magnetic field and the diode has a large magnetoresistance. We characterize our device as a current switch. The high- and low-current states are well defined and are determined by the magnetic field. A field of constant value and positive or negative orientation is an appropriate selector. We then describe an integrated avalanche diode logic device in which the magnetic field is provided by the local fringe field of a patterned ferromagnetic film with nanometer dimensions. The magnetization orientation of the nanomagnet, and the sign of the magnetic field, is set by spin torque transfer (STT) using small amplitude current pulses. We describe how simple arrangements of these integrated devices can be used as dynamically reconfigurable logic gates. Reconfigurable Boolean AND/OR gates using early prototype structures with micron dimensions are shown. Scaling arguments that justify the plausibility of fabricating an integrated device with dimensions of 100 nm are presented. These arguments suggest that such a device could have current gain, capable of driving STT write processes in spintronic circuits.

8813-89, Session 23

Soft x-ray microscopy: facing the mesoscale challenge in magnetism *(Invited Paper)*

Peter Fischer, Mi-Young Im, Lawrence Berkeley National Lab. (United States)

Over the last decade magnetism research focused on a fundamental understanding and controlling spins on a nanoscale. The next step beyond the nanoscale will be governed by mesoscale phenomena , since they are expected to add complexity and functionality, which are essential design parameters e.g. for the realization of future spintronic devices. The development and application of multidimensional visualization techniques, such as tomographic imaging and the investigations of fast and ultrafast spin dynamics will play key roles in achieving mesoscience goals.

Soft X-ray spectromicroscopy offers the unique combination of high spatial and temporal resolution, elemental specificity, and magnetic sensitivity by using the strong X-ray dichroism effect in the soft x-ray regime as magnetic contrast. Three-dimensional (3D) soft X-ray tomography using Fresnel zone plate based transmission soft x-ray microscopies is routinely used at synchrotron sources but almost exclusively for biological imaging. 3D imaging of magnetic structures is of large interest to understand e.g. interfaces in magnetic multilayers, the inner structure of magnetic nanocrystals, nanowires or the functionality of artificial 3D magnetic nanostructures. In this talk we will discuss the opportunities and limitations of new analytical approaches for magnetic x-ray tomography by presenting first results obtained with a new tomographic setup at the full-field soft x-ray microscope at the Advanced Light Source in Berkeley.

The collaboration with D. Rueffer, A. Fontcuberta i Morral , Th. Schwarze, R. Huber, D. Grundler, D. Makarov, R. Streubel, , J. Lee and S.-K. Kim is highly appreciated.

Supported by DOE BES MES Contract No. DE-AC02-05-CH11231.

8813-90, Session 23

Spin wave logic devices for general and special task data processing *(Invited Paper)*

Alexander Khitun, Univ. of California, Riverside (United States)

Spin wave logic devices constitute a type of magnetic logic exploiting spin waves for information transmission and processing. The utilization of waves for data transmission makes it possible to code logic 0 and 1 in the phase of the propagating wave, use waveguides as passive logic elements for phase modulation and exploit wave interference for achieving logic functionality. In this talk, we describe the current status of spin wave logic devices and present most recent experimental data. We also discuss the possibility of building Boolean and special task data processing circuits exploiting spin waves.

8813-91, Session 23

Magnetic bipolar junctions devices for spin logic applications at room temperature *(Invited Paper)*

Bruce W. Wessels, Northwestern Univ. (United States)

Narrow gap III-V semiconductors have been investigated for semiconductor spintronics. By alloying these semiconductors with manganese, magnetic semiconductors result. Giant magnetoresistance has been observed in narrow gap magnetic semiconductor p-n heterojunctions. The giant magnetoresistance which is positive is attributed to spin selective carrier scattering in the magnetic semiconductor. For a InMnAs/InAs heterojunction diodes a giant magnetoresistance of 2680 % is observed at room temperature. This work indicates that highly spin-polarized magnetic semiconductor heterojunctions can be realized that operate at room temperature. Devices based on the giant magnetoresistance include spin diodes and bipolar magnetic junction transistors. We utilize the diode magnetoresistance states to create a binary spin logic family.

8813-92, Session 24

Theory of electromechanical coupling in dynamical graphene *(Invited Paper)*

Mircea Trif, Pramey Upadhyaya, Yaroslav Tserkovnyak, Univ. of California, Los Angeles (United States)

Graphene has become one of the most remarkable existing materials, hosting a plethora of exotic effects, such as Klein tunneling, the half-integer quantum Hall effect, {it zitterbewegung} etc. All of these effects are consequences of the low-energy Dirac spectrum exhibited by the electronic quasiparticles, even though the underlying theory is nonrelativistic. This two-dimensional (2D) material is embedded in a three-dimensional (3D) space, which allows for large out-of-plane displacements (limited by surface tension and a weak bending rigidity). The electronic properties are sensitive to such mechanical distortions, offering new pathways for controlling both the charge and valley degrees of freedom. In this paper we study the coupling between the Dirac electrons and the time-dependent elastic distortions in graphene, for a general 3D excitation of the lattice. We show, using time-dependent perturbation theory, that the effective gauge field resulting from the electromechanical coupling has four contributions, two of which are quasistatic and the other two being dynamic. The quasistatic gauge field is due to both strain and curvature, while the dynamic gauge field arises due to translations and rotations of the local atomic orbitals, and vanish in the static case. We find that the quasistatic and dynamic gauge fields can become comparable in magnitude for finite frequencies and, in particular, such couplings can be of relevance for valleytronics effects in graphene, as the mechanical fluctuations mediate an indirect coupling between charge and valley degrees of freedom.

8813-93, Session 24

Spin pumping at Permalloy/graphene interfaces *(Invited Paper)*

Enrique del Barco, Simranjeet Singh, Univ. of Central Florida (United States); Ajit Patra, National Univ. of Singapore (Singapore); Brett Barin, Univ. of Central Florida (United States); Barbaros Özyilmaz, National Univ. of Singapore (Singapore)

We present evidence of large spin relaxation effects in CVD graphene observed by means of ferromagnetic resonance (FMR) measurements of Permalloy/graphene (Py/Gr) films. A substantial increase of the FMR linewidth in the Py/Gr film, as compared to the Py film alone, is interpreted in terms of an enhancement of the Gilbert damping in the ferromagnetic layer as a consequence of spin pumping at the Py/Gr interface, which is driven by the Py magnetization dynamics (i.e. precession of the magnetization induced by the microwave stimulus at resonance). The remarkable increase in the FMR linewidth compares with observations in other bilayer systems in where thick layers (thicker than the spin diffusion length) of heavy metals with strong spin-orbit interaction are employed as the non-magnetic layer. Our results indicate that spin relaxation in CVD graphene must be greatly enhanced in order to account for the losses of angular momentum in the ferromagnet. We will also present a comparative study of the Gilbert damping in Py/NM films employing highly ordered pyrolitic graphene as the non-magnetic layer, for which a more moderate broadening of the FMR linewidth is observed.

8813-94, Session 24

Graphene as a spin channel for spintronic based logic *(Invited Paper)*

Abdelmadjid Anane, Bruno Dlubak, Marie-Blandine Martin, Pierre Seneor, Albert Fert, Unité Mixte de Physique CNRS/Thales (France)

Electronic devices based on spin transport will play a major role in future Information and Communication Technologies (ICT), to that respect, they are fully considered in the ITRS road map. Spin information processing requires the ability to inject, manipulate and detect spins. Yet, it was soon understood that this concept will be very difficult to achieve with conventional semiconductors (GaAs or Si).

Here we will present a set of results on an alternative route where the channel is no longer a conventional semiconductor but graphene. Graphene is expected to be a good candidate for spin information transport : its mobility at room temperature outperforms that of any other material and its spin orbit coupling as well as its hyperfine interaction are expected to be very small. Using high quality multilayer graphene grown on SiC wafers together with finely tuned Al2O3 tunnel barrier, we experimentally demonstrate using spin transport experiments in the lateral spin-valve geometry that the spin diffusion length is at least of the order of 100 µm [1]. The spin signal obtained is in the MW range and the spin channel efficiency is as high as 75%. Our results make experimentally relevant theoretical propositions for spin logic devices [2]. An overview of the latest experimental results as well as the theoretical framework governing spin injection in graphene will be presented.

Structural optimization of MTJs with a composite free layer *(Invited Paper)*

Alexander Makarov, Viktor A. Sverdlov, Siegfried Selberherr, Technische Univ. Wien (Austria)

Magnetoresistive random access memory with spin transfer torque (STT-MRAM) is a promising candidate for future universal memory. However, improvement regarding the essential parameters is still needed. Finding alternative architectures for magnetic tunnel junction (MTJ) structures is of considerable importance for the success of STT-MRAM. A MTJ with a composite free layer (C-MTJ) was proposed in our early work. The free magnetic layer of such a structure consists of two equivalent parts of half-elliptic form separated by a narrow non-magnetic spacer. The C-MTJs demonstrate a substantial decrease of the switching time and switching current as compared to the standard MTJ with the monolithic free layer.

In this work, we perform the structural optimization of C-MTJs by means of extensive micromagnetic simulations and propose a new structure of the composite free layer, C2-MTJ. In a C2-MTJ the free layer consists of the two ellipses with the major axes a/2 and b (a>2b) inscribed into a rectangle a x b. This structure is easier to fabricate as compared to the previous generation of C-MTJs. We investigated the switching statistics depending on the geometry. We find that the new C2-MTJ switches as fast as the previous one, which is 2 times faster than the structure with a monolithic free layer, without loss of thermal stability. The narrow switching time distribution characteristic of C-MTJs is also preserved in C2-MTJs. Therefore, the newly proposed C2-MTJ offers greater potential for performance optimization of STT-MRAM devices.

8813-96, Session 25

Magnetic circular dichroism in (Ga,Mn)As and what it tells us about its band structure *(Invited Paper)*

Margaret Dobrowolska, Xinyu Liu, Jacek K. Furdyna, Univ. of Notre Dame (United States); Mona Berciu, The Univ. of British Columbia (Canada); Kin Man Yu, Wladek Walukiewicz, Lawrence Berkeley National Lab. (United States)

GaMnAs is a ferromagnetic semiconductor that is considered to be an ideal candidate for spintronic applications. However, despite a decade of research, the properties of GaMnAs are still not fully understood, thus preventing strategies for optimizing the preparation procedures of GaMnAs with Curie temperatures sufficiently high for realistic device applications. This talk will address the unresolved issue of ferromagnetism in GaMnAs, focusing on the question of whether the ferromagnetic order in this material is mediated by valence band holes or by holes residing in an impurity band. The results to be presented are based on the study of a wide range of GaMnAs samples, using a comprehensive set of experiments that include magnetic circular dichroism, magnetization, and electrical transport measurements, along with studies of microscopic composition by channeling Rutherford back-scattering and particle-induced x-ray emission. These experiments show unambiguously that the holes underlying ferromagnetic order in GaMnAs reside in the impurity band; and that it is not only the concentration of Mn and of holes that establishes the Curie temperature of this material, but also the specific location of the Fermi level in the impurity band. Since the location of the Fermi level can be controlled by a variety of means both during and after growth, this new understanding automatically leads to important insights and guidelines for increasing the critical temperature of this material.

8813-97, Session 25

Introducing and manipulating magnetic dopant exchange interactions in III-V semiconductor nanowires *(Invited Paper)*

Manu Hegde, Ian D. Hosein, Shokouh S. Farvid, Pavle V. Radovanovic, Univ. of Waterloo (Canada)

Control of electron spins in transition metal-doped semiconductor nanostructures has considerable potential for spintronics. Specifically, diluted magnetic semiconductor nanowires (DMS-NWs) are promising building blocks for the bottom-up assembly of functional devices, and may enable microscopic understanding of the origin of transition-metal dopant spin ordering in semiconductors. However, the control of dilute magnetic interactions has largely been restricted to low temperatures, limiting their potential technological applications.

In this talk I will review our recent work on the synthesis, and spectroscopic and magnetic properties of manganese-doped III-V NWs. Using high-resolution circularly polarized X-ray microscopy imaging we directly showed intrinsic magnetization of manganese dopants in individual GaN NWs at room temperature, and demonstrated the dependence of the manganese exchange interactions on the NW orientation relative to the external magnetic field. The NW anisotropy allows for the control of dilute magnetization in a single NW. A comparison between the single and ensemble NW spectroscopic and magnetic measurements suggests co-deposition of Mn secondary phases alongside nanowires, which can lead to erroneous conclusions about the origin of magnetic ordering. An extension of these measurements to other nanostructured DMS systems will also be discussed. The application of bottom-up approaches, such as in-situ nanowire growth control or targeted positioning of individual NWs, allows for the design of networks for quantum information technologies.

8813-98, Session 25

Imaging spin wave with micro-Brillouin light scattering *(Invited Paper)*

Xiaoqin Li, The Univ. of Texas at Austin (United States)

The continuing demands of advancing information storage and processing technologies have attracted much attention to spin waves in magnetic microstructures. Numerous experiments have demonstrated that spin waves play an important role in the operation of spin torque based memory devices and spin torque nano-oscillators. In addition, several spintronic devices based on propagating spin waves have been proposed, such as the spin wave bus and a Mach Zehnder-type interferometer for performing logic operations. We investigate fundamental properties of spin waves via Micro-Brillouin Light Scattering technique. I will discuss two examples in this presentation. In the first example, we observed a surprising oscillatory behavior when measuring the decay length of spin waves in a Permalloy thin film excited by an asymmetric coplanar antenna. The oscillations can be modeled as the interference between a propagating spin wave and a background magnetization with spatially uniform phase. Calculations suggest that this interference arises from nonlocal characteristics of the magnetization susceptibility and is largely independent of the antenna geometry. In the second example, we demonstrate that magnon spectra can be used as a local temperature sensor. The frequency shift of magnon spectra provides an absolute temperature scale. The capability of characterizing magnon temperature is critical for understanding thermally driven spin transport in magnetic thin films, essential for the emerging field of spin caloritronics.

8813-99, Session 26

Spintronics of weakly spin-orbit coupled semiconductors *(Invited Paper)*

Christoph M. Boehme, The Univ. of Utah (United States)

While the term “Spintronics” was originally introduced as label for technologies that represent information through spin states rather than charge states, it is nowadays oftentimes used solely in the context of spin-polarization, spin-injection, spin-transport and spin-orbit effects. Carbon based semiconductors display only weak spin-orbit coupling and - in the case of organic semiconductors - charge transport via hopping through strongly localized states. These materials appear at first glance therefore to be entirely unsuitable for spintronics. However, they also exhibit spin related effects not seen in materials with strong spin-orbit coupling which can be used for an alternative, different approaches to spintronics based on spin-permutation symmetry states of charge carrier pairs rather than spin-polarization states. Reading spin-permutation symmetry is straight forward when pronounced spin-selection rules exist. In contrast to spin-polarization, permutation symmetry does not depend directly on temperature and magnetic field strength. Furthermore, the absence of spin-orbit coupling can also allow for long spin-coherence times and thus, the possibility to connect spintronics to an all spin based memory which may be applicable to spin-based quantum information concepts. While spin-orbit coupling is needed in traditional spintronics for electric field controlled spin-manipulation, low-spin-orbit coupled devices may achieve the same via electric field controlled spin-exchange interaction. In this talk, our work on the development of this alternative organic spintronics concept will be presented and the state of its experimental implementation will be discussed.

8813-100, Session 26

Measurement of spin-flip scattering time and photon echo response in GaMnAs *(Invited Paper)*

Kimberley C. Hall, Murat Yildirim, Sam A. March, Reuble Mathew, Angela Gamouras, Dalhousie Univ. (Canada); Xinyu Liu, Margaret Dobrowolska, Jacek K. Furdyna, Univ. of Notre Dame (United States)

The III-V diluted magnetic semiconductors (DMS) offer the ability to actively tune ferromagnetic characteristics through control of the hole population using electrical gates or optical excitation, making these materials attractive for a whole host of magneto-sensitive semiconductor devices. Despite this promise, open questions remain regarding the fundamental properties of these materials due to the complex interplay of defect-induced localization and exchange coupling. Here we demonstrate the power and flexibility of femtosecond four-wave mixing spectroscopy for investigating the electronic structure and magnetic properties of DMS. Spectrally-resolved four-wave mixing measurements on GaMnAs indicate that (s,p)-d hybridization leads to optical signatures in the nonlinear emission spectrum consistent with an enhancement in the valence band density of states [1], in agreement with local tight-binding calculations [2]. Direct measurement of the interband dephasing kinetics using time-resolved four-wave mixing provides an upper bound on the time scale for spin-flip scattering between holes and Mn ions of 40 fs [3], providing new insight into exchange coupling in this system. We also show that the interband response exhibits the characteristic signatures of a photon echo, despite the presence of defect-induced band tailing.

Giant collective spin-orbit field in quantum wells: fine structure of spin plasmons *(Invited Paper)*

Carsten A. Ullrich, Univ. of Missouri (United States); Irene D'Amico, The Univ. of York (United Kingdom)

Spin-orbit (SO) coupling is a relativistic quantum mechanical effect which contributes to the fine structure splitting of atomic spectral lines. In extended solids, SO coupling causes many important phenomena which can be quite different from the atomic case. For instance, itinerant electrons in doped semiconductors have a distribution of momenta, and each electronic spin precesses in its own momentum-dependent SO field (leading to the D'yakonov-Perel' dephasing of nonequilibrium spin distributions). However, many-body effects can lead to a striking collective reorganization of the SO fields, causing an electronic behavior like in a macroscopic quantum object. Intersubband spin plasmons in quantum wells are subject to a giant collective SO field that splits the spin-plasmon spectrum into a triplet. This theoretically predicted effect [1] is experimentally verified [2] using inelastic light scattering in the presence of magnetic fields for an asymmetrically doped GaAs quantum well. We also demonstrate the same effect for spin waves in a CdMnTe quantum well. These results provide a powerful indication that these constructive phenomena are universal to collective spin excitations of conducting systems. We also demonstrate that spin plasmon damping is dominated by the spin Coulomb drag effect [3].

8813-102, Session 26

Spins in silicon MOSFETs: electron spin relaxation and hyperpolarization of nuclear spins *(Invited Paper)*

Cheuk Chi Lo, Univ. College London (United Kingdom); Christoph D. Weis, Lawrence Berkeley National Lab. (United States); Johan van Tol, National High Magnetic Field Lab. (United States); Jeffrey Bokor, Univ. of California, Berkeley (United States); Thomas Schenkel, Lawrence Berkeley National Lab. (United States); John J. L. Morton, Univ. College London (United Kingdom)

The spin degree of freedom of both mobile and localized electrons in silicon have extraordinary long spin relaxation times, making silicon an attractive candidate for spintronics applications and quantum information processing. In this talk, we will discuss recent results in measuring the conduction electron spin relaxation and coherence times in silicon MOS systems using electrically detected magnetic resonance. We will also discuss an all-electrical donor nuclear spin polarization method in silicon by exploiting the tunable interaction of donor bound electrons with conduction electrons, and achieve over two orders of magnitude nuclear hyperpolarization at T=5K and B=12T with an in-plane magnetic field. Both nuclear hyperpolarization and antipolarization can be achieved when operating the device in the quantum Hall regime with an out-of-plane magnetic field*. Our results demonstrate that donor nuclear spins can be initialized through local gate control of electrical currents without the need for optical excitation, enabling the implementation of nuclear spin qubit initialization in dense multi-qubit arrays.

8813-103, Session 26

Discontinuous envelope function in semiconductor heterostructures *(Invited Paper)*

Henri-Jean Drouhin, Ecole Polytechnique (France); Federico Bottegoni, Politecnico di Milano (Italy); Hoai T. L. Nguyen, Institute of Physics (Viet Nam); Jean-Eric Wegrowe, Ecole Polytechnique (France); Guy Fishman, Univ. Paris-Sud 11 (France)

The notions of probability current and of spin current play central roles when dealing with transport properties. The notion of spin current is

known to be complicated due to the existence of source terms. However, even the notion of probability current raise a number of questions in systems described by an effective Hamiltonian which contains cubic or higher order momentum terms. In previous papers, we have shown that including spin-orbit interaction induces drastic changes in the properties of the related current operators and implies revisiting the boundary conditions satisfied by the wave functions.1-5 We have given a systematic construction of the probability-current operator ˆJ, based on an effective Hamiltonian written as a ˆp-power series expansion and we have proposed an extension of the envelope function technique to comply with current conservation. We have put into light the simple structure of the extra terms. In the present paper, we relate these new current operators to several transport currents involving charge, spin, and angular momentum. We discuss transport properties of model systems in this context and we connect the results to phenomenological thermokinetics descriptions. This provides practical tools which are valuable for spin engineering of heterostructures.

8813-104, Session 26

Multifunctional Mn1.5Ga films with ultrahigh coercivity, giant perpendicular magnetocrystalline anisotropy and large magnetic energy product *(Invited Paper)*

Jianhua Zhao, L. J. Zhu, S. H. Nie, K. K. Meng, D. Pan, H. Z. Zheng, Institute of Semiconductors (China)

Magnetic materials with high coercivity, perpendicular magnetic anisotropy and magnetic energy product have great application potential in ultrahigh-density perpendicular magnetic recording media, high-performance permanent magnets and ferromagnetic electrodes of spintronic devices with high magnetic-noise immunity and thermal stability. Our experiments demonstrate how novel fabrication of epitaxial films of Mn1.5Ga on GaAs can simultaneously achieve desirable tunable perpendicular coercivity, perpendicular magnetocrystalline anisotropy and magnetic energy product, all at room temperature.

Conference 8814: Carbon Nanotubes, Graphene, and Associated Devices VI

Wednesday - Thursday 28–29 August 2013

Part of Proceedings of SPIE Vol. 8814 Carbon Nanotubes, Graphene, and Associated Devices VI

8814-1, Session 1

Development of an analytical bond order potential for C-H-Cu systems

Xiaowang Zhou, Bryan M. Wong, Donald K. Ward, Sandia National Labs., California (United States)

Carbon nanostructures (nanotubes, nanoribbons, and ordered sheets) continue to attract widespread attention due to their unique properties and use in next-generation electronics. The performance of these materials is critically affected by the defects. Unfortunately, the detailed mechanisms of defect formation during nanostructure growth are either unknown or very poorly characterized. Direct molecular dynamics simulation of nanostructure growth provides powerful means to study defect formation from theories without any prior assumptions regarding the defect formation mechanisms. Such simulations, however, are extremely difficult to achieve requiring the interatomic potential used in the simulations to be transferrable, at least qualitatively, to any configurations that can possibly form on the growth surface. Here we describe our recent efforts on developing an analytical order potential for C-H-Cu systems aiming at enabling direct molecular dynamics simulations of graphene growth on Cu substrate through chemical reactions (i.e., the vapor fluxes are composed of various C-H molecules).

8814-3, Session 1

Different techniques for characterizing single-walled carbon nanotube purity

Neslihan Yuca, Zeyneb Camtakan, Nilgün Karatepe, Istanbul Technical Univ. (Turkey)

Single-walled carbon nanotubes (SWCNTs) have exceptional strength and stiffness and high thermal and electrical conductivity, making them promising candidate (or nanomaterials) in numerous applications, including hydrogen storage, probe tips, quantum wires, and electronic devices. However, they often need to be produced with high purity, especially with defined properties and controlled structures, such as length, diameter, chirality, and so forth. Chemical vapor deposition method has been developed to produce CNTs with high yield while it is still very difficult to get carbon nanotubes pure enough. Transition-metal catalysts, fullerenes, graphitic carbon, amorphous carbon, and graphite flakes are the main impurities in carbon nanotubes.

The purpose of this study was to develop a simple purification process for SWCNTs, along with an understanding of the purification process. In addition, uncomplicated analytical methods were sought to screen and compare various purification methods. We demonstrated an easy and optimum method of cleaning SWCNTs and evaluating their purity. The purification method, which employed oxidative heat treatment followed by 6M HNO_3, H_2SO_4, HNO_3:H_2SO_4 and HCl acid reflux for 6h at 120°C and microwave digestion with 1.5M HNO_3 for 0.5h at 210°C, was straightforward, inexpensive, and fairly effective. Also, it was shown that a combination of thermal gravimetric analysis and nuclear techniques such as NAA and XRF as quantitative screening tools and XRD for the structure analysis to determine the relative purity of SWCNTs.

8814-4, Session 1

Carbon nanotube synthesis with different support materials and catalysts

Fatih Gumus, Nilgün Karatepe, Neslihan Yuca, Istanbul Technical Univ. (Turkey)

Having remarkable characteristics, carbon nanotubes (CNTs) have attracted a lot of interest. Their mechanical, electrical, thermal and chemical properties make CNTs suitable for several applications such as electronic devices, hydrogen storage, textile, drug delivery etc. CNTs have been synthesized by various methods, such as arc discharge, laser ablation and catalytic chemical vapor deposition (CCVD). In comparison with the other techniques, CCVD is widely used as it offers a promising route for mass production. High capability of decomposing hydrocarbon formation is desired for the selected catalysts. Therefore, transition metals which are in the nanometer scale are the most effective catalysts. The common transition metals that are being used are Fe, Co, Ni and their binary alloys. The impregnation of the catalysts over the support material has a crucial importance for the CNT production.

In this study, the influence of the support materials on the catalytic activity of metals was investigated. CNTs have been synthesized over alumina (Al_2O_3), silica (SiO_2) and magnesium oxide (MgO) supported Fe, Co, Fe-Co catalysts. Catalyst – support material combinations have been investigated and optimum values for each were compared. Single walled carbon nanotubes (SWCNTs) were produced at 800° C. The duration of synthesis was 30 minutes for all support materials. The synthesized materials were characterized by thermal gravimetric analysis (TGA), Raman spectroscopy and transmission electron microscopy.

In this study, the influence of the support materials on the catalytic activity of metals was investigated. CNTs have been synthesized over alumina (Al_2O_3), silica (SiO_2) and magnesium oxide (MgO) supported Fe, Co, Fe-Co catalysts. Catalyst – support material combinations were investigated and optimum values for each were compared. Single walled carbon nanotubes (SWCNTs) were produced at 800° C, whereas multi walled carbon nanotubes (MWCNTs) were synthesized at 500° C. The duration of synthesis was 30 minutes for all temperatures and support materials. The synthesized materials were characterized by thermal gravimetric analysis (TGA), Raman spectroscopy and transmission electron microscopy.

8814-5, Session 1

Hydrogen and carbon nanotube production via catalytic decomposition of methane

Cansu Deniz, Yalova Univ. (Turkey); Nilgün Karatepe, Istanbul Technical Univ. (Turkey)

Owing to an increasing world population and demands for higher standards of living and better air quality, the future energy demand is expected to increase significantly. Hydrogen is considered as an energy carrier due to its high conversion efficiency and low pollutant emissions. It can be produced from various sources and transformed into electricity and other energy forms with a low pollution.

The catalytic decomposition of hydrocarbon has been seen as a really useful method for production of pure hydrogen and for the environmental concern. The objective of this study was to assess the impact of catalyst composition and processing parameters on CO_x–free hydrogen production and to produce an available solid form of co-product carbon as carbon nanotubes via catalytic decomposition of methane. The optimum experimental conditions for methane decomposition have been investigated. Fe, Co and Ni are used as catalysts (nanomaterials) over different substrates as SiO_2 and MgO to produce hydrogen at optimum temperatures.

8814-6, Session 2

The role of H2 reduction in the growth of single-walled carbon nanotube

Nilgün Karatepe, Neslihan Yuca, Fatih Gumus, Istanbul Technical Univ. (Turkey)

Carbon nanotubes (CNTs) have attracted considerable attention due to their suitability in potential applications. CNTs have high electronic and thermal conductivity and excellent mechanical strength along their axis, which depends on their diameter, length and chirality. The exact growth mechanism of CNTs has been a progressing effort to understand the growth of CNTs. In the synthesis of CNTs it is clear that hydrogen is an essential element having been implicated in a number of surface morphology changes of the catalyst.

In this study we focused on chemical state and morphology of the catalyst which induces growth of SWCNTs directly from iron catalyst on magnesium oxide support material using chemical vapor deposition method . We reported on the effect of hydrogen gas introduced before and/or during the synthesis of SWCNTs. The synthesis conditions were selected as: catalyst calcination temperatures of 500 and 700°C, calcination time of 30 and 45 minutes, hydrogen concentrations of 50 and 100 % vol, synthesis temperature of 800°C and synthesis time of 30 minutes. The synthesized materials were characterized by thermogravimetric analysis (TGA), XRD and XPS. Effect of H2 reduction on catalyst calcination and CNT synthesis were investigated

8814-7, Session 2

Nitrogen doped graphene band gap engineering by chemical vapor deposition

Isaac Ruiz, Wei Wang, Zafer Mutlu, Mihrimah Ozkan, Cengiz S. Ozkan, Univ. of California, Riverside (United States)

Much attention and excitement has revolved around graphene since the University of Manchester first isolated small flakes in 2004. Being the first 2D material ever observed pristine graphene has demonstrated to have remarkable optical, electrical, mechanical and thermal properties that are expected to one day revolutionize science and technology. One unique property is the cone shaped conduction and valence bands that converge at the K points of the Brillouin zone, which give graphene it remarkable mobility values but also zero bandgap. In order to utilize graphene devices to their full potential a band gap needs to be opened and one proposed method of opening a band gap is through doping. Here a one-step process for synthesizing graphene and substitutionally nitrogen doped graphene (N-graphene) by chemical vapor deposition on thin copper foils is presented. It is demonstrated that the doping concentration can be a controlled by varying the dopant gas exposure time during the growth. The doping concentration and doping uniformity is determined by X-ray Photoelectron Spectroscopy (XPS), and is further confirmed by Raman Spectroscopy and Raman Mapping. Scanning Electron Microscopy (SEM) and Atomic Force Microscopy (AFM) also determine the uniformity and quality of the prepared graphene samples once transferred on 300nm SiO2/Si substrates. Finally it is shown that by doping graphene, a bandgap can be opened while still having respectable electron mobility by measuring the performance of a graphene MOSFET.

8814-8, Session 2

Industrial metrology of doped graphene sheets

Maziar Ghazinejad, Jennifer Reiber Kyle, Shirui Guo, Mihrimah Ozkan, Cengiz S. Ozkan, Univ. of California, Riverside (United States)

We report the implementation of fluorescence quenching microscopy (FQM) for quick visualization of doping in large regions of graphene. Through reactive ion plasma etching, patterns of p-type graphene, doped with fluorine, are generated. We employ 4-(dicyanomethylene)-2-methyl-6-(4-dimethylaminostyryl)-4H-pyran (DCM) as the fluorescent agent. The emission of DCM is quenched to a different extent by fluorinated and pristine graphene, which provides the fluorescence-imaging contrast essential for this metrology. Fluorescence images of dye-coated graphene distinctly reveal the difference between the doped and as-grown regions. The pristine graphene quenches the DCM emission more efficiently than the fluorinated graphene. Therefore, the regions with pristine graphene appear darker on the fluorescence images than the regions with fluorinated graphene, enabling large-scale mapping of the functionalized regions in CVD grown graphene sheets. Steady-state and time-resolved absorption and emission spectroscopy are used to comparatively characterize the photophysical properties of the dye when immobilized in PMMA films coating bare glass, pristine graphene, and fluorinated graphene. We observe that a three-fold increase in the in the rate constant of non-radiative decay is the principal reason for the DCM fluorescence quenching for the graphene regions of the samples. The spectral overlaps reveal the propensity for energy transfer from DCM to graphene, causing the increase in the rates of non-radiative deactivation of the photo excited dye. Due to its simplicity and consistent results, FQM is now poised for widespread adoption by graphene manufacturers as a basis for facile and high throughput metrology of large-scale graphene sheets.

8814-9, Session 2

Effects of substrate tilt angle and process tube position on graphene layers

Zafer Mutlu, Isaac Ruiz, Hamed Hosseini Bay, Mihrimah Ozkan, Cengiz S. Ozkan, Univ. of California, Riverside (United States)

Graphene, with unique electrical, optical and mechanical properties is a promising material in industrial applications, such as batteries, supercapacitors, transistors and semiconductor devices. These potential applications of graphene have motivated the development of large-scale synthesis of graphene on copper substrates by chemical vapor deposition (CVD). To enable practical applications of large-area, high quality graphene layers at the centimeter and wafer scales, process control needs to be implemented for optimizing the morphology and electrical properties and enable repeatable growth-cycle of graphene layers for process-line implementation. Here we investigate the effects of process tube position and substrate tilt angle on the optical, morphologic and electronic properties of graphene layers. Furthermore, we describe a procedure for process optimization of the growth parameters. Graphene is grown on copper foils or nickel foils by a chemical vapor deposition technique, and transferred to the SiO2/Si and glass substrates. The detailed characterization of the graphene layers are conducted using Raman spectroscopy, optical microscopy (OM), scanning electron microscopy (SEM) and UV-vis spectroscopy. The experimental results show that the position of copper foil into the quartz tube plays a significant role in the Raman features of the graphene, and influences the optical and morphology properties of graphene layers. In addition, the growth process on the tilted copper foils promotes the uniformity of graphene due to geometrical fluidic dynamics. We believe that these results will be useful for determining the optimum processing conditions of high quality graphene layers at the centimeter and wafer scales.

8814-10, Session 2

Large area graphene growth optimization using fluid mechanics

Jeffrey Bell, Univ. of California, Riverside (United States)

Chemical Vapor Deposition (CVD) is a useful method for synthesis of large area graphene sheets. Pulling knowledge from various disciplines of engineering, we investigated a method for optimizing process conditions for large area synthesis of graphene using Fluid Mechanics. Altering the fluid mechanics of the system resulted in shorter growth times yet still achieving the same uniform high quality graphene previously achieved with a standard recipe. The benefit of reducing growth times translates to an industrial scale, allowing for graphene to become produced on a large scale efficiently and timely. Through our experimental procedures, synthesis of uniform, large area graphene could be grown on Cu foil at 1000 C for 3 minutes with a H2 flow rate of 60 sccm, CH4 flow rate of 30 sccm, Argon flow rate of 60 sccm, total pressure of 20 torr and a slow cooling rate of 25 C a minute.

8814-39, Session 2

3D laser micro fabrication of single-wall carbon nanotube/polymer composite microstructures

Shota Ushiba, Satoru Shoji, Kyoko Masui, Osaka Univ. (Japan); Junichiro Kono, Rice Univ. (United States); Satoshi Kawata, Osaka Univ. (Japan)

We demonstrated 3D laser micro fabrication of single-wall carbon nanotube (SWCNT)/polymer composites. Our approach allows one to fabricate three-dimensional SWCNT/polymer composites with a minimum spatial resolution of a few hundreds nm. A near-infrared femtosecond pulsed laser beam was focused onto a SWCNT-dispersed photo resin, and the laser light solidified a nanometric volume of the resin through two photon photopolymerization. The focus spot was three-dimensionally scanned, resulting in the fabrication of arbitrary shapes of the composites. SWCNTs were uniformly distributed throughout the whole structures. We also found that SWCNTs were aligned in polymer nanostructures.

8814-11, Session 3

Sb2Te3-coated multiwalled carbon nanotube arrays for thermoelectric power waves *(Invited Paper)*

Seunghyun Hong, Wonyoung Kim, Seong-Jae Jeon, Seongchu Lim, Hoo-Jeong Lee, Sungkyunkwan Univ. (Korea, Republic of); Seungmin Hyun, Korea Institute of Machinery & Materials (Korea, Republic of); Young Hee Lee, Seunghyun Baik, Sungkyunkwan Univ. (Korea, Republic of)

Multi-walled carbon nanotubes coated by cyclotrimethylene trinitramine (MWCNT/TNA) have recently demonstrated the direct conversion of chemical energy to electricity known as thermoelectric power waves. However, the Seebeck coefficient of carbon nanotubes still needs to be enhanced to produce greater electrical potential. Here we present Sb2Te3-coated MWCNT arrays by a simple sputtering method [1]. By combining Sb2Te3 with a greater Seebeck coefficient, the Seebeck coefficient of the annular multi-shell structure could be enhanced by ~75%. Resultantly, the heterostructure coupled with exothermic chemical reaction of TNA demonstrated an increase in peak electrical potential by 175 % (~198 mV), compared with typical outputs of bare MWCNT/TNA (~72 mV) [1].

8814-12, Session 3

Zinc oxide/carbon nanotube based nanocomposite for electrochemical supercapacitors

Badekai Ramachandra Bhat, National Institute of Technology, Karnataka (India); Aravinda L. S. Bhat, National Institute of Technology Karnataka (India); Udaya Bhat, National Institute of Technology, Karnataka (India)

The usage of fossil fuels to meet the demands of energy leading to global warming and resource depletion, hence there is a need for the development of improved methods of energy storing systems and retrieving it whenever we required. Electric double layer capacitors (EDLCs) consisting of carbon based electrode materials like activated carbon, carbon aerogels and carbon nanomaterial in which charge storage is exclusively electrostatic. On the other hand metal oxides and conducting polymers exhibit pseudocapacitance behavior due to fast faradaic process but due to low electrical conductivity of the metal oxides limit its use as supercapacitor electrodes. To overcome this problem, nanocomposites electrode materials for EDLCs and pseudocapacitors have been studied. Various transition metal oxides CNT composites have been studied, out of which Ruthenium oxide (RuO2) based capacitors show high capacitance and high specific power, but due to its high cost and toxicity limit their use. So it is important to develop low cost metal oxide as substitute.

Here in we report a facile route for the synthesis of ZnO decorated carbon nanotubes (CNTs) using Microwave irradiation method. This composite material was investigated for its supercapacitance property in non-aqueous electrolyte. A symmetric double layer super capacitor stack was fabricated by using carbon paper as electrodes. The investigation of the capacitance property of the fabricated super capacitor stack was investigated using cyclic voltammetry, chronopotentiometry and electrical impedance spectroscopy studies. The composite material shows an improved capacitance of 42 Fg-1 compared with the CNTs with better electrochemical reversibility.

8814-13, Session 3

Nanoporous graphene sponge for supercapacitor electrodes

Hamed Hosseini Bay, Wei Wang, Univ. of California, Riverside (United States); Zafer Mutlu, Univ of California, Riverside (United States); Paige Romero, Mihrimah Ozkan, Cengiz S. Ozkan, Univ. of California, Riverside (United States)

Graphene is a unique two dimensional material with exceptional physical and chemical properties. The theoretical surface area of graphene is reported to be 2630 m2g-1, which is significantly higher than activated carbons, graphite and single-walled carbon nanotubes. As a result, graphene and graphene based composite materials have been of great interest for various applications in energy storage/production. Accordingly, owing to its high surface area, graphene is a decent candidate as an electrode in electrochemical supercapacitors. Recent studies indicate that graphene demonstrates the highest capacitance among all carbon-based electrodes for supercapacitors. Moreover the graphene sheets surface is readily accessible by electrolyte. Herein, to increase the capacitance of graphene as well as the power and energy density, a novel porous 3-dimensional graphene-based structure is synthesized by a modified CVD method. In this case, no chemical treatment or activation is necessary and the process is not subjective to particular catalyst substrates. To prepare precursor materials for such structure, a modified sol-gel process has been implemented. Nanostructure samples were characterized by Raman Spectroscopy, Optical Microscopy, Scanning Electron Microscopy, Transmission Electron Microscopy and BET technique. Cyclic voltammetry measurements were also carried out and the results suggest that the use of 3-dimensional nanoporous graphene sponge as electrodes for supercapacitors can be a potential way to achieve enhanced gravimetric capacitance as well as higher energy and power density.

8814-14, Session 4

Supercapacitor electrode based on mixtures of graphite and carbon nanotubes *(Invited Paper)*

Paolo Bondavalli, Thales Research & Technology (France)

This contribution deals with the fabrication of electrodes and supercapacitor cells using a new dynamic air-brush deposition technique. We analyze the effect of mixtures of CNTs and graphite on the electrode and cell properties (energy, power and capacitance) and observe that with a mixture of 75% of graphite and 25% of CNTs, we increase the power by a factor 2.5 compared to bare CNT-based electrodes. This effect is not linked to an increase of the electrodes conductivity, as pointed out in previous papers, but on the mesoporosity of the composites. This is reached thanks to the fact nanotubes tend to act as spacer between the graphite flakes and so enhance the surface but also achieve an optimized mesoporous network. We also analyze the effect of the electrodes' weight first on the capacitance and specific energy and second on the specific power. We report a specific power of 200kW/Kg and a specific energy of 9.1Wh/Kg with electrodes having a surface of 2cm^2 and a weight of 0.25mg composed by 50% of CNTs and graphite (using a common aqueous electrolyte). Our deposition technique delivers supercapacitors with ad-hoc characteristics, by simply modulating the weight and the concentration of the CNT/graphite mixture in a completely reproducible way and with an industrially suitable and low-cost method.

8814-15, Session 4

CNT/PEDOT:PSS nanocomposite based thermoelectric device *(Invited Paper)*

Woochul Kim, Hoon Kim, Sung-Geun Park, Yonsei Univ. (Korea, Republic of)

In this study, PEDOT:PSS which is well-known conducting polymer, and single-walled carbon nanotube which has good electrical conductivity, are used to make a thermoelectric nanocomposite. A novel device architecture was proposed, what we called the spacer-inserted thermoelectric device. Performance of the device was measured and analyzed. The device was used to harvest human body heat. We expect that this new device architecture based on the SWCNT/PEDOT:PSS could be used to recover low quality waste heat recovery.

8814-16, Session 4

Pillared graphene and silicon nanocomposite architecture for anodes of lithium ion batteries

Wei Wang, Isaac Ruiz, Zachary J. Favors, Aaron S. George, Robert Ionescu, Dennis Pleskot, Mihrimah Ozkan, Cengiz S. Ozkan, Univ. of California, Riverside (United States)

In this work, we successfully demonstrated the fabrication of a hybrid carbon-silicon composite nanostructure via using a sputtering evaporation system. Three dimensional pillared graphene nanostructure was grown on metal substrates through a one-step chemical vapor deposition (CVD) by introducing a mixture precursor gases (H2, C2H4). The as-grown carbon nanostructure can be potentially used for the electrodes of energy storage devices such as supercapacitors and battery. We further explored sputtering evaporation system to uniformly deposited a layer of amorphous silicon on the as grown 3D carbon nanostructure. The surface morphologies were investigated by scanning electron microscopy (SEM), transmission electron microscopy (TEM). The results demonstrated relatively homogeneous and densely packed 3D hybrid carbon-silicon nanostructure with a very high porosity. Cyclic voltammetry, charge-discharge, and electrochemical impedance spectroscopy (EIS) are conducted to determine the performance of the 3D hybrid carbon-silicon nanostructure for lithium ion battery anode. The lithium-ion battery based on this hybrid carbon-silicon nanostructure shows a high specific capacity of ~3000 mA h g-1. This hybrid carbon-slicon nanostructure offers a facile and binder-free technique to obtain high capacitive lithium ion battery anodes.

8814-17, Session 4

Covalently functionalized single-walled carbon nanotubes and graphene composite electrodes for pseudocapacitor application

Pierre L. Le Barny, Thales Research & Technology (France); Bernard Servet, Thales Research and Technology (France); Stephane Campidelli, IRAMIS (France); Paolo Bondavalli, Christophe Galindo, Thales Research & Technology (France)

The use of carbon-based materials in electrochemical double-layer supercapacitors (EDLC) is currently being the focus of much research. Even though activated carbon (AC) is currently the state of the art electrode material, AC suffers from some drawbacks including its limited electrical conductivity, the need for a binder to ensure the expected electrode cohesion and its limited accessibility of its pores to solvated ions of the electrolyte. Owing to their unique physical properties, carbon nanotubes (CNTs) or graphene can overcome these drawbacks. It has been demonstrated that high specific capacitance could be obtained when the carbon accessible surface area of the electrode was finely tailored by using graphene combined with other carbonaceous nanoparticles such as CNTs(1).In this work, to further increase the specific capacitance of the electrode, we have covalently grafted onto the surface of single-walled carbon nanotubes (SWCNTs) or graphene oxide (GO), a series of anthraquinone (AQ) derivatives which are electrochemically active materials. The modified SWCNTs (AQ-SWCNT) or GO (AQ-GO) have been characterized by Raman spectroscopy and X-ray photoemission. Then these carbonaceous materials have been transformed into bucky papers by filtration of a solvent nanomaterial suspension, leading to a self-supporting electrode having a pseudocapacitor behavior. We report here for the first time the electrochemical behavior of bucky papers obtained by filtration of mixtures of AQ-SWCNT AQ-GO suspensions.

8814-33, Session PWed

Improvement in photo-induced charge separation utilizing conjugated ZnO quantum dots and carbon nanomaterials

Dong Ick Son, Won Kook Choi, Korea Institute of Science and Technology (Korea, Republic of)

We report on the successful conjugation of carbon nanomaterials on the surface of ZnO quantum dots (QD) and their application in multi-layer structured ultraviolet (UV) photovoltaic (PV) devices. In situ growth of carbon nanomaterials on the surface of ZnO QDs with a core-shell structure was realized via a mild solution-process method, which resulted in an improvement in photo-induced charge separation and transport of carriers to the collecting electrodes in a fabricated device. The conjugation of the C60 to ZnO QDs or graphene to ZnO QDs leads to a PL quenching of about 71% and 99%, which can be attributed to an efficient transfer of photo-induced electrons from the ZnO QDs to the C60 or from the ZnO QDs to the graphene through a Zn-O-C chemical bonding.

8814-34, Session PWed

Simulation of Au particle interaction on graphene sheets

Angus R. Mcleod, Queensland Univ. of Technology (Australia) and Commonwealth Scientific and Industrial Research Organisation (Australia); Kristy C. Vernon, Queensland Univ. of Technology (Australia); Amanda E. Rider, Kostya Ostrikov, Commonwealth Scientific and Industrial Research Organisation (Australia) and The Univ. of Sydney (Australia)

The interaction of Au particles with few layer Graphene is of interest for the formation of the next generation of sensing devices (Rider, Kumar et al. 2012). In this project we investigate the coupling of single gold nanoparticles to a Graphene sheet, and multiple gold Nanoparticles with a Graphene sheet using COMSOL Multiphysics. By using these simulations we are able to determine the electric field strength and

associated hot-spots for various gold Nanoparticle-Graphene systems. The Au Nanoparticles were modelled as 8nm diameter spheres on a 1.5nm thick (5 layers) Graphene, with properties of Graphene obtained from the refractive index data from (Weber, Calado et al. 2010) and the Au refractive index data from Palik.

The field was incident along the plane of the sheet with polarisation tested for both s and p. The study showed little interaction between the Au and Graphene itself with limited evidence of coupling; however the double particle case where the Graphene sheet separated two Au nanoparticles showed distinct interaction between the particles and graphene. An offset was introduced (up to 4nm) resulting in much reduced coupling between the opposed particles as the distance apart increased. Findings currently suggest that the Graphene layer has limited interaction with incident fields with a single particle present whilst reducing the coupling region to a very fine area when opposing particles are involved. It is hoped that the results of this research will provide insight into Graphene-Plasmon interactions and spur the development of the next generation of sensing devices.

8814-36, Session PWed

Graphene-doped zinc oxide gas sensor

Kanika Anand, Ravi Chand Singh, Guru Nanak Dev Univ. (India); Manmeet Pal Singh, Khalsa College of Engineering & Technology (India)

In this work we have fabricated thick film gas sensors based on graphene doped zinc oxide. The samples were synthesized by in situ reduction of graphene oxide with the formation of zinc oxide nanostructures. Gas sensing properties of the synthesized samples have been investigated at different operating temperatures and gas concentrations. The results indicate that the graphene doped zinc oxide exhibits high sensitivity. Formation of p-n heterojunctions were proposed as the sensing mechanism underlying the enhanced sensitivity of this hybridized gas sensor. Photoluminescence study was performed to find potential application as photoelectric material. The X-ray diffraction (XRD) and field emission scanning electron microscopy (FESEM) were also done for morphological investigations.

8814-37, Session PWed

Boron-doped graphene by chemical vapor deposition

Isaac Ruiz, Mihrimah Ozkan, Cengiz S. Ozkan, Univ. of California, Riverside (United States)

Graphene has stimulated a vast amount of research into 2D materials due to the unique properties graphene has been able to demonstrate. Although new 2D materials such as h-Boron Nitride are beginning to capture much attention, graphene still has much room for research. One important aspect to consider in order further reveal the full applicable potential of graphene is the effects of substitutional doping of graphene. Although there has been much study of nitrogen doped graphene by various methods including, chemical, plasma and epitaxial, there has not been an extensive study of the affect of boron doped graphene. In this study the first synthesis of p type Boron doped graphene by chemical vapor deposition using boron trichloride as a precursor gas. The substitutionally boron doped graphene is confirmed by X-ray photoelectron spectroscopy. The affects of different boron concentrations on the Raman spectra of graphene are studied. Conductive atomic force microscopy is also use to demonstrate the presence and affects of the boron doping.

8814-38, Session PWed

Sodium manganese oxide nanowires for high stability sodium ion battery cathode

Robert Ionescu, Wei Wang, Univ. of California, Riverside (United States)

As the society tends to move towards more efficient and low cost energy resources, a new way of achieving relatively low cost energy storage will be to change our Li-ion battery dependency to a more friendly and abundant resource such as Sodium. Sodium ion batteries will be a new approach of achieving low cost energy storage applications. In this work, an innovative NaxMnyO2 compound nanowire was produced though a hydrothermal process and the as-synthesized nanowires can be used as a cathode material for sodium storage. Hallow carbon nanotubes are introduced in the system as an anode material. Cyclic voltammetry, charge-discharge, and electrochemical impedance spectroscopy (EIS) are conducted to determine the performance of the NaxMnyO2 compound nanowire for sodium ion battery cathode. The sodium-ion battery based on this innovative NaxMnyO2 compound nanostructure shows a high specific capacity with long cycling stability.

8814-18, Session 5

Selective detection of homemade TATP and precursors with CNTFET arrays *(Invited Paper)*

Gilles A. Feugnet, Paolo Bondavalli, Thales Research & Technology (France); Fabrice Pardo, Lab. de Photonique et de Nanostructures (France); Céline Frenois, Commissariat à l'Énergie Atomique (France)

This paper deals with the demonstration of low cost Carbon Nanotube Field Effect transistors (CNTFETs) for TATP and precursor detection. Such devices exploit the extremely sensitive change of the Schottky barrier heights between carbon nanotubes (CNTs) and drain/source metal electrodes. Indeed the main effect is related the gas adsorption creating an interfacial dipole that modifies the metal work function and so the bending and the height of the Schottky barrier at the contacts with the CNTs. This change is strictly dependent of the metal/CNTs junction and of the gas involved. Thus to reach sufficient selectivity, the sensor includes on the same chip an array of 4 CNTFETs composed of 4 different metals (Pd, Pt, Au, Ti) leading to the measurement of a very specific sort of electronics fingerprinting. We will expose results obtained when such sensors are exposed to vapor of TATP, peroxide as well as interferent such a toluene or home-care cleaning product.

8814-19, Session 5

Humidity and temperature investigation in electrical transport properties through random multi-walled carbon-nanotubes networks *(Invited Paper)*

Ibtissem Oueriemi, Univ. Catholique de Louvain (Belgium)

Due to their high surface area to volume ratio, carbon nanotubes (CNTs) have been extensively investigated to enhance the sensitivity of humidity sensors. In this work, multi-walled carbon nanotubes (MWCNTs) were randomly deposited in gaps of microstrip interdigitated capacitive (IDC) structure. I-V measurements and RF characteristics were performed. These experimental results clearly demonstrate the non-linear behaviour of the MWCNTs films. Furthermore, we show that the temperature and humidity have a tremendous impact on the electrical transport in multi-walled carbon nanotubes (MWCNTs) networks. The resistance increases with relative humidity from 30% to 95%. The humidity sensing mechanisms are discussed. The carbon nanotubes junctions may play a more important role in the overall resistance change for water molecule

absorption. The temperature effect of the CNT films on resistance changes cannot be neglected.

The environment sensitivity of carbon nanotubes network indicate it promise as a kind of Humidity and Temperature sensitive material. This study is of importance to master and explore the non-linear behaviour and the environment sensitivity for new potential applications of CNT-based electronic devices.

8814-20, Session 5

Current transport in graphene tunnel field effect transistor under constant electric field

M. S. Fahad, Ashok Srivastava, Louisiana State Univ. (United States); Ashwani K. Sharma, Clay Mayberry, Air Force Research Lab. (United States)

In this work, two different current transport mechanism of graphene tunnel FETs considering constant and variable electric fields are proposed and corresponding I-V characteristics are obtained. The constant electric field model is based on tunneling mechanism of Esaki tunnel diode. The variable electric field model exhibits nearly a linear I-V characteristic of a p-channel graphene T-FET. Contrary to a variable electrical field, constant field model exhibits both resistive and saturation regions of operation characterizing n- and p-channel graphene T-FETs. Effect of oxide thickness on GNR T-EFT performance is also discussed. The performance of GNR T-FET under the constant electric field model is compared with the ITRS projected 2016 MOSFET model and found that the proposed model exhibits seven times lower power and eight times higher intrinsic speed in the upper GHz range. Such high performance makes graphene tunnel FET extremely suitable for design of ultra-low power RF integrated circuits.

8814-21, Session 6

Characteristic study of CNTs and graphene using terahertz time domain and continuous wave spectroscopy *(Invited Paper)*

Horacio Lamela Rivera, Sujitha Puthukodan, Ehsan Dadrasnia, Univ. Carlos III de Madrid (Spain); Dong-Mok Lee, Seunghyun Baik, Sungkyunkwan Univ. (Korea, Republic of); Guillaume Ducournau, Jean-François Lampin, Univ. des Sciences et Technologies de Lille (France); Mohan-Babu Kuppam, Frédéric Garet, Jean-Louis Coutaz, IMEP-LAHC (France)

Carbon nanotubes (CNTs) and graphene have been considered as alternative materials for Indium-Tin Oxide (ITO) as flexible, transparent, and high conductance devices because of unique electrical, optical and mechanical properties (Z. Wu et al., 2004). CNTs and graphene have been applied for electronic devices such as touch screens (S.Bae et al., 2010), conductive flexible adhesives (R.Ma et al., 2012), and field-effect transistor (Y. Lee et al., 2010). In order to suggest electronic applications of carbon nanostructures, it is essential to evaluate electrical and optical properties more accurately with noncontact method.

Many materials that are opaque to visible and infrared light are transparent to THz radiation . As a result, Terahertz spectroscopy has become an important method in studying CNTs and graphene(C. Kang et al., 2004). The parameters of these nanostructures have characteristic resonant frequencies within THz range which is another advantage. Of the many techniques related to THz spectroscopy, Terahertz time domain spectroscopy (THz- TDS) is one of the common methods under study (Y. Ueno et al, 2008).

THz-TDS technique has been intensively used to study the properties of carbon nanostructures thin-films (Kang et al., 2004, Jung et al., 2010, H. Lamela et al., 2011). We have already reported the noncontact and nondestructive THz-TDS tool at high frequencies to get insight of the DC conductivity values for multi-walled carbon nanotubes (MWNTs) thin-film (H. Lamela et al., 2012).

In this work, the characteristics of MWNTs and graphene are explored using a combination of two different THz spectroscopy techniques. Physical modeling and extracted measurement data will be demonstrated for the terahertz and sub-terahertz regimes using TDS in the range of 100 GHz–2 THz and continuous wave (CW) in the range of 325 GHz-500 GHz, respectively.

8814-22, Session 6

Graphene nanomesh gas sensors with sub-10 nm neck size by block copolymer lithography directly on graphene surfaces

Aaron S. George, Isaac Ruiz, Wei Wang, Mihrimah Ozkan, Cengiz S. Ozkan, Univ. of California, Riverside (United States)

The opening of a bandgap in graphene has been observed by etching graphene into nanoscale laterally confined sheets, or graphene nanoribbons. Although graphene nanoribbons with widths of less than 10 nm have shown substantial ON/OFF ratios, the current and conductance of individual graphene nanoribbons is far too low for practical applications. To obtain higher currents in field effect transistors a network of graphene nanoribbons, or graphene nanomesh, should be utilized. We present a scalable method by the ordering of poly(styrene)-block-poly(4-vinylpyridine) block copolymer templates directly on top of chemical vapor deposited graphene. Our technique is advantageous due to multiple reasons. First, we avoid the use of toxic gases (SF6, CHF3, CF4) and HF which have been used in many previous works and may cause defects in the SiO2 layer, effecting device performance. Second, we reduce the number of processing steps and the necessity for any interface materials. Third, is superior control over graphene neck sizes due to the choice and position of the block copolymer etching mask template directly on top of graphene. The graphene nanomesh morphology is demonstrated as a highly sensitive gas sensor due to the ability of molecules to bind at broken graphene edges and the high surface area to volume ratio.

8814-23, Session 6

Transformation of the electrical characteristics of graphene field-effect transistors with fluoropolymer

Taejun Ha, Ananth Dodabalapur, Deji Akinwande, Jongho Lee, Peter Rossky, The Univ. of Texas at Austin (United States)

We report on the improvement of the electronic characteristics of monolayer graphene field-effect transistors (FETs) by an interacting capping layer of a suitable fluoropolymer. Capping of monolayer graphene FETs with CYTOP® improved the on-off current ratio by up to a factor of 2 as well as increased the field-effect mobility also by as much as a factor of two compared to plain graphene FETs. Favorable shifts in the Dirac voltage toward zero with shift magnitudes in excess of 60 V are observed. The residual carrier concentration is reduced to ~2.8x1011 cm-2. Removal of the fluoropolymer from graphene FETs results in a return to the initial electronic properties before depositing CYTOP®. This suggests that weak, reversible electronic perturbation of graphene by the fluoropolymer favorably tune the electrical characteristics of graphene, and we hypothesize that the origin of this improvement is in the strongly polar nature of the C-F chemical bond to self-organize upon heat treatment. We demonstrate a general method to favorably restore or transform the electrical characteristics of graphene FETs which will open up new applications.

8814-24, Session 6

Nonvolatile memories based on graphene related materials: state of the art

Paolo Bondavalli, Thales Research & Technology (France)

The interest for graphitic layers for the fabrication of non-volatile resistive memories (memresistive –like memories) is quite recent. This interest has been outlined also in the 2011 ITRS chapter concerning Emerging Research Devices (i.e. ERD) and more specifically memory devices where ultrathin graphite layers are mentioned as interesting materials for macromolecular memories thanks to the potential fabrication costs that are considered as the primary driver for this type of memory. In this contribution we will present all the major works concerning graphitic memories based on graphene, GO and R-GO exploiting planar and vertical configurations. We will to explain the physics phenomenon behind the nonvolatile resistive effect and to give an overview of the pros and cons of this kind of materials for nonvolatile memories also considering the potential applications related to flexible electronics.

8814-25, Session 6

Single molecule sensing with carbon nanotube devices

Philip G. Collins, Yongki Choi, Gregory A. Weiss, Univ. of California, Irvine (United States)

Nanoscale electronic devices like field-effect transistors have long promised to provide sensitive, label-free detection of biomolecules. In particular, single-walled carbon nanotubes have the requisite sensitivity to detect single molecule events, and have sufficient bandwidth to directly monitor single molecule dynamics in real time. Recent measurements have demonstrated this premise by monitoring the dynamic, single-molecule processivity of three different enzymes: lysozyme (1), protein Kinase A (2), and the Klenow fragment of DNA polymerase I (3). The recordings resolve tens of thousands of individual chemical events, providing excellent statistics as well as insight into rare transitions to chemically-inactive conformations.

8814-26, Session 7

Photoacoustic molecular imaging using carbon nanotubes and its biomedical applications *(Invited Paper)*

Adam de la Zerda, Stanford Univ. (United States)

Many cancer-specific biomolecules are dynamic in space, time and local environments. Hence, in order to truly understand their role in cancer progression, it is important to visualize them in living subjects – their most natural environment. In this invited talk, I will show how we utilize the ‘photoacoustic effect’ - the conversion of short light pulses into ultrasound waves, for performing highly sensitive disease detection in a living body. By measuring the ultrasound waves emanating from the body, one can create a detailed 3D image of the blood vessels structure, oxygen saturation levels and track external contrast agent molecules as they target diseased tissues such as cancer. I will present our experimental photoacoustic imaging system and the customized carbon nanotube-based nanoparticle agents we synthesized. Specifically, we have recently synthesized a family of carbon nanotubes conjugated to a variety of optical dyes to greatly enhance their photoacoustic properties. We will review a number of in vivo molecular assays we performed using this technology in cancer and eye diseases. Finally, I will present our work on a multi-modality nanoparticle technology that can visualize and guide the resection of a brain tumor along its true margins, including the tumor’s finger-like protrusions that extend into the healthy brain.

8814-27, Session 7

Theoretical investigation of graphene-based waveguide integrated photonic and plasmonic modulators

Jacek Gosciniak, Singapore Univ. of Technology & Design (Singapore)

Theoretical investigations of graphene-based electro-optic plasmonic and photonic modulators will be analyzed and the results will be presented. The effect of different ridge materials and different spacer dielectrics is analyzed showing that a 3 dB modulation with 65 nm-long waveguide is possible with dielectric-loaded surface plasmon polariton waveguides (DLSPPWs) resulting in an energy per bit only 0.08 fJ/bit. The figure of merit defined as the ratio between an extinction ratio and insertion loss was found to be about 5.2 with a low refractive index ridge and increases to over 17.3 for a high refractive index Si ridge compared to 3.5 calculated and measured with photonic graphene-based waveguides. Additionally, it is shown that further improvement in terms of a figure of merit is possible with the rib photonic waveguides with a double-layer graphene placed between slab and a ridge where it is calculated to exceed 250! For such photonic waveguides, a 3 dB modulation is achieved with 6 ?m-long waveguides with the energy per bit of 0.3 fJ/bit. Additionally, the wavelength dependence of the graphene sheet was analyzed showing a redshift with increasing chemical potential what influences on the attenuation of the waveguide which redshifts as well – increasing a gate voltage applied across a graphene layer shifts the attenuation curve to the shorter wavelengths with a 3 dB modulation bandwidth exceeding 15 THz for a 12 ?m-long DLSPP waveguide.

8814-28, Session 7

Long-range surface plasmon polariton detection with graphene field-effect transistor

Ho-Seok Ee, Jinhyung Kim, Chun-Ho Lee, KAIST (Korea, Republic of); You-Shin No, Hong-Gyu Park, Korea Univ. (Korea, Republic of); Min-Kyo Seo, KAIST (Korea, Republic of)

Plasmonic nano-circuits would interface with similar-speed photonic devices and with similar-size electronic components. For a seamless integration, it is required to convert surface plasmon polariton (SPP) signals to electrical signals by an ultra-compact SPP detector. In this study, we demonstrate direct detection of surface plasmon polaritons (SPPs) propagating on a silver nanowire by employing a graphene field-effect transistor (FET). One end of the nanowire is coupled to the grapheme FET channel and the other end is open to the free-space light injection for SPP excitation. The scanning photocurrent imaging technique showed that photocurrents are successfully generated in the graphene FET from long-range SPPs launched by a 660-nm laser incidence. By measuring the dependence of the photocurrent on the incident light polarization, we confirmed that the currents are generated by propagating SPPs, which is excited by coupling of incident laser at opposite end of the nanowire. When a laser beam of ~0.5 mW was incident on the nanowire free-end, a photocurrent of ~0.5 nA is detected even without any bias. Surprisingly, it is one fourth of the photocurrent generated when the pump laser is directly incident on the graphene FET. Considering the conversion efficiency of the pump laser into SPP modes at the nanowire free-end is about a few percent, estimated external quantum efficiency of our device is ~10^-5 at zero-bias. We believe that SPP detectors based on graphene FETs would be a tailored solution to high-speed and broadband detection components for plasmonic nano-circuitry.

8814-29, Session 8

Coherent control of photocurrent in molecular nanojunctions with graphene contacts

Boris D. Fainberg, Holon Institute of Technology (Israel)

The optical response of nanoscale molecular junctions has been the topic of growing experimental and theoretical interest in recent years, fueled by both the rapid advance of the experimental technology and the premise for long range applications. We consider a new kind of graphene-molecule-graphene junctions [1] that exhibit a large conductance and are potentially useful as electronic and optoelectronic devices. The junction consists of a conjugated molecule connecting two parallel graphene sheets and is excited by an electromagnetic field of frequency w polarized in the plane of the graphene sheets. We have studied the photon assisted tunnelling in graphene-molecule-graphene junctions under electromagnetic excitation of electrons and holes in the graphene contacts. Due to their massless energy spectrum [2], graphene electrodes exhibit strongly non-linear electromagnetic response that leads to unique properties of the photon assisted tunnelling in graphene-molecule-graphene junctions. The system shows a slow falling down current evaluated at side-band energies ~ nhw with harmonics index n (~ 1/n^2) in comparison to nanojunctions with metallic leads (~ (J_n)^2, according to famous Tien-Gordon model [3]) where J_n denotes the n-th order Bessel function of the first kind. We also predict the effect of coherent destruction of tunneling in graphene-molecule-graphene junctions. Our results illustrate the potential of graphene contacts in coherent control of photocurrent.

8814-30, Session 8

Nonlinear optical properties characterization of semiconducting and metallic single-wall carbon nanotubes

Antonio Carlos Brandão-Silva, Univ. Federal de Alagoas (Brazil); Rogério Lima, Univ. Federal de Minas Gerais (Brazil); Márcio A. R. C. Alencar, UFAL (Brazil); Jandir M. Hickmann, Univ. Federal de Alagoas (Brazil); Cristiano Fantini, Marcos Pimenta, Univ. Federal de Minas Gerais (Brazil); Eduardo J. da Silva Fonseca, Univ. Federal de Alagoas (Brazil)

Single-wall carbon nanotubes (SWNTs) are among the most promising materials aiming the development of new devices. Due to its peculiar physical and chemical properties, they have been exploited in different fields, from nanoelectronics to optics and photonics. Nowadays, it is possible to separate metallic from semiconducting SWNTs, opening new research frontiers and the design of novel applications.

In this work, we characterized the third-order nonlinear optical responses of the samples containing SWNTs separated by its electronic properties, i. e., semiconducting and metallic carbon nanotubes, using the Z-scan technique with thermal management.

Semiconducting and metallic SWNTs samples were separated by gel chromatography method and characterized by Raman and optical absorption spectroscopies. The investigated samples present metallic or semiconducting nanotubes with more than 90% purity and diameter distributions equal to 0.89-1.18 nm for metallic and 0.67-0.83 nm for semiconducting SWNTs. The concentration of nanotubes in each sample was 7.85 x 10-3 mg/ml and 8.53 x 10-3 mg/ml for metallic and semiconducting, respectively.

The nonlinear optical characterization was performed using, as the light source, a pulsed Ti:Sapphire laser, delivering pulses of 200 fs, linearly polarized, with 76 MHZ repetition rate. The measurements were carried out varying the laser wavelength in the range of 755 to 825 nm. It was observed that both systems present large negative nonlinear refractive indexes values, about 10-14 cm2/W, with a strong resonance around 800 nm, but negligible nonlinear absorption in this wavelength length.

Our results indicate that both SWNTs kinds are promising materials for ultrafast nonlinear optical applications.

8814-31, Session 8

Investigation of carbon nanotubes used for the transparent electrode in organic solar cells

Osman Urper, Zeynep Dalkilic, Nilgün Karatepe, Istanbul Technical Univ. (Turkey)

Solar energy is more environmentally friendly energy source compared to traditional energy sources (fossil fuels, nuclear, coals, etc.) due to no carbon dioxide emission or hazardous wastes for this technology. Unfortunately, high costs and low efficiencies are still problem for its applications. Organic solar cells are being pursued as a viable alternative to inorganic devices due to low cost, flexibility and scale-up production. Transparent electrode in organic cells allows the light to pass through to the active material and act as an ohmic contact. Indium-tin oxide (ITO) is currently used in solar cells due to its high conductivity and transparency. However, ITO is expensive in fabrication and also mechanically brittle, which increases the costs and limits the flexibility of devices. In recent years, several transparent electrode materials are used instead of ITO. Among these materials, carbon nanotubes (CNT), is a good alternative having with its unique features such as optical transmissions, electrical and flexibility properties.

The aim of the study is the production of carbon nanotubes by the chemical vapor deposition method, removal of CNT's impurities and the use of obtained single and multi-walled carbon nanotubes as a transparent electrode in organic solar cells. For this purpose, firstly, single-and multi-walled carbon nanotube films as a transparent material, secondly, PEDOT:PSS as hole conductor, and thirdly, P3HT: PCBM as a donor- acceptor were coated on glass substrates. Lastly, the solar cells were obtained with the aluminum coating. The efficiency, fill factor, permeability and other properties of organic solar cells obtained in different conditions were determined in detail.

8814-32, Session 8

Towards graphene photonics and plasmonics

Shin Mou, Don C. Abeysinghe, Joshua Myers, Gail J. Brown, William C. Mitchel, Nima Nader, Justin W. Cleary, Joshua R. Hendrickson, Air Force Research Lab. (United States); Kuei-Hsien Chen, Academia Sinica (Taiwan); Li-Chyong Chen, National Taiwan Univ. (Taiwan); Christian W. Smith, Masahiro Ishigami, Univ. of Central Florida (United States)

Graphene has remarkable optical properties that it is highly transparent while owning large optical absorption coefficient. However, from an optical sensing point of view, it is less attractive due to the low interband optical absorbance resulting from its thinness. An alternative method to achieve optical absorption/ sensing is to utilize the tunable resonant absorption by plasmons in the two-dimensional electron gas (2DEG) of grating-gated field effect transistors (FETs), which is known for a variety of semiconductor systems, giving promise of frequency-agile Infrared/ THz image sensors and spectrometers. Graphene-based plasmonics shows highly tunable and sharp plasmon THz resonance at room temperature while all other semiconductor 2DEG systems generally have plasmon resonance at much lower temperatures (< 77 K.) In addition, graphene has the capability to operate at higher frequencies (shorter wavelength in mid-infrared) due to higher sheet carrier density. As a result, graphene grating-gated detectors have the potential to be the next-generation frequency-agile infrared detectors. We investigate the dc transport of both CVD graphene (grown on Cu) and epitaxial graphene (grown on SiC) with Hall measurement, by which we obtain important parameters such as Hall mobility and sheet carrier density helping us estimate the plasmon resonance frequency and the absorption spectrum. Furthermore, to complement the dc transport characterization, optical transmission/reflection measurements are carried out in Fourier transform infrared spectrometers (FTIRs) to obtain the infrared ac conductance. From that, the carrier density, carrier mobility, sheet resistivity, intraband scattering rate, and graphene layer number can be inferred. Last, we observe graphene plasmon resonances in far-infrared (~ 100 cm-1) by optical transmission measurements through graphene ribbon grating structures.

8815-1, Session 1

Imaging the non-fluorescent materials in living cells *(Invited Paper)*

YanYi Huang, Peking Univ. (China)

Optical probes for live cell imaging are valuable tools in biomedical researches. The inside of a living cell is a rather complex biochemical environment, making it difficult to choose suitable probes that are both highly specific and biochemically inert. Numerous types of nanoparticles, including quantum dots, carbon nanotubes, and metallic nanorods, have been developed as optical imaging probes. Some nanoparticle probes are intrinsically fluorescent, however, many are not. We directly observe the non-fluorescent nanomaterials in living cells using stimulated Raman scattering and transient absorption microscopies. These label-free technologies provide new modalities to study the dynamic behavior of nanomaterials inside the cells with intrinsic three-dimensional imaging capability.

8815-2, Session 1

Orientational imaging of single molecules in polymers *(Invited Paper)*

Zouheir Sekkat, Moroccan Foundation for Advanced Science, Innovation and Research (Morocco)

I discuss the experimental determination of 3 dimentional; 3d; dipole orientations of single fluorescence molecules by using both azimuthal and radial polarizations. I report on the determination of the 3d absorption dipole orientation of single DiI molecules embedded in polymethylmethacrylate (PMMA) films. Theoretical calculations of the electric field distributions created by a focused radially and azimuthally polarized laser beam in the presence of the interface between air and a polymer, shows that the fluorescence intensity is strongly dependent on the depth position of the molecule and that the variation of fluorescence intensity in radial polarization is considerably larger than the one in azimuthal polarization. These findings were confirmed by comparing experimental results using different film thicknesses with theoretically calculated electric field distributions.

8815-3, Session 1

In vivo photoacoustic imaging of breast cancer tumors with HER2-targeted nanodiamonds

Ti Zhang, Huizhong Cui, The Univ. of Kansas (United States); Chia-Yi Fang, Huan-Cheng Chang, Academia Sinica (Taiwan); Xinmai Yang, M. Laird Forrest, The Univ. of Kansas (United States)

Radiation-damaged nanodiamonds (DNDs) are ideal optical contrast agents for photoacoustic (PA) imaging in biological tissues due to their good biocompatibility and high optical absorbance in the near-infrared (NIR) range. Acid treated DNDs were oxidized to form carboxyl groups on the surface, functionalized with polyethylene glycol (PEG) and HER2 targeting ligand for breast cancer tumor imaging. Because of the specific binding of the ligand conjugated DNDs to the HER2-overexpressing murine breast cancer cells (4T1.2 neu), the tumor tissues were significantly delineated from the surrounding normal tissue at wavelength of 820 nm under the PA imaging modality. Moreover, HER2 targeted DNDs result in higher accumulation in tumors as compared to non-targeted DNDs after intravenous injection (i.v.). This demonstrates that targeting moiety conjugated DNDs have great potential for the sensitive detection of cancer tumors and provide an attractive delivery strategy for anti-cancer drugs.

8815-4, Session 1

Deterministic spatio-temporal focusing of light through complex media

Daria Andreoli, Sylvain Gigan, Giorgio Volpe, Ori Katz, Sébastien Popoff, Samuel Gresillon, Institut Langevin (France)

Focusing light in space and time through complex media is paramount in many applied topics in biology, imaging and nanomanipulation. However, light is strongly scattered when propagating through inhomogeneous media, thus preventing the achievement of this goal. Recently, active wavefront shaping techniques have emerged as a powerful way to control light propagation through complex media by relying on the use of spatial light modulators (SLM). The first approaches used phase-conjugation or optimization methods to either spatially focus light and/or to correct for the temporal distortion of an ultrashort pulse after propagating through the scattering medium. An alternative solution to the problem is a matricial approach, where the transmission matrix of the medium is measured. While optimization or phase-conjugation techniques have been shown to allow some degree of temporal control, the matrix approach has been monochromatic so far. Here, we propose to measure and use the transmission matrix to not only focus in space and in time through a complex medium, but to generate an arbitrary spatiotemporal distribution. In essence, we operate a femtosecond laser in CW mode around 800 nm, and measure the monochromatic transmission matrices at several wavelengths that composes the spectrum of the pulse. Once this 3D spatio-spectral matrix is known, we show that it is possible to use only spatial degrees of control on a SLM to deterministically control the pulse propagation through the medium and to focus in space and time at its far side. This approach opens up opportunities to have a full deterministic control of a nano-object through a complex medium.

8815-5, Session 1

Atherosclerotic plaque characterization in apolipoprotein E-deficient mice with micro-Raman spectroscopy and high-frequency acoustic microscopy

Pavlos Anastasiadis, Shiv K. Sharma, Univ. of Hawai'i (United States); Joshua J. Rychak, Targeson, Inc. (United States); John S. Allen III, Univ. of Hawai'i (United States)

Coronary artery disease and its underlying molecular pathology of atherosclerosis are still not completely understood. Murine animal models allow for a more rigorous and systematic way of studying the onset and progression of atherosclerotic plaques than human subjects; however, the associated microscopic size of plaques makes their optical and mechanical characterization a challenging task. This study aims at correlating the biochemical and elastic composition of atheromatous plaque lesions in apolipoprotein E-deficient mouse aorta sections. Near-infrared micro-Raman spectroscopy provides a biochemical characterization of the aorta sections. A complimentary acoustic microscopy study of the same samples determines their elastic properties. Five month old apolipoprotein E-deficient mice on a fat- and cholesterol-rich diet were euthanized in order to excise their aortas. The aorta tissues were sliced using a microtome and kept in -80 °C until investigated with both micro-Raman spectroscopy and acoustic microscopy. Raman spectra were excited by an Invictus 785-nm NIR laser and measured with a fiber-coupled micro-Raman RXN system (Kaiser Optical Systems, Inc., Ann Arbor, MI) equipped with a 785 nm CW laser and CCD detector. The elastic characterization study utilized a high-frequency acoustic microscope (Fraunhofer IBMT, St. Ingbert, Germany) at a center frequency of 100 MHz. The acoustic setup was mounted onto an inverted optical microscope for additional simultaneous optical analysis.

8815-6, Session 1

Observing the growth of single nanoparticles in real time through supercontinuum spectroscopy

Lars O. Herrmann, Jeremy John Baumberg, Univ. of Cambridge (United Kingdom)

A fast scattering spectroscopic technique capturing full broadband spectra with millisecond time resolution enables us to monitor the synthesis or assembly of individual nanoparticles in situ and in real time. Applying this technique for quantitative growth studies of single gold nanorods reveals new information about their growth kinetics. Such experiments open up real time monitoring of chemical reactions at individual nanoparticles as well as new routes towards tailoring nanostructures through opto-chemical feedback.

8815-8, Session 2

Three-dimensional optical nanoscopy with opposing lenses *(Invited Paper)*

Alexander Egner, Laser-Lab. Göttingen e.V. (Germany); Roman Schmidt, Daniel Aquino, Stefan W. Hell, Andreas Schönle, Max-Planck-Institut für Biophysikalische Chemie (Germany); Claudia Geisler, Laser-Lab. Göttingen e.V. (Germany)

Far field optical microscopy is a well established method for the non-invasive 3D-investigation of cellular structures. However, the resolution of conventional light microscopy is limited by diffraction to ~200nm in the focal plane and ~600nm along the optic axis. In order to discern identical labels which are much closer than this, one has to overcome the diffraction barrier.The utilization of optical switching events allows one to circumvent Abbe's diffraction limit: The switching of only markers within an area which is much smaller than the size of a diffraction limited spot to a visible "bright" state while all other markers are switched to a non-visible "dark" state defines a sub-diffraction area. By sequentially recording all areas within the diffraction spot, it is possible to assemble a sub-diffraction image.

The first radical concept for improving the resolution of a far field microscope was Stimulated Emission Depletion (STED) microscopy. In this concept the saturated depletion of the excited state of the fluorescent molecule is used to generate a fluorescent spot that is narrower than the diffraction limit. isoSTED microscopy proved a resolution of up to 21 nm in the lateral and 30 nm in the axial direction, meaning that the resolution is higher by more than an order of magnitude as compared to confocal microscopy.

Another method utilizing molecular switching events for achieving nanoscale resolution in microscopy uses a more pointillist approach. Single molecules which are initially in a dark state are sequentially activated, located and deactivated. The localization accuracy of each molecule depends, of course, on the number of detected photons per molecule and can be as high as 2 nm. Over the whole field of view, these methods provide an average resolution in the order of several tens of nanometers.

8815-9, Session 2

Advances in STED microscopy: adaptive optics and total internal reflection microscopy *(Invited Paper)*

Travis J. Gould, Edward Allgeyer, Yale School of Medicine (United States); Daniel Burke, Martin Booth, Univ. of Oxford (United Kingdom); Joerg Bewersdorf, Yale School of Medicine (United States)

By breaking the classical diffraction limit, Stimulated Emission Depletion (STED) Microscopy has revolutionized far-field fluorescence microscopy. 25 nm resolution and better have been achieved in two dimensions imaging cultured cells.

We will present recent results on combining total internal reflection (TIR) with STED microscopy in our custom-built STED setup. The combination of TIR with STED limits excitation to a vicinity of about 100 nm to the cover slip and reduces bleaching and photo damage in live cell imaging.

STED microscopy has also recently been applied very successfully to imaging neurons even in the brain of living mice in two dimensions. The expansion to 3D super-resolution has also been demonstrated utilizing two opposing objectives or phase filters with a top-hat profile, its application to tissue has however been hampered by aberrations introduced by refractive index inhomogeneities.

Here we present our latest results in 3D STED microscopy of scattering specimens enabled by the integration of adaptive optics into a custom STED microscope. We will present our current research about the physical and technical concepts of adaptive optics STED microscopy as well as the latest biological applications of adaptive optics STED microscopy.

8815-10, Session 2

Far-field photostable optical nanoscopy (PHOTON) for super-resolution imaging of single protein-ligand binding complexes

X. Nancy Xu, Tao Huang, Lauren M. Browning, Old Dominion Univ. (United States)

We have developed a new-generation sub-diffraction imaging nanoscope, far-field photostable optical nanoscopy (PHOTON), for mapping individual ligand molecules and their binding sites in single protein-ligand complexes at nanometer resolution. Unlike fluorescence-based super-resolution imaging methods, PHOTON uses a standard far-field optical microscope equipped with a multi-spectral imaging system (MSIS) and a standard microscopic white-light illuminator (halogen lamp) as an illumination source. No laser excitation source is needed. Thus, conventional optical microscope is well suited for super-resolution imaging. Notably, PHOTON uses Rayleigh scattering of single noble metal nanoparticles as optical imaging probes, overcoming the drawbacks (auto-fluorescence, photo-bleaching, photo-blinking, phototoxicity) of fluorescence microscopy for imaging of proteins and living organisms. Intrinsic size- and shape- dependent localized-surface-plasmon-resonance (LSPR) spectra of single noble nanoparticles provide multiple-spectral (color) nanoprobes for sub-diffraction imaging, offering feasibility of probing of binding structures and functions of single protein-ligand complexes at nm resolution in real-time. PHOTON represents major breakthrough in sub-diffraction optical imaging with distinguished advantages, including superior photostability, superior spatial and temporal resolution, and no need of laser excitation sources and thereby effectively avoiding auto-fluorescence of proteins and phototoxicity to living organisms. Single nanoparticle optical biosensors serve as nanoprobes for both PHOTON and HRTEM, which enables us toward locate individual nanoparticles using both PHOTON and HRTEM and to validate nanometer spatial resolution of PHOTON. The work is supported in part by NSF (CBET 0507036) and NIH (R01 GM0764401; 3R01 GM076440-04S1).

8815-11, Session 2

High-resolution fluorescence imaging of a multi-layer cell cluster by saturated excitation (SAX) microscopy

Masahito Yamanaka, Kumiko Uegaki, Nicholas I. Smith, Satoshi Kawata, Katsumasa Fujita, Osaka Univ. (Japan)

To investigate cellular functions present in tissues, it becomes important to observe cell clusters in 3D culture, not merely cells on a hard glass or plastic substrate. However, specimens in 3D culture are typically thick and strongly scatter light, making high-resolution imaging difficult using conventional optical microscopy. Although recent developments in fluorescence microscopy have overcome the diffraction limit, super resolution imaging of thick samples still remains a challenge.

Here, we demonstrate the use of saturated excitation (SAX) microscopy for high-resolution fluorescence imaging of a multi-layer cell cluster. SAX microscopy improves the spatial resolution in three dimensions by detecting the nonlinear fluorescence emission induced by saturated excitation. Because the nonlinear fluorescence response is given predominantly in the laser focus, fluorescence signals from out-of-focus planes hardly contribute to the image formation, resulting to improvement of the depth resolution in a manner similar to two-photon excitation microscopy.

Using a SAX microscope and a typical confocal microscope, we observed HeLa cells cultured in a 3D matrix and stained by ATTO488-phalloidin. In the image obtained with SAX microscopy, the cross-sections of actin filaments are clearly separated at any observation depth, but not with confocal microscopy. From this experiment, we confirmed that SAX microscopy maintains the improved spatial resolution even in the observation of deeper parts of the sample.

Here, we also confirmed that SAX induces higher nonlinear fluorescence response in two-photon excitation, and demonstrated improvement of the spatial resolution in two-photon excitation microscopy.

8815-28, Session 2

Image resolution in optical nanoscopy *(Invited Paper)*

Bernd Rieger, Sjoerd Stallinga, Robert P. Nieuwenhuizen, Technische Univ. Delft (Netherlands)

Fourier Ring Correlation is proposed as a resolution measure for superresolution microscopy based on single emitter localization. The measure incorporates the effects of the emitter localization uncertainty and the density of localized emitters as well as the structure of the underlying object. It has been applied to simulated PALM and STORM images and experimental dSTORM data. In addition, an analytical expression has been derived for the resolution for two lines.

Common resolution concepts are either based on the localization uncertainty or on the Nyquist criterion for the average density of localized emitters. We propose a resolution measure that takes both localization uncertainty and density into account: the Fourier ring correlation (FRC). These concepts have long been used in electron tomography, but are new to the field of superresolution fluorescence microscopy. The definition of the FRC can be used to derive an explicit expression for the smallest distance between two parallel lines that can still be resolved. This expression provides new insights into the trade-off between the density of localized emitters and the localization uncertainty (following from the photon count per emitter), which we will discuss in great detail.

In order to correctly estimate resolution the number of on average localization of a single emitter are needed. To this end we present a method for estimating this count, without requiring prior knowledge about the spatial structure of the imaged structure. This presents one step closer to make localization microscopy a quantitative tool.

8815-12, Session 3

Cryogenic intra-molecular co-localization with Angstrom precision *(Invited Paper)*

Siegfried Weisenburger, Vahid Sandoghdar, Max Planck Institute for the Science of Light (Germany)

The advent of super-resolution microscopy during the past decade has advanced fluorescence microscopy beyond the diffraction limit [1]. One prominent technique - single molecule localization - is based on finding a fluorescent molecule's position by determining the center of its point-spread function with a much higher precision than the spot width. The localization precision is only dependent on the available signal-to-noise ratio, which is in turn mainly given by the number of photons that reach the detector [2]. Since the number of emitted photons of a dye molecule at ambient temperatures is limited by irreversible photobleaching, typical localization precisions are on the order of ten nanometers.

Here, we show that both the survival time and the number of emitted photons can be improved by more than two orders of magnitude at cryogenic temperatures. We use a high-NA cryogenic microscope and utilize the natural photoblinking and photobleaching of several dye molecules attached to a single biomolecule to demonstrate co-localization at Angstrom precision. We discuss the challenges, solutions and promise of this method for intra-molecular distance measurements with implications for super-resolution microscopy in general.

8815-13, Session 3

Simpler 3D STORM in tissue *(Invited Paper)*

Ryan McGorty, Daichi Kamiyama, Bo Huang, Univ. of California, San Francisco (United States)

Obtaining super-resolution images tens of microns past the coverslip into tissue samples presents a number of challenges including depth-dependent aberrations, high background and the need for focus stabilization. In our investigations of Drosophila embryos we have dealt with these issues without using complicated systems such as two-photon excitation. We used a STORM compatible a high refractive index medium so that we could use high numerical aperture oil immersion objectives while avoiding the spherical aberration from the medium-coverglass refractive index mismatch. Due to the resulted absence of reflection at the sample-coverglass interface, we implemented a novel image-correlation-based method for active stage drift compensation. By correlating continually acquired bright-field images of the sample with reference images at multiple focal planes simultaneous to STORM data acquisition, we are able to stabilize the sample in all three dimensions. Finally, we are combining confocal techniques with STORM to reduce the amount of background when imaging deeper into tissue samples. Taken together, these modifications to STORM broaden the range of samples that can be investigated at the nanoscale level.

8815-14, Session 3

Targeting and tracking of individual proteins in live animals with nanometer accuracy *(Invited Paper)*

Fabien Pinaud, The Univ. of Southern California (United States); Hong Zhan, Christian Stigloher, Ecole Normale Supérieure (France); Ingo Gregor, Jörg Ederlein, Georg-August-Univ. Göttingen (Germany); Maxime Dahan, Jean-Louis Bessereau, Ecole Normale Supérieure (France)

It can be complicated to detect and image individual biomolecules in their native cellular environment. This task becomes even more challenging for living tissues. In animals, variable protein expression levels and inadequate intravital probe delivery can strongly complicate the specific detection of single biomolecules within the complex and generally highly auto-fluorescent environments of tissues. Recently we have developed a methodology named Complementation Activated Light Microscopy (CALM) that circumvents some of these limitations. In CALM, proteins of interest are fused to dark split-fluorescent proteins (split-FP) which are stochastically activated into bright FPs by irreversible complementation with exogenous synthetic peptides. We will describe how we use CALM to target and specifically image and track individual proteins with nanometer accuracy in cells and in living C. elegans nematodes. In C. elegans tissues, split-FP fusion protein can be used as stochastic single-pair FRET donors to a fluorophore attached to injected synthetic peptides, which allows for precise imaging of individual proteins with minimal interference from auto-fluorescence background, independently of protein expression levels and at micromolar probe concentrations.

8815-15, Session 3

Localization microscopy for the study of amyloid fibril formation

Dorothea Pinotsi, Gabriele Kaminski Schierle, Eric Rees, Clemens F. Kaminski, Univ. of Cambridge (United Kingdom)

Optical Localization Microscopy, a super-resolution technique, is a powerful tool for studying processes in biochemistry and cell biology due to its non-invasive and thus compatible with physiological environments nature. In this project we develop and apply a localization microscopy technique in order to study biological processes at the level of nanoscale. In particular, we use the direct stochastic optical reconstruction microscopy (dSTORM) with the main focus to study amyloid fibril self-assembly processes associated with protein aggregation in the context of neurodegenerative diseases, such as Alzheimer's and Parkinson's diseases. High resolution structural information on the fibrillar structures at each stage of the aggregation process is obtained through correlative atomic force microscopy (AFM) and dSTORM with molecule specific labeling. The dSTORM technique is ideally suited to determine the morphology of aggregates and of small intracellular structures with a 20 nm resolution, revealing details on a scale much smaller than the wavelength of the probing light. We are thus able to distinguish different oligomeric species and to relate the structure of the aggregates with their functional roles and effects in live cells. One of the main objectives is to study the interaction of protein aggregates with potential inhibitors in vitro and in cells. Furthermore, dSTORM offers us the ability to observe the dynamics of the aggregation process directly and non-intrusively; we follow the pathway of amyloid formation in real-time and in situ, with the ultimate goal to obtain a practical and reproducible model of protein aggregation for use in drug discovery.

8815-16, Session 4

Light manipulation for imaging application based on plasmonic nanostructures and metasurface *(Invited Paper)*

Wei Ting Chen, National Taiwan Univ. (Taiwan); Chia Min Chang, National Taiwan Univ. (Taiwan) and Academia Sinica (Taiwan); Shulin Sun, National Taiwan Univ. (Taiwan); Kuang Yu Yang, Academia Sinica (Taiwan); Ming Lun Tseng, Yao-Wei Huang, Pin Chieh Wu, National Taiwan Univ. (Taiwan); Bo Han Cheng, Yen Ju Liu, Academia Sinica (Taiwan); Yueh-Hung Cheng, Chun Yen Liao, Hung-Kuei Tsai, Kuang Sheng Chung, Yu Lin Chen, Ding-Wei Huang, National Taiwan Univ. (Taiwan); Ai Qun Liu, Nanyang Technological Univ. (Singapore); Chih-Ming Wang, National Dong Hwa Univv. (Taiwan); Guang-Yu Guo, National Taiwan Univ. (Taiwan) and National Chengchi Univ. (Taiwan); Lei Zhou, Fudan Univ. (China); Din Ping Tsai, National Taiwan Univ. (Taiwan) and Academia Sinica (Taiwan)

It is very important to manipulate surface plasmon polarization (SPP) waves both in the near- and far-field. Lately, three-dimensional focusing and diverging of SPP waves by a quarter circular structure composed of Au nanobumps have been studied. Such nanostructures show the promising light manipulation by way of providing additional wave vectors on SPP waves. By various plasmonic structures composed of arranged nanobumps, the scattering of SPP waves could be manipulated into specific light patterns in free space. By controlling the feature geometries of the plasmonic structures, we can modify the altitude, position, and focusing shape of scattered light as desired.

On the other hand, gradient-index meta-surfaces had been also found to exhibit extraordinary light-manipulation abilities, governed by a generalized Snell's law with an additional parallel wave vector provided by the radiation phase gradient of the meta-surface. Recently, we presented a new type of gradient meta-surface which can convert a propagating light into a surface wave with 100% efficiency. It provided that the phase gradient is large enough, and experimentally verified the idea in the microwave regime. Here, we designed and fabricated a gradient meta-surfaces working in visible region (~850nm) with broad-band functionality (750-900nm), and demonstrated by both experiments and numerical simulations that it can redirect an input light to a non-specular channel with high efficiency (~80%).

In summary, we provide two methods for light manipulation via designed plasmonic nanostructures. Our results lead to many practical applications, such as plasmonic micro-projector, plasmonic beam splitters, three-dimensional plasmonic circuitry, holography, etc.

8815-17, Session 4

Radiative and non-radiative properties of individual plasmonic nanostructures investigated by single particle spectroscopy *(Invited Paper)*

Stephan Link, Rice Univ. (United States)

A surface plasmon in a metal nanoparticle is the coherent oscillation of the conduction band electrons leading to both absorption and scattering. Ensemble extinction spectroscopy only measures the sum of both processes. However, single particle spectroscopy techniques allow one to separately determine the plasmon absorption and scattering. We have employed different polarization sensitive single particle spectroscopy techniques to investigate both radiative (scattering, luminescence) and non-radiative (absorption) properties of individual plasmonic nanostructures. In particular, we have used by dark-field scattering spectroscopy, photothermal heterodyne imaging, and confocal luminescence microscopy, which were all combined on one setup to study the same structures. Simulations aided in the interpretation of the results and allowed us to determine quantitative optical cross sections, which are difficult to obtain by ensemble measurements. To gain further insight about the relationship between structure and plasmon resonance, we correlated the optical response with the morphology of the nanostructure using electron microscopy.

8815-18, Session 4

3D dynamic imaging of intracellular molecules by surface enhanced Raman scattering

Kazuki Bando, Jun Ando, Osaka Univ. (Japan); Kai-Chih Huang, National Taiwan Univ. (Taiwan); Nicholas I. Smith, Katsumasa Fujita, Satoshi Kawata, Osaka Univ. (Japan)

Recent progress in Raman scattering microscopy has gained great interests from biologists and molecular scientists for label-free imaging of the molecular distribution of a sample. However, Raman scattering is an extremely weak photon process so that it requires a long exposure time for imaging, and the spatial resolution is limited to around half the wavelength of light. To overcome these limitations for live cell imaging, we use a gold nanoparticle captured in a living cell as a probe to analyze the biochemical composition along its path. The nanoparticle explores the living cell by detecting surface enhanced Raman scattering (SERS) signals, which contain local molecular information, resulting to the mapping of molecules along the cellular pathway with spatial resolution at nanometer scale. We introduced 80nm gold nanoparticles in a cell through endocytosis and observed the motion of a nanoparticle in three dimensions by using a dual-focus dark-field microscope. Raman scattering from the nanoparticle of interest was then obtained by a confocal Raman spectrophotometer with 676nm excitation laser. The laser focus position was controlled three dimensionally by a feedback system to trace the particle motion in real-time. As a result, we achieved a temporal resolution of 100ms for both particle tracking and Raman spectroscopy. Moreover, we observed a change in SERS spectra depending on the type of particle motion such as straight-forward motion and confined motion. Our results indicate that SERS spectra

from the nanoparticle could reveal information about the cellular function of biomolecules associated with organelle transportation and lysosomal accumulation.

8815-19, Session 4

Raman spectroscopy for intracellular localisation of meso-Tetraphenylporphyrin-gold nanoparticles conjugates

Rasoul Al-Majmaie, Nebras E. Al-Attar, Mohamed Al-Rubeai, James H. Rice, Dominic Zerulla, Univ. College Dublin (Ireland)

Biocompatible gold nanoparticles (GNPs) have gained significant interests in recent years for potential applications in nanomedicine due to their unique physical and chemical properties. Their use has become prominent in cancer research due to their inherently low toxicity and strongly enhanced optical properties associated with localized surface plasmon resonance (LSPR). GNPs have resonant light scattering properties and high absorption cross sections per unit volume that can enhance local fluorescence and plasmonic signals, making them invaluable tools in photothermal and photodynamic cancer therapy, diagnostic bioimaging and Raman spectroscopic detection.

The use of nanoparticles to deliver attached agents to a specific site is a promising tool to enhance efficacy, reduce toxicity, improved imaging, and tenability of the bio-distribution of a given therapeutic or imaging agent.

Raman spectroscopy is an analytical tool with many advantages over fluorescence spectroscopy in that it can provide a molecular fingerprint of a sample, which makes it attractive for material analysis and for biomedical applications. Surface enhanced Raman (SERs) can enhance the Raman signature enabling few and single molecules to be observed when the probe molecule is in close proximity to a plasmon active support such as a GNP.

In this study, we apply SERs as a non-destructive tool for intracellular localisation of porphyrin-GNP conjugates in cancer cells. We prepared conjugates of the hydrophobic photosensitizer meso-Tetraphenylporphyrin (TPP) and GNPs. The TPP-GNPs were characterized by by ultraviolet—visible absorption spectroscopy, fluorescence spectroscopy and transmission electron microscopy.

TPP-GNPs with a mean diameter of 12 nm were introduced into SW480 human colon adenocarcinoma cells. SERs was applied in conjunction with fluorescence microscopy to study the resulting materials. Our results show that the TPP-GNP nanomaterials are distributed inside the cell at particular locations. Overall our results indicate that Raman spectroscopy has the potential to be a high-throughput tool to localise nanoparticles in the subcellular environment.

Some improved techniques for better nanoimaging through tip-enhanced Raman scattering *(Invited Paper)*

Prabhat Verma, Osaka Univ. (Japan)

Due to the strong confinement of light near the apex of a metallic nanotip used in the tip-enhanced Raman scattering (TERS) measurements, microscopy based on TERS can achieve a high spatial resolution far beyond the diffraction limit of the probing light. Since light can interact with the intrinsic properties of a sample, TERS images provide information not only about the topographical distribution of the sample, but also the distribution of the intrinsic physical and chemical properties of a sample at nanoscale resolution. However, due to the physical restrictions, the ongoing research in TERS has arrived to a stage where further improvement looks difficult. Such high spatial resolution and enhancement of light field achieved in TERS is associated with the plasmonic effects at the metallic nanotip. Nevertheless, we have shown that by including some other effects in TERS, we can further improve the enhancement and spatial resolution. Some of these effects are based on Fano interactions, nonlinear phenomenon, chemical interactions and mechanical interactions. Here, we will show inclusion of such effects in TERS that can give much better results in enhancement and spatial resolution. Furthermore, by controlling the tip-sample separation with a precision of sub-nanometer scale, we can distinguish three different kinds of interactions between the tip and the sample, namely the plasmonic, the chemical and the mechanical interactions. This gives further strength to TERS in analyzing samples at extremely high spatial resolution.

8815-21, Session 5

High-resolution spectroscopic mapping of polymer fullerene blend films for organic solar-sell applications

Alfred J. Meixner, Dai Zhang, Xiao Wang, Eberhard Karls Univ. Tübingen (Germany)

Polymers and fullerenes are widely employed in the field of organic solar cells as the electronic donors and acceptors. The morphology and the photo-physical properties of the polymer and fullerenes blends at nanometer scale are critical for achieving a high performance of the solar cells. Employing a home-built parabolic mirror assisted apertureless near-field optical (Raman and photoluminescence) microscope, we demonstrated high resolution near-field spectroscopic mappings of the polymer:fullerene blend films. From the simultaneously recorded morphology and spectroscopic information, the interplay among the blend film morphology, the local donor and acceptor molecular distributions, and the photoluminescence quenching efficiency were discussed. The PL and Raman signals of the electron donor and acceptor have been probed at an optical resolution of approximately 10 nm which allow the direct identification of the chemical nature of the different domains. Moreover, we were able to reveal and quantify the local quenching, which is related to the electron transfer from donor to acceptor.

8815-22, Session 5

High-resolution tip-enhanced fluorescence imaging by controlling the tip-sample separation

Jun Yu, Satoshi Kawata, Prabhat Verma, Osaka Univ. (Japan)

While tip-enhanced Raman scattering (TERS) shows a continuous enhancement with the approach of a metallic nanotip towards the sample, the situation in tip-enhanced fluorescence (TEF) is different. A metallic nanotip not only enhances fluorescence, but it can also quench the fluorescence when it comes very close to the sample. As the tip approaches the sample in TEF, the resultant fluorescence signal is a result of these two competitive effects. Therefore, an efficient TEF microscopy can only be performed by maintaining an optimized tip-sample separation, where the resultant fluorescence signal is maximum. This requires a very precise control on the location of the tip, particularly in the direction perpendicular to the sample surface. Through our modified technique for controlling the tip-sample separation, we demonstrate high-contrast, high-resolution TFL imaging. This technique is also very useful in TERS, where by controlling the tip-sample separation, once can separate out three enhancements effects, namely the plasmonic enhancement, the chemical effect in enhancement and the mechanical effect in enhancement, because these three effects have different interaction lengths. Through our modified technique, we can control the location of the tip with a precision better than one nanometer and show how this leads to high spatial resolution nanoimaging.

8815-23, Session 5

A new technique for fabrication of better metallic nanotips for nanoimaging through tip-enhanced Raman spectroscopy

Takayuki Umakoshi, Osaka Univ. (Japan); Yaka-aki Yano, Tokyo Institute of Technology (Japan); Yuika Saito, Prabhat Verma, Osaka Univ. (Japan)

Tip-enhanced Raman spectroscopy (TERS) offers one of the best techniques for analysis and imaging of samples through Raman study at nanoscale spatial resolution. Important issue in TERS is to improve the detection sensitivity of inherently weak Raman scattering so as to observe varieties of samples. For enhancement of the Raman signal, fully metallized tips are utilized, which enhance signals through plasmon resonance at the apex. However, length of metal along the axis of the tip is on the order of a few to a few tens of micrometers, which means the plasmon resonant wavelength is much longer than the wavelength of the visible light used in TERS. From that point, if tips have metallic nanostructures on the apex, it gives better enhancement in the visible range compared with fully metallized tips.

In this research, we employed photoreduction as a facile fabrication method of metallic nanostructures at the tip apex. We found particular property of photoreduction that it occurs selectively at sharp corners, such as the tip apex of silicon cantilevers. Through this property, we succeeded in growing silver nanoparticles selectively at the tip apex. One of the advantages of the photoreduction is that the size of metal nanostructures is well controlled by optimizing various parameters. We controlled the size of silver nanoparticles from 100 nm to 400 nm by changing the laser exposure time. Furthermore, we obtained an order of magnitude higher enhancement of our fabricated tip compared with fully metalized tips by performing TERS measurements.

8815-24, Session 6

Multimodal and multispectral nano-imaging: accessing the structure underlying the function in polymers, proteins, biominerals

(Invited Paper)

Markus B. Raschke, Univ. of Colorado at Boulder (United States)

The properties of many functional soft-matter systems, including polymer heterostructures, organic photovoltaics, and biomembranes are typically defined on the mesoscopic few nm to sub-micron scale. Scattering scanning near-field optical microscopy (s-SNOM) has demonstrated its ability to access the relevant spatial regime. In combination with IR-vibrational spectroscopy s-SNOM provides molecular structural information. However, a yet higher degree of specificity, sensitivity, and selectivity with respect to specific molecular functional features is desired. I will discuss the strength of s-SNOM in a new combination with other nano-spectroscopic imaging modalities including nonlinear, ultrafast, and Raman, as well as other scanning probe modalities. In addition the multi-spectral combination of the strength of different coherent and incoherent IR sources including narrow band wavelength tunable continuous wave lasers, femtosecond OPO and OPA sources, broadband synchrotron radiation, and thermal near-field radiation provides an enhanced dynamic range to probe at the level of the microscopic intra- and intermolecular interaction. I will discuss several specific implementations from our recent work on block-copolymers, organic photovoltaics, proteins, self-assembled monolayers, and biominerals,

8815-25, Session 6

Super resolution mapping of the near optical field and the gradient optical force

Ryan M. Gelfand, Alireza Bonakdar, Omer G. Memis, Hooman Mohseni, Northwestern Univ. (United States)

We have developed a super resolution NSOM technique that can map both the near optical field and the optical force using an atomic force microscope. This technique could be very useful for characterizing MEMs/NEMs devices, plasmonic nano-antennas, nano-photonic devices and biologically active substrates. Unlike conventional NSOM techniques that rely on an aperture fabricated on the end of an AFM tip to collect the optical signal this apertureless technique uses a lock-in amplifier locked to the AFM tip vibrational frequency, to correlate the amplitude modulation of the back reflected optical signal to the strength of the optical field. And since we are not limited by the fabrication of an aperture the spatial resolution of the map is limited only by the size of a sharp AFM tip which for metallic coated tips can have a radius of curvature of 10 to 20 nm.

For optical force mapping the incident laser is modulated and the lock-in amplifier is used to correlate the amplitude modulation of the vibrating AFM tip to strength of the optical gradient force. And in this way one can get a very accurate mapping of both the optical force and the optical field for any substrate of interest as long as it can be back illuminated.

Lastly with an electrically monolithic substrate it is possible to correlate the amplitude modulation of the tunneling current to the optical field and obtain a spatial mapping that has a resolution of an STM, about 1 nm or maybe less.

8815-26, Session 6

Numerical modeling of apertureless scanning near-field optical microscopy

Arvindvivek Ravichandran, Edward C. Kinzel, Missouri Univ. of Science and Technology (United States); Robert L. Olmon, Univ. of Colorado at Boulder (United States); James C. Ginn III, Plasmonics, Inc. (United States); Jeffrey A. D'Archangel, The Univ. of North Carolina at Charlotte (United States); Brian A. Lail, Florida Institute of Technology (United States); Markus B. Raschke, Univ. of Colorado at Boulder (United States); Glenn D. Boreman, The Univ. of North Carolina at Charlotte (United States)

We present a HFSS model of a physically accurate SNOM probe (Arrow-NC) scanning over a patch antenna operating at 10.6 ?m. As in the real SNOM system, the probe/antenna are excited with an off-normal Gaussian beam. We calculate how the probe scatters light into the far-field (through a common lens with the illumination) for different positions of the antenna relative to the probe (both x-y scanning and separation of the height of the probe to capture tapping). The far-field signal is fitted as a function of the height of the probe relative to the surface. We use a Fourier analysis to construct the SNOM signal resulting from locking to different harmonics of the tapping frequency. This allows us to map the SNOM signal over the patch antenna. We compare this to the simulated near-field for the same antenna. This analysis shows that while the SNOM signal principally scales with the normal component of the field around the antenna there are some discrepancies in addition we see that for a small aperture detector, its position in the image plane effects the SNOM map of the antenna.

8815-27, Session 6

Transfer matrix for scattering-type near-field scanning optical microscopy

Nan Zhou, Yan A. Li, Xianfan Xu, Purdue Univ. (United States)

The scattering-type near-field scanning optical microscopy (s-NSOM) has been shown experimentally to be able to determine the amplitude and phase of near fields of nanostructures by polarization-resolved interferometric detection. However, it is challenging to compute the true near field from the measured signal because of the difficulties in simulating an actual s-NSOM measurement. In this work, we employ 3D numerical simulations to compute high harmonic signals in an s-NSOM measurement, scattered from various types of tips that are normally used in s-NSOM measurement. The strong interactions between tip and nanostructures to be measured, e.g., a bowtie nanoaperture, are considered. Demodulation of higher harmonic signals illustrates that with increasing harmonic order, the measured near field is in closer agreement with the anticipated results. Our results also show the limitations of spherical and small tip models commonly used in literature. More importantly, using the 3D calculations, we can establish a tip-dependent transfer matrix that relates the local near-field components with the s-NSOM signals, which characterizes the scattering of the tip with respect to different components. The transfer matrix greatly facilitates recovering the true local field from the measured s-NSOM signal through a simple backward transformation calculation.

8815-7, Session 7

Image scanning microscopy *(Invited Paper)*

Jörg Enderlein, Georg-August-Univ. Göttingen (Germany)

Classical fluorescence microscopy is limited in resolution by the wavelength of light (diffraction limit) restricting lateral resolution to ca. 200 nm, and axial resolution to ca. 500 nm (at typical excitation and emission wavelengths around 500 nm). However, recent years have seen a tremendous development in high- and super-resolution techniques of fluorescence microscopy, pushing spatial resolution to its diffraction-dictated limits and much beyond. One of these techniques is Structured Illumination Microscopy (SIM). In SIM, the sample is illuminated with a spatially modulated excitation intensity distribution, and the emerging fluorescence is imaged with a conventional wide-field imaging setup. By moving and rotating the excitation intensity distribution pattern in different positions and orientations, taking each time a wide-field image, a final fluorescence image is composed which has roughly double the resolution (laterally) of a conventional wide-field or a confocal laser scanning image alone. A similar technique is Image Scanning Microscopy (ISM). In ISM, the focus of a conventional laser-scanning confocal microscope (LCSM) is scanned over the sample, but instead of recording only the total fluorescence intensity for each scan position, as done in conventional operation of an LCSM, one records a small image of the illuminated region. The result is a four-dimensional stack of data: two dimensions refer to the lateral scan position, and two dimensions to the pixel position on the chip of the image-recording camera. This set of data can then be used to obtain a super-resolved image with doubled resolution, completely analogously to what is achieved with SIM. However, ISM is conceptually and technically much simpler, suffers less from sample imperfections like refractive index variations, and can easily be implemented into any existing LSCM. I will present the theoretical background of ISM and several of its applications in cell imaging.

8815-29, Session 7

Accurate 3D superresolution using phase retrieved pupil functions *(Invited Paper)*

Keith A. Lidke, Sheng Liu, Wesley D. Krueger, The Univ. of New Mexico (United States)

Single Molecule Localization based Superresolution requires the position determination of up to millions of fluorophores for each superresolution image. For speed and simplicity, fluorophore position estimation in three dimensions has often been implemented using simple Gaussian models, theoretical Point Spread Functions (PSFs) that do not account imaging system aberrations, or large, unwieldy, experimentally acquired 3D PSFs that can be prone to artifacts. Here we introduce a localization algorithm based on phase retrieved pupil functions and the maximum likelihood estimator. Pupil functions can contain information about specific aberrations present in the imaging system and can be used to calculate realistic 3D PSFs from a small set of Zernike polynomial coefficients that describe the pupil magnitude and phase [1]. This compact representation of the 3D PSF allows the PSF to be efficiently calculated as needed in an iterative update method implemented on GPU hardware in a similar fashion to our two dimensional localization algorithms [2,3]. We demonstrate the use of phase retrieved pupil functions for 3D localization by imaging several structures throughout whole cells using both dual focal plane and astigmatic imaging.

Drift estimation for single marker switching based imaging schemes

Alexander Egner, Claudia Geisler, Laser-Lab. Göttingen e.V. (Germany); Thomas Hotz, Georg-August-Univ. Göttingen (Germany); Andreas Schönle, Stefan W. Hell, Max-Planck-Institut für Biophysikalische Chemie (Germany); Axel Munk, Georg-August-Univ. Göttingen (Germany)

In recent years, the diffraction barrier in fluorescence imaging has been broken and optical nanoscopes now routinely image with resolutions of down to 20 nm, an improvement of more than 10 fold. Because this allows imaging much smaller features and because all superresolution approaches trade off speed for spatial resolution, mechanical instabilities of the microscopes become a limiting factor. Here, we propose a fully data-driven statistical registration method for drift detection and drift correction for single marker switching (SMS) imaging schemes, including a guideline for parameter choice and quality checks of the drift analysis. The necessary assumptions about the drift are minimal, allowing a model-free approach, but more specific models can easily be integrated. We determine the resulting performance on standard SMS measurements and show that the drift determination can be routinely brought to the range of precision achievable by fiducial marker-tracking methods.

Approaching quantitative results in localization-based super-resolution microscopy: a robust and essential rejection algorithm and its applications in super fast live cell imaging

Fang Huang, Yu Lin, Tobias M. P. Hartwich, Joerg Bewersdorf, Yale Univ. (United States)

Single molecule localization techniques such as PALM/STORM/FPALM/dSTORM/GSDIM have been proven to be a promising technique which breaks the diffraction limit of light microscopy and provide images with resolutions as low as tens of nanometer in both fixed and living cells. Although these stunning super-resolved images provide helpful insights for biophysicist and microbiologists, quantitative analysis on the single molecule level such as protein number estimation and co-localization quantification has yet to be consider sophisticated. The main reason for the lack of quantitative analysis development resides in the additional

complexities that are introduced during analysis processes in this technique. In particular, the statistical behavior of rejection algorithms and localization estimate combination are not statistically addressed.

Here, we presents a specific tailored metric based on Log-likelihood Ratio (LLR) as an essential metric for rejection algorithms used in localization nanoscopy. We demonstrate its application as being one of the essential components which facilitate super-fast localization nanoscopy by strictly testing and obtaining the most accurate position estimates. By combining with our recent discoveries of a multi-emitter fitting algorithm and sCMOS technology, we demonstrate super-fast localization-based super-resolution microscopy on live cells by monitoring dynamics of protein clusters, vesicles and organelles at reconstruction speeds from 2 to 30 frames per second.

Mechanical and optical design and characterization of a 4Pi-FPALM super-resolution microscope

Edward Allgeyer, George Sirinakis, Fang Huang, Whitney Duim, Travis J. Gould, Joerg Bewersdorf, Yale School of Medicine (United States)

Light microscopy has long been established as a work horse in biology, with prolific applications spanning all areas of science. Unfortunately, the inability to resolve structures below the diffraction limit has greatly reduced the application of conventional light microscopy at length scales where many critical biological processes take place. As a result, innovations relying on marker switching have emerged that circumvent this fundamental limit and allow investigations at the sub-diffraction level [1]. Of these, localization based microscopy, in which sparse subsets of markers are stochastically activated, localized, and used to reconstruct images below the diffraction limit, has emerged as a popular modality.

Recently, combining a dual objective 4Pi geometry with stochastic switching localization based microscopy has realized sub-diffraction resolutions on the order of tens of nanometers in both the lateral and axial dimensions [2-3]. This improvement is achieved by taking advantage of the increased aperture angle and photon self-interference. Here we detail the mechanical design and function of a new auto-aligning 4Pi-FPALM system designed specifically with user functionality in mind. The instrument not only provides excellent 3-dimensional resolution improvements but additionally demonstrates outstanding optical and mechanical stability, reducing the need for user maintenance. In this presentation, we characterize the current localization precision, acquisition speed, and improvements of the microscope and present the first applications in biological systems.

Advances in plasmonic sensing: new mechanisms for increasing chemical sensitivities *(Invited Paper)*

Naomi J. Halas, Rice Univ. (United States)

Recent developments in plasmonic nanoantenna design have extended the range of chemical sensors into the mid-infrared chemical fingerprinting region of the optical spectrum. These structures can be tuned to enhance the surface enhanced infrared absorption (SEIRA) signature of specific chemical functional groups. We have recently shown that individual antennas with a cross geometry manifest large SEIRA enhancements, eliminating the need for using large antenna arrays to obtain chemical signals. Antenna designs with narrow surface plasmon resonances and an electrical readout due to hot electron decay also have the potential to serve as chemical sensors: the geometry of these structures will also be discussed.

8815-34, Session 8

A new statistical approach for molecular identification by SERS

Thibault Brulé, Alexandre Bouhlier, Hélène Yockell-Lelièvre, Alain Dereux, Lab. Interdisciplinaire Carnot de Bourgogne (France); Renaud Seigneuric, Carmen Garrido, Univ. de Bourgogne (France); Eric Finot, Lab. Interdisciplinaire Carnot de Bourgogne (France)

SERS is a powerful measurement technique to obtain vibration modes of single biomolecules or more complex systems such as blood plasma. Existing SERS spectra result from a cumulative contribution of multiple proteins with different conformations and concentrations that are depending on SERS-active template utilized.

We propose a selective description of the serum by analyzing SERS contribution of individual proteins using a specific experimental approach [1] and multivariate analysis. The dynamics of rare events characterizing the Raman activity [2] of the serum on specially-synthesized nanoflowers was monitored. The observed large amplitude fluctuations of the spectra both in wavenumber and intensity require a careful and extensive multivariate data analysis. We will show that the use of the log-logistic distribution coupled with Principal Component Analysis (PCA) proved to be a robust and systematic technique to provide a unique spectral differentiation between the different serum proteins.

PCA is a specific linear transformation to convert the set of spectra having correlated variables into a set of linearly uncorrelated variables called principal components. This helps to gain valuable information about the degree of complexity of the results and reduces the dimension of observables to some principal spectra. PCA was so used to isolate the main spectra families [3].

The practical outcome of this study is the analysis of Heat Shock Protein 70 (HSP-70) in blood (SPEDOC European Project).

Surface-enhanced infrared absorption using individual plasmonic antennas

Ke Zhao, Lisa V. Brown, Naomi J. Halas, Peter Nordlander, Rice Univ. (United States)

The development of antenna structures for surface-enhanced infrared absorption spectroscopy (SEIRA) is a topic of intense and growing interest for extending IR spectroscopy to zeptomolar quantities and ultimately to the single molecule level. Here we show that strong infrared spectroscopic enhancements can be obtained from individual gold nanoantennas using conventional infrared spectrometric sources.[1] The antenna structure dimensions can be tuned to enhance the IR modes of specific chemical moieties. Simulations of the electric field intensity in the antenna junction region reveal a maximum SEIRA enhancement factor of more than 12,000. These findings open new opportunities for analyzing infrared vibrations of exceptionally small quantities of molecules through widely accessible means.

Blinking from surface-enhanced Raman scattering from individual single-walled carbon nanotubes: the effect of chemical modification of the nanotube

Nebras E. Al-Attar, Rasoul Al-Majmaie, Univ. College Dublin (Ireland); Ilona Kopf, Silvia Giordani, Trinity College Dublin (Ireland); James H. Rice, Univ. College Dublin (Ireland)

Single-walled carbon nanotubes (SWCNT) possess optical and electronic properties that can be potential tailored by the addition of a chemical group via covalent bonding to the nanotube thereby altering the conjugative network of the graphene sheet and creating changes in the electronic structure of the SWCNT. Surface-enhanced Raman (SERs) spectroscopy enables the imaging of single molecules.

SERs from single molecules possess random fluxing or blinking in the SERs intensity as a function of time. The study of such blinking processes has the potential to inform on the electronic structure of the molecule and how it interacts with its local environment.

SWCNTs with chemical groups covalently to the SWCNT surface were investigated using surface-enhanced Raman (SERs) spectroscopy at the single nanotubes level assessing the impact of such altering of the nanotube on the blinking process and in turn its interaction with the local environment.

We studied specifically SWCNTs and SWCNTs that have been chemically treated to improve their purity and also to alter the structure of the nanotube surface via covalently attaching carboxylic acid groups. Excitation of the nanotube samples at wavelengths in resonance with metallic and also semiconductor nanotubes was undertaken. Temporal fluctuations of SERs of purified and oxidised SWCNTs have been observed for both excitation wavelengths. These spectral features were assigned to arising from Raman scattering from single and few carbon nanotube molecules.

We studied both the spectral features and also the SERs blinking rates. The effect of chemical introduction of carboxylic acid moieties to the surface of the nanotubes was seen to tentatively reduce the temporal fluctuations in the SERs spectra. In addition both the power density and thickness of the silver substrate dependence on the Tangential modes G-band and disorder-induced feature D-Band have been studied for both highly purified and oxidised SWCNT.

8815-44, Session 8

Residual pesticide detection on food with particle-enhanced Raman scattering

Bikas Ranjan, Huang LiChuan, Kyoko Masui, Yuika Saito, Prabhat Verma, Osaka Univ. (Japan)

Modern agriculture relies highly on pesticides to protect agricultural food items from insects for high yield and better quality. Increasing use of pesticides has raised concern about its harmful effects on human health and hence it has become very important to detect even small amount of pesticide residues. Raman spectroscopy is a suitable nondestructive method for pesticide detection, however, it is not very effective for low concentration of pesticide molecules. Here, we report an approach based on plasmonic enhancement, namely, particle enhanced Raman spectroscopy, which is rapid, nondestructive and sensitive. In this technique, Raman signals are enhanced via the resonant excitation of localized plasmons in metallic nanoparticles. As plasmonic resonance frequency highly depends on the shape, size and material of nanostructures, hence it is possible to grow nanoparticles of a chosen shape and size to tune its plasmonic resonance with the resonance of Raman signals of any desired pesticide for better enhancement. Gold is a promising material that has ability to tune surface plasmon resonance frequency in visible to near-IR, which depends on shape and size of nanostructures. We synthesized desired shape and size of gold nanoparticles by using seed mediated growth method, and successfully detected very tiny amount of two pesticides, named benomyl and polycarbamate. We also confirmed that the detection of these pesticides was not possible by usual Raman spectroscopy.

8815-37, Session 9

Electron-tunneling assisted tip-enhanced Raman nanoimaging and nanospectroscopy *(Invited Paper)*

Alfred J. Meixner, Dai Zhang, Kai Braun, Eberhard Karls Univ. Tübingen (Germany)

We report about electron-tunneling assisted non-resonant Raman scattering spectroscopy and nanoimaging of molecules bound to a gold surface via a laser illuminated Au-tip Au-sample tunneling junction with a STM combined with a confocal microscope/spectrometer. For low bias voltages the TERS-spectra look similar to those recorded with shear-force tip-sample distance control. As the bias voltage increases we observe reversible mode specific enhancement and suppression of bands. Furthermore, reproducible differences in the Raman spectra are observed that are recorded at locations being only four nanometers apart from each other.

Efficient optical access to the tunneling junction is provided with a parabolic mirror for tip illumination and optical signal collection that are performed from above the sample under perfect diffraction and polarization conditions with a radially polarized laser beam. No restrictions apply with respect to the conductivity or transparency of the samples.

8815-38, Session 9

Raman spectral mapping of a single molecule with sub-nm resolution *(Invited Paper)*

Zhenchao Dong, Univ. of Science and Technology of China (China)

Visualizing individual molecules with chemical recognition is a longstanding target in catalysis, bio-science, and molecular nanotechnology. Molecular vibrations provide a valuable “fingerprint” for this identification. The spectroscopy based on tip-enhanced Raman scattering (TERS) has opened a path to obtain enhanced spectral signals thanks to the strong localized plasmonic field originated at the tip apex. The use of TERS has been pioneered by several groups in an effort to drive down the spatial resolution of molecules with chemical identification through vibrational fingerprints. However, the best spatial resolution of the TERS imaging reported to date is still limited to a few nm, obviously not adequate for resolving a single molecule chemically. Here we demonstrate unprecedented sub-molecular Raman spectral imaging with spatial resolution below 1 nm, resolving even the inner structure of a single molecule and its configuration on the surface. This is achieved by spectrally matching the resonance of the nanocavity plasmon to the downward molecular vibronic transitions, thanks to exquisite tuning capability provided by low-temperature ultrahigh-vacuum scanning tunneling microscopy. Our spectral-matching technique not only allows for chemical imaging at the single-molecule level, but also offers a new avenue to study optical processes and photochemistry of a single molecule.

8815-39, Session 9

Low-frequency Raman investigation and tip-enhanced Raman imaging of graphene

Kazumasa Uetsuki, Junto Tsurumi, Yuika Saito, Satoshi Kawata, Prabhat Verma, Osaka Univ. (Japan)

We have investigated a mechanically exfoliated graphene sample and imaged its number of layers through the G/2D intensity ratio in Raman microscopy. We investigated the interlayer interaction to understand the stacking for 2, 3, and 4 layer graphene samples by exploring the low-frequency E*(low) mode in Raman scattering. This low-frequency mode was successfully observed through our specifically modified experimental system for the observation of low-frequency Raman modes. While most part of sample showed AB stacking, a small area showed ambiguous behaviour due to random stacking of layers. We could conclude that this area consisted of 4 graphene layers, which were stacked either in the form of two pairs of closet-packed stacking, or in the form of 2 layers in closet-packed stacking plus two single layers. In addition, tip-enhanced Raman scattering (TERS) microscopy allowed us to image the sample at high spatial resolution, where we were able to analyze the interlayer interactions at nano-scale. We were also able to analyze the defects in our graphene sample at high spatial resolution, where we particularly investigate the defects at the edges of a graphene sample.

8815-40, Session 9

Polarization analysis in tip-enhanced near-field Raman imaging

Toshihiro Mino, Yuika Saito, Prabhat Verma, Osaka Univ. (Japan)

Tip-enhanced Raman spectroscopy (TERS) has revealed molecular vibrations in nano-scale beyond the diffraction limit. However, polarization of near-field light in TERS measurements is still ambiguous, because we have only little control on the near-field light due to the difficulty of precise shape regulation of the metalized tip apex. Here, we investigated the plasmon mode excited at the tip apex under dipole approximation, and performed polarization near-field imaging with TERS. Scattered light from the tip apex was measured by defocus technique, which revealed that the dipolar plasmon mode was excited in a certain direction when the tip apex was small enough compared to the wavelength of incident light. The xy- (perpendicular to the tip axis) and z- (parallel to the tip axis) polarization in near-field were determined from the analysis of the dipolar pattern. We successfully obtained polarization TERS images of carbon nanotubes using the tips evaluated by our method. The G-band in Raman scattering of our sample was strongly excited when the nanotubes were aligned in the dipolar direction, whereas radial breathing mode was observed only in the case where the dipole had enough polarization components in z-direction. The results agreed well with our expectation in both xy- and z-polarization directions. This method allows us to successfully utilize not only for polarization analysis but also for quantitative analysis in near-field Raman imaging.

8815-41, Session 10

Plasmonic Fano resonances: applications in surface enhanced spectroscopies *(Invited Paper)*

Peter Nordlander, Rice Univ. (United States)

Metallic nanostructures with their ability of confining and enhancing incident light offer unique possibilities for manipulating light at the nanoscale.[1] Plasmonic nanostructures can also exhibit coherence effects such as Fano resonances where the interference between superradiant and subradiant modes produces extinction features with characteristic narrow and asymmetric line shapes.[2] Due to their narrower spectral width compared to standard plasmon resonances, Fano resonances can provide very large field enhancements. Using symmetry breaking it is possible to tune the Fano interference into specific regimes: a weak coupling regime suitable for LSPR sensing; and a critical coupling regime providing large field enhancements suitable for plasmon enhanced spectroscopies. Finally I will discuss several recent applications where plasmonic Fano resonances have been used to enhance surface enhanced spectroscopies such as SERS[4] and four wave mixing.[5]

Nanogap-enhanced Raman spectroscopy (NERS) controlled by DNA *(Invited Paper)*

Yung Doug Suh, Korea Research Institute of Chemical Technology (Korea, Republic of)

A series of research efforts have been devoted to generate more reliable SERS hot spots endowing single molecule sensitivity in the past decade. Based on an idea that controlling the gap at the junction of two noble metal nanoparticles and putting only a single molecule into this gap a priori is the key to systematically study single-molecule SERS phenomena, we have adopted DNA double helix tethered with a single Raman dye at the center position to bind two gold nanosphere cores with a known distance determined by DNA double helix ruler. Then we narrowed down this initial gap to sub-1-nanometer with standard silver staining method in solution.

This nanogap-enhanced Raman scattering (NERS) controlled by DNA with single molecule sensitivity seems to share the same gap-plasmon based physics with gap-mode STM/AFM-TERS, nanogap SERS sensor array including bowtie nano-antenna, and even conventional SERS, although only very rare portion of these nanogap sites can be formed in colloidal or thin film samples, resulting relatively low SERS enhancement factor compared with smSERS after ensemble average over a large area. In this presentation, I would like to review our own research effort to investigate this DNA-controlled NERS as well as the other kind of NERS phenomena.

8815-43, Session 10

Flocculation of metal nanoparticles towards efficient single molecule characterization in SERS *(Invited Paper)*

Masayuki Futamata, Saitama Univ. (Japan)

Single molecule detection by Raman scattering can be achieved using a coupled localized surface plasmon (LSP) of adjacent metal nanostructures, by controlling the nanogap size and the adsorption of target molecules. For this purpose, we have studied flocculates of silver and gold nanoparticles (AgNPs, and AuNPs), which are a few closely adjacent nanoparticles, providing various molecules with enormous SERS intensity in solutions1-2. First, the adsorption of cationic and neutral R6G molecules on Au nanoparticles was elucidated by surface enhanced Raman scattering on the basis of the flocculation method3. The steric hindrance at hydroethyl amino (-N(H)Et) groups in R6G was evidenced by the observation that R6G+ adsorb on as-prepared AuNPs only with electrostatic forces, in contrast to the electrostatic and chemical adsorption of R123+ with dihydro amino (-NH2) groups on as-prepared AuNPs. Large steric hindrance at the amino groups in R6G yielded saturated coverage of 700 molecules/AuNP for R6G+ significantly fewer than 1000 molecules/AuNP for R123+. In addition, neutral R6G0 on AuNPs showed markedly enhanced peaks at 1200-1600 cm-1, which were not observed in Raman spectra of R6G0 in bulk solution, and also in SERS of R6G+ on AuNPs. These bands are attributed to vibrational modes of an outer-phenyl ring and ethyl amino groups, which are vertical to a xanthene plane, on the basis of theoretical analysis of molecular vibrations. Thus Raman scattering of these bands are enhanced under an inclined orientation of R6G0 molecules chemisorbed on AuNPs via lone pair electrons at amino groups. Second, flocculates of AgNPs were formed using p-mercaptobenzoic acid (PMBA) to prove the relevance of this method for various species4. Electrostatic interaction between dissociated PMBA and counter ions, as well as van der Waals force between protonated PMBAs on AgNPs plays a crucial role in the flocculation. Dissociation of PMBA on AgNPs is determined not only by pH in solutions but also by surface coverage of PMBA. Mono- and divalent cations modified the ?COO- band at 1420 cm-1 by 20 cm-1 indicating distinct interaction of the cations with dissociated carboxylate anions of PMBA on AgNPs.

Conference 8816: Nanoengineering: Fabrication, Properties, Optics, and Devices X

Tuesday - Thursday 27–29 August 2013

Part of Proceedings of SPIE Vol. 8816 Nanoengineering: Fabrication, Properties, Optics, and Devices X

SPIE Optics+Photonics
NanoScience + Engineering

8816-1, Session 1

High volume nanoscale roll-based imprinting using jet and flash imprint lithography *(Invited Paper)*

Douglas J. Resnick, Molecular Imprints, Inc. (United States)

The ability to pattern materials at the nanoscale can enable a variety of applications ranging from high density data storage, displays, photonic devices and CMOS integrated circuits to emerging applications in the biomedical and energy sectors. These applications require varying levels of pattern control, short and long range order, and have varying cost tolerances.

Extremely large area roll to roll (R2R) manufacturing on flexible substrates is ubiquitous for applications such as paper and plastic processing. It combines the benefits of high speed and inexpensive substrates to deliver a commodity product at low cost. The challenge is to extend this approach to the realm of nanopatterning and realize similar benefits. The cost of manufacturing is typically driven by speed (or throughput), tool complexity, cost of consumables (materials used, mold or master cost, etc.), substrate cost, and the downstream processing required (annealing, deposition, etching, etc.). In order to achieve low cost nanopatterning, it is imperative to move towards high speed imprinting, less complex tools, near zero waste of consumables and low cost substrates.

The Jet and Flash Imprint Lithography (J-FILTM) process uses drop dispensing of UV curable resists to assist high resolution patterning for subsequent dry etch pattern transfer. The technology is actively being used to develop solutions for memory markets including Flash memory and patterned media for hard disk drives.

In this paper, we have developed a roll based J-FIL process and applied it to technology demonstrator tool, the LithoFlex 100, to fabricate large area flexible bilayer wire grid polarizers (WGP) and high performance WGPs on rigid glass substrates. Extinction ratios of better than 10000 were obtained for the glass-based WGPs. Two simulation packages were also employed to understand the effects of pitch, aluminum thickness and pattern defectivity on the optical performance of the WGP devices. It was determined that the WGPs can be influenced by both clear and opaque defects in the gratings, however the defect densities are relaxed relative to the requirements of a high density semiconductor device.

Performance metrics of the LithoFlex 100, including throughput and pattern quality will be addressed. The application of this technology to the display market in addition to other markets will also be discussed.

8816-2, Session 1

Ultra-fast microfluidic and optofluidic prototyping based on controlled polymer dissolution

Andreas E. Vasdekis, Michael J. Wilkins, Jay W. Grate, Ryan T. Kelly, Sarah J. Fansler, Allan E. Konopka, Sotiris S. Xantheas, Pacific Northwest National Lab. (United States); Tsun-Mei Chang, Univ. of Wisconsin-Parkside (United States)

In this presentation, we discuss our recent results in developing a new polymer imprinting technique based on controlled polymer dissolution for microfluidic applications. The technique enables both the imprinting and bonding of thermoplastic polymers in very short time-scales; typically, complete assembly can be achieved in less than a minute. This represents a significant improvement over conventional thermal imprinting techniques, as well more recently developed injection techniques. We will present the details of the method and specifics of the involved underlying interfacial mechanisms as probed by chemical imaging methods and molecular simulations. Applications of the method in optofluidics as well as microfluidic cell-cultures will be discussed. Regarding the latter, as an example in microbiology, the growth of pure and mixed microbial populations was investigated in polystyrene micro-pore scale models; a double mean generation lifetime was revealed for the thermophile anaerobe Clostridium Thermocellum than under ideal culture conditions. Solvent based imprinting has been previously reported with enhanced performance in thin film applications and down to nm-scale resolution. The present work focuses on micro-scale features, with depths ranging from a few microns up to 100 µm.

8816-3, Session 1

Nano imprinted indium tin oxide sol-gel in light emitting diodes for effective elimination of total internal reflection

Sungjoo Kim, Chul Jong Ryu, Yang Hee Song, Gyeongmin Go, Jong-Lam Lee, Pohang Univ. of Science and Technology (Korea, Republic of)

In the field of Group III-nitride light-emitting diodes (LEDs), much room remains for enhancement of light extraction efficiency because most of the generated photons from the active layer remain inside the LEDs because of the total internal reflection (TIR) at the semiconductor-air interface. To circumvent this problem, nano-imprint lithography has been offered for significant improvements of light extraction efficiency of the GaN LED device. However, reported imprinted materials such as SU-8 and PDMS are polymeric which have lower refractive index then that of top transparent electrode, indium-tin-oxide (ITO). Therefore, TIR and Fresnel reflection are occurred at the interface of ITO and soft resin, which limit the overall efficiency of the LEDs.

In this respect, we demonstrated the fabrication of novel hexagonal pyramid-shaped nanostructures with nano-imprinted index-matched ITO to eliminate TIR. Based on Monte-Carlo 3D ray tracing, we clearly confirm that light output intensity was increased with refractive index matching. Through refractive index matched nano structure, we enhanced the out-coupling efficiency of GaN based light emitting diodes (LEDs) about 12%. The 300C annealed ITO sol-gel has refractive index of 1.95, remaining the transparency (92%) and nano-structure. The nano-structured ITO sol-gel increases the diffused transmittance from 0.76% to 38%, leading to extract the wave-guided light from total internal reflection and fresnel reflection.

8816-4, Session 1

Engineering nano-particles for liquid bistable memory devices

Pascal André, Univ. of St. Andrews (United Kingdom) and RIKEN (Japan); Tsuyoshi Muto, M. Uchiyama, Tetsuya Aoyama, RIKEN (Japan); Jean-Charles Ribierre, RIKEN (Japan) and Ewha Womans Univ. (Korea, Republic of)

Hybrid materials based on inorganic nanocolloids (nCs) and organic semiconducting molecules have recently been the subject of intensive studies. This is due to potential advantages such as their relatively low cost and the opportunities to complement the properties of the organic materials by those of the inorganic constituents. Optoelectronics applications currently under investigation can been seen as having started with solar cells, but now include light-emitting diodes, and bistable memories. The latter class of device relies on hysteretic behavior of the conductivity when a voltage is swept between two electrodes. For each of them the mechanical flexibility is a key-concern for which emerging Liquid Electronics might have intrinsic advantages.[1-5]

Here, we report on and discuss the fabrication of optoelectronic devices based on a blend of inorganic nCs and 9-(2-ethylhexyl) carbazole (EHCz), coined as liquid carbazole. In contrast with other approaches which are based on solid thin films, these devices have a very simple structure with a single liquid layer sandwiched between two electrodes. Devices based on a liquid material and inorganic nanoparticles are an important step for the future development of organic liquid optoelectronic devices.[5]

8816-5, Session 1

Nanofluidics integrated with plasmonics for ultra-high sensitivity devices *(Invited Paper)*

Irene Fernandez-Cuesta, Corrado Carbone, Enrica Montinaro, Scott D. Dhuey, Daniel J. Gargas, James P. Schuck, Stefano Cabrini, Lawrence Berkeley National Lab. (United States)

Plasmonic bowtie nanoantenna are able to confine and enhance the field intensity several orders of magnitude at a very small spot, that is the gap: this intense, nano-focused light is ultra-sensitive, what can be exploited for (bio)sensing. But there is a major challenge: placing the target element right at the antenna gap.

In this work, we have integrated a nanochannel running along a bowtie-shaped nanoantenna gap, what allows to deliver the analyte right into the sensitive area in a controlled fashion. The nanochannel dimensions are chosen to fit one particle or (bio)molecule, to be read one-by-one. The nanochannel is integrated in a complete fluidic system to facilitate the liquid control.

We have developed a wafer-scale fabrication process, based on nanoimprint lighotraphy (NIL), for the device fabrication. The all-transparent, multidimensional, multilevel polymeric device is made in one single step, by direct UV-NIL using the a stamp to imprint a hybrid polymer. The bowtie antenna are defined by shadow evaporation of chromium, a normal evaporation of gold, and lift-off.

Preliminary sensing results show the capabilities of the device. Single molecules of ?-DNA haven been stretched and driven trough the nanochannels by electrophoresis. The dark field resonant peak shifts 15 nm when the empty channel is filled with water. The antenna have been used also for “antenna-enhanced” Raman spectroscopy, and real time fluorescent single particle detection.

8816-6, Session 1

Impact of the Marangoni effect on the polymer thin film thickness profile after drying polymer solution coated on a flat substrate

Hiroyuki Kagami, Nagoya College (Japan)

We have proposed and modified a model of drying process of polymer solution coated on a flat substrate for flat polymer film fabrication supposing resist coating process in photolithography process. And we have clarified dependence of distribution of polymer molecules on the substrate on various parameters based on analysis of numerical simulations of the model. Above model consists of two elements. One is vaporization at the gas-liquid interface. The other is the diffusion inside the liquid film. The diffusion is divided into two kinds of diffusion, that is, diffusion of solvent with solutes due to gradient of the number density of particles per space and diffusion of concentration of solution. Because it is assumed that coated solution film on a flat substrate is very thin and therefore both Rayleigh number and Marangoni number are small enough, it is thought that Bénard convection or Marangoni convection does not occur and therefore it is sufficient to consider only above-mentioned two kinds of diffusion inside the liquid film. However there may be some sort of Marangoni effect regardless Marangoni convection does not occur. Therefore, in this study we add the Marangoni effect to the model. Concretely, we add Marangoni effect as pseudo-negative diffusion on an upper gas-liquid interface to the model. Then we evaluate effects of the Marangoni effect in the drying process through numerical simulation. And we see that solute on upper gas-liquid interface is attracted more strongly to the edge due to Marangoni effect.

8816-7, Session 1

Electrically tunable diffraction grating

Sun Il Kim, Jun-Hee Choi, Ho Young Ahn, Chan-Wook Baik, Jungkweuen An, Chilsung Choi, Kyungsuk P. Pyun, Samsung Advanced Institute of Technology (Korea, Republic of); Hong-Seok Lee, SAIT (Korea, Republic of)

We report on electrically tunable diffraction grating, where the refractive index of a Liquid Crystal (LC) was changed by applying DC bias to a metal nanograting (NG) structure. The structure consists of two parallel plates separated by a gap filled with LC molecules. The front and rear plates have structures of a rubbed polyimide (PI)/ITO electrode/fused silica glass substrate and a titanium NG electrode/n-type Si wafer, respectively. In the absence of DC bias of Vapp, the LC molecules are aligned parallel to the plate, in the rubbing direction of the PI. As Vapp increases from 0 V, the e-field near the metal grating strengthens sufficiently to rotate the LC molecules into the vertical direction following the e-field direction, while the orientation of the LC molecules in the space between the stripes remains unchanged. Up to the certain Vapp, the fraction of the vertically aligned LC volume increases to a maximum. With a further increase in Vapp above that value, the e-field even in the space between stripes is strong enough to drive the LC molecules to rotate into the vertical direction, hence reducing spatial modulation in the refractive index. At sufficiently high Vapp, all of the LC molecules are align nearly vertically and the spatial LC alignment contrast eventually disappears. Finally we obtained an active diffraction grating having a maximum refractive index difference (?n) of 0.088 and diffraction efficiency (?) variation of 0-16% with a large diffraction angle of 64° for incident light of 633 nm wavelength

8816-61, Session 1

Optical microscope combined with the nanopipette-based quartz tuning fork: atomic force microscope for nanolithography

Sangmin An, Seoul National Univ. (Korea, Republic of); Corey Stambaugh, National Institute of Science and Technology (United States); Soyoung Kwon, Kunyoung Lee, Bongsu Kim, Qwhan Kim, Wonho Jhe, Seoul National Univ. (Korea, Republic of)

We demonstrated the optical microscope (OM) combined with nanopipette-based quartz tuning fork - atomic force microscope (QTF-AFM) for nanolithography. The nanoparticle (Au, 5 nm), nanowire, PDMS solutions are ejected onto the substrate through the nano/microaperture of the pulled pipette, and the nano/microscale objects were in-situ formed on the surface with the proposed patterning system, while the position is defined by monitoring the phenomena on the substrate with a home-made OM. After forming of capillary condensation between apex of the pipette tip and the surface, the electric field is applied to extract out the inside liquid to the substrate and the nano/microscale objects are fabricated. The nanoscale patterning size can be controlled by the aperture diameters of the pulled pipette.

8816-8, Session 2

Vapor phase synthesis of XS2 atomic layers on SiO2/Si substrates

Zafer Mutlu, Isaac Ruiz, Robert Ionescu, Hamed Hosseini Bay, Mihrimah Ozkan, Cengiz S. Ozkan, Univ. of California, Riverside (United States)

Although single or few layer graphene has been shown to have many interesting properties as a supplement to silicon-based semiconductor technologies, its zero band gap limits its applications for optoelectronic and nanoelectronics technologies. Therefore, there have been considerable e?orts to open and tailor the band gap of graphene and shown that the band gap opening and tuning in graphene can be achieved by various methods such as doping and applying external electrical field. However, it is still far from satisfactory for practical applications. Very recently, atomic layered the transition metal dichalcogenides such as molybdenum disulfide (MoS2) and tungsten disulfide (WS2) with a direct band gap has attracted much scientific interest as an alternative to graphene due to its many potential applications. Here, we report the synthesis of XS2 (X: M, W) atomic layers on SiO2/Si substrates by a scalable chemical vapor deposition (CVD) technique based on the vapor phase reaction mechanism between MO3 (M: Mo, W) and sulfur. The effect of the various preparative parameters such as the sulfur concentration, pressure and deposition temperature on the structural, morphological, optical and electrical properties of XS2 atomic layers has been studied. The layers have been characterized by the scanning electron microscopy, optical microscopy, atomic force microscopy and Raman spectroscopy. The results have showed that sulfur concentration controls the grain morphology of XS2 layers, and MO3 determines the nucleation density. In conclusion, sulfur concentration, deposition temperate and MO3 morphology are very important process parameters in achieving atomic layers of XS2 with high quality and large scale. This synthetic approach is simple, scalable and applicable to other transition metal dichalcogenides such MoSe2 and WSe2.

8816-9, Session 2

Nanofabrication of integrated optical delay lines for RF and IR radiation pattern generation and steering

Louay A. Eldada, Quanergy, Inc. (United States)

We present advanced nanofabrication technologies used for the production of dynamic on-chip optical delay lines that generate and steer arbitrary radiation patterns using thermo-optic and electro-optic tuning. Photonic integrated circuits (PICs) designed for radio frequency (RF) and infrared (IR) radiation are described. RF PICs are combined with integrated detectors and RF antenna arrays, and used in applications ranging from phased array radar to communications, broadcasting and astronomy. IR PICs in the form of optical phased arrays with integrated grating-based optical nanoantennas enable solid state light detection and ranging (LiDAR), free space communications, and the selective excitation of modes in multimode fibers.

8816-10, Session 2

Artificially designed gold nanoparticles based on oblique-angle-deposition

Jung-Sub Wi, Tae Geol Lee, Korea Research Institute of Standards and Science (Korea, Republic of)

Well-defined homogeneous plasmonic nanoparticles are imperative to localize light and to use it for scientific interest and practical applications. In that sense, physical synthesis of nanoparticles by top-down routes, in which materials are vacuum deposited in a lithographically patterned polymer template, is a precise and reliable method to control material composition, particle size, and shape.[1-2] Here, we demonstrate that various shapes of the physically synthesized nanoparticles can be obtained by simple adjustment of incidence angle of deposited materials. Using nanoimprint lithography and oblique-angle-deposition, disk-, Petri-dish-, and ring-shaped gold nanoparticles are generated as well as their intermediate forms such as gold disks having a central bump or a central hole. Since it is possible to yield artificially designed gold nanoparticles with their unique light absorption/scattering properties, we expect the proposed method is quite useful to prepare various nanoprobes for bio-medical imaging and detection.

8816-12, Session 2

Adjustable-density silicon nanoparticles prepared by femtosecond laser irradiation in alcohol

Dongshi Zhang, Feng Chen, Qing Yang, Guangqing Du, Hao Bian, Jiale Yong, Jinhai Si, Xun Hou, Xi'an Jiaotong Univ. (China)

Silicon micro/nanostructure (m/ns-Si) has attracted significant attention in recent years for both fundamental research and technical applications, such as self-cleaning, solar cell, photoluminescence generation, photodetectors and photodiodes. Several techniques (e.g., lithography and chemical etching) have been used to produce m/ns-Si with controllable size, shape and distribution. Compared with these methods, femtosecond laser (fs) micromachining is particularly attractive for its ease to simultaneously produce periodic micro/nanostructures and fabricate complex structures. However, they suffer from the disadvantages of complexity and high cost. In this paper, we present a new method to achieve adjustable-density silicon nanoparticles (NPs) by high energy femtosecondlaser irradiating on silicon under flowing alcohol circumstance.

Figure 1 shows the experimental setup. A Si (p-100) wafer is placed in a glass container filled with alcohol which is mounted on a three dimensional translation stage. The alcohol is continuously added in to insure the sample was always underneath the liquid-air interface of 200μm.

A series of large areas (300*300μm) of NPs are fabricated on silicon using this method at different scanning speed (V) with laser energy of 20μJ, as shown in Fig. 2. The line-by-line scanning method is employed. The interval of adjacent lines is 2μm. It can be clearly seen that the sizes of NPs achieved at different scanning speed are very uniform and almost all equals to 100nm. The density of NPs varies significantly with 4.1μm-2 (V=3000μm/s) to 13.4μm-2 (V=100μm/s).

8816-13, Session 2

The cause of irregular shape of the photonic crystal fabricated with recycled solvent

Kwang Sun Kang, Kyungil Univ. (Korea, Republic of)

Abstract

Managing the solvent waste has to be the most cost effective and environmentally acceptable method. Minimizing or reducing technique for the generation of waste solvent is essential investigation before planning feasibility of the large quantity preparation of the target product. To reduce the waste solvent, this investigation focused on the solvent ratio dependent diameter of the spheres and the effect on the photonic crystal by using the recycled solvent. The sphere diameter reduced, as the NH4OH concentration reduced without defect until 25 volume % of NH4OH. However, reducing further to 14 volume % of NH4OH produced different diameters of the spheres. To investigate the effect on the silica

sphere when the recycled solvent is used, the recycled solvent has been repeatedly used until 5 times. The diameter and shape of the silica spheres were same and without defect when the solvent used two times. However, the sphere shape became more and more irregular shape when the recycling time increased. The FTIR spectra of the spheres fabricated with various times recycled solvents are identical. To fine out the cause of the irregular shape, the solvent was evaporated after using the solvent 5 times and analyzed the residual. The FTIR result shows that the residual compound composed of Si-O-Si and Si-OH, which indicates that the irregular shape of the photonic crystal is caused by the residual compound. Therefore, the ideal concentration of NH_4OH is approximately 25 %, and the solvents can be used two times and then have to be distilled to remove the silica compound.

8816-14, Session 2

Solvent-dependent optical limiting response of platinum nanoparticles stabilized by [60] fullerene derivative

Yachen Gao, Yimeng Wang, Heilongjiang Univ. (China); Jifeng Zu, Shanghai Institute of Optics and Fine Mechanics (China)

The optical limiting performance of platinum nanoparticles protected by C60 derivative in chloroform, ethanol and dimethylformamide (DMF) was investigated experimentally with 532nm, 8ns duration laser pulses. It was found that the optical limiting ability is solvent-dependent. The solvent effect and origins of the optical limiting were analyzed. It was proposed that the absorption-induced scattering is the main mechanism causing the optical limiting behavior and solvent effect.

8816-15, Session 2

Effect of laser fluence and shot number on the diameter of hole in gold film

Yimeng Wang, Yachen Gao, Heilongjiang Univ. (China); Jifeng Zu, Shanghai Institute of Optics and Fine Mechanics (China)

In this paper, we demonstrated the fabrication of laser-induced holes in the 50nm gold film using 120fs laser pulses at 800nm wavelength in air environment. The surface morphologies-microstructures and diameters of holes were characterized using atomic force microscopy (AFM). It was found that, there are two kinds threshold of laser fluence for the formation of hole. And the diameters of holes were influenced by pulse energy and shot numbers. Based on the investigation above, the origin of hole was discussed.

8816-16, Session 2

Fabricating 3D spiraling metallic nanostructures with controlled chirality using metal-assisted chemical etching

Owen Hildreth, National Institute of Science and Technology (United States); C. P. Wong, The Chinese Univ. of Hong Kong (China) and Georgia Institute of Technology (United States)

Fabricating nanostructures with complex, 3D geometry for applications such as chiral photonics can be extremely challenging using existing photolithography and etching processes. In this work we demonstrate a simple method to etch large arrays of chiral, 3D geometry in a single lithography/etch cycle using Metal-assisted Chemical Etching (MaCE) of silicon in conjunction with shaped catalysts. We also demonstrate that takes advantage of the catalyst remaining at the bottom of the template to electrolessly fill the templates from the bottom up using electroless deposition - enabling the facile fabrication of 3D metallic nanostructures with controlled, predefined chirality. The mechanism behind catalyst motion is detailed along with how catalyst shape controls etching mechanics and the resulting etching path.

Briefly, in MaCE a metal catalyst, such as Au, is patterned on a silicon wafer and then immersed in an etchant solution composed of Hydrofluoric Acid (HF) and an oxidizing agent, such as Hydrogen Peroxide (H_2O_2). The metal serves to create a traveling galvanic etching reaction by first catalytically reducing H_2O_2, consuming two electrons, and then injection two holes (h+) into the valance band of the silicon in contact with the metal. This creates a hole (h+) rich region of silicon surrounding the metal catalyst that is readily oxidized by the HF to form soluble H_2SiF_6. The etching reaction is perpetuated at the metal catalyst is driven into the substrate as the silicon around and beneath the catalyst is removed.

8816-27, Session 2

Surface-confined self-assembled Janus tectons: towards optical trapdoors *(Invited Paper)*

Antoine Colas, Ping Du, David Kreher, Fabrice Mathevet, Univ. Pierre et Marie Curie (France); Fabrice Charra, Commissariat à l'Énergie Atomique (France); André-Jean Attias, Univ. Pierre et Marie Curie (France)

One of the critical challenges in the field of two-dimensional (2D) supramolecular self-assemblies at surfaces is: how to exploit the room above the substrate, i.e. the third dimension perpendicular to the surface, to provide to the physisorbed adlayer potential functionalities in view of applications in nanoscience?

This is why developed a strategy aimed at the decoupling of conjugated molecules from a metallic surface, by lifting photoactive entities a few Å above the surface while maintaining the lateral organization of the array. We introduced the concept of Janus-like 3D molecular tectons [3,4], which are dual-functionalized building blocks exposing two opposite faces (A and B) linked by a rigid spacer : A is a pedestal designed for steering 2D self-assembly on the substrate (HOPG) and B a functional conjugated moiety.

Here we will present Janus tectons self-assembled as nanoporous networks and equipped with azobenzene derivatives. Due to the electronic decoupling we are able to observe the photoisomerization on a metallic substrate. By positioning the azobenzene over the cavities we can control the access.Then these janus tectons act as optical trapdoors

8816-18, Session 3

Chirped photonic crystals for spatial light filtering *(Invited Paper)*

Vytautas Purlys, Vilnius Univ. (Lithuania); Lina Maigyte, Univ. Politècnica de Catalunya (Spain); Darius Gailevicius, Martynas Peckus, Magirdas Malinauskas, Vilnius Univ. (Lithuania); Kestutis Staliunas, Univ. Politècnica de Catalunya (Spain) and Institució Catalana de Recerca i Estudis Avançats (Spain)

Spatial filtering plays an important role in optics as a tool for improving the spatial quality of the light beams. Usually a confocal system of lenses and diaphragm is used, which is however a bulky and sensitive to mechanical positioning system. Photonic crystals (PhCs) possess the angular bandgaps, which, properly engineered, can also provide the spatial filtering, as recently proposed. In particular, the larger angle spatial radiation components are reflected or deflected to diffraction maxima, and the lower angle components pass unaffected. Such PhC spatial filters could be an attractive alternative due to their tiny size and mechanical stability.

The first proof-of-principle experiments demonstrated the angular

filtering [L.Maigyte et al., Phys.Rev.A 82, 043819 (2010)], however the filtering efficiency was very small. The filtered-out angular areas were very narrow, of less than 1 degree. Here we extend the idea by using chirped PhCs, where the longitudinal period of the PhC linearly varies along the structure. Such linear chirp results in broadening of the angular bandgaps, and in much wider filtered angles. According to our calculations the performance of angular filters increase several times for proper chirp parameters.

We inscribed chirped PhCs into silicate glass using femtosecond direct laser writing technique and measured their filtering performance for 633 nm wavelength. Chirped PhCs exhibited up to 4 degrees wide filtering angle, which is around 10 times wider compared to the regular ones. In addition, we support the experimental data with theoretical calculations and show that PhC filtering performance could be improved even more.

8816-19, Session 3

Generation and collision of optical similaritons in dispersion-engineered silicon photonic nanowires

Spyros Lavdas, Univ. College London (United Kingdom); Jeffrey B. Driscoll, Richard R. Grote, Richard M. Osgood Jr., Columbia Univ. (United States); Nicolae C. Panoiu, Univ. College London (United Kingdom)

We use a rigorous theoretical model that describes optical pulse dynamics in sub-micron silicon (Si) wire waveguides and comprehensive numerical simulations to demonstrate the formation of parabolic optical pulses in dispersion-engineered (tapered) Si waveguides. In particular, our theoretical model describes pulse reshaping due to the effects of free-carrier (FC) dispersion, FC absorption, second- and third-order dispersion (TOD), self-phase modulation, two-photon absorption, and frequency dispersion of the effective nonlinearity, as well as the influence of FCs on pulse dynamics. In the proposed scheme for the generation of parabolic pulses, a Gaussian pulse with width T0 = 200 fs and peak power P = 10 W is launched into an exponentially tapered Si waveguide whose width (w) and second-order dispersion coefficient (β2) vary between w = 820 nm and β2 = 4.63x10-2 ps2•m-1 at the input facet and w = 1030 nm and β2 = 0.575 ps2•m-1 at the output. The device operates in the mid-IR (2 µm). Our numerical simulations show that the adiabatically varying dispersion induces the generation of parabolic optical pulses, also called similaritons. The pulse reaches an optimally parabolic shape after a propagation distance of 7.5 mm, with the corresponding misfit parameter being I = 0.0025. Our simulations demonstrate that if the TOD and nonlinearity dispersion are negligible the misfit parameter becomes as small as I = 0.0019, illustrating the significance of higher-order linear and nonlinear effects. We anticipate that these ideas will find important applications in chip-scale nanophotonic devices for distortion-free pulse amplification.

8816-20, Session 3

Fast and high accuracy FDTD computations using numerical green functions based on a nonstandard finite difference model for photonics design

James B. Cole, Univ. of Tsukuba (Japan)

The finite difference time domain (FDTD) method is easy to implement and can compute scattering and propagation in arbitrary structures, but it has two major drawbacks: (i) accuracy is low unless a fine grid is used – which greatly increases the computational cost, and (ii) when the structure has features that are much smaller than a wavelength, many grid points are needed just to represent the structure. Problem (i) has been addressed with the nonstandard (NS) FDTD method. In this paper we address problem (ii) by introducing a discrete Green's function (DGF), which is evaluated using NS-FDTD. The DGF is not simply a numerical approximation to the Green's function of Maxwell's equations.Although a DGF can be costly to compute and requires more storage than FDTD, it need be computed only once and gives solutions for arbitrary incident fields – no further FDTD computations required. We have compared the accuracy of conventional FDTD, NS-FDTD and the NS-DGF calcuation and that the 3rd is superior to the 1st method, although the second is best of all. In computational photonics the DGF approach is advantageous for computing transmission and reflection spectra of subwavelength structures.

8816-21, Session 3

Optical mode modulation of AlGaInP multi quantum well laser diodes

Chih Tsang Hung, Sheng-Chieh Huang, Tien-Chang Lu, National Chiao Tung Univ. (Taiwan)

High efficiency AlGaInP-GaInP visible laser diodes (LDs) are critical components for applications such as laser display, distance measurement instrument, and photodynamic therapy for the therapy of cancer. In order to achieve high performance single mode operation, typical AlGaInP LD structure utilized GaAs regrowth or narrow ridge strip design for lateral carrier and optical confinement. However, these designs often lead to a low quantum efficiency or too high facet power density.

In this letter, high power AlGaInP-GaInP multi quantum wells (MQWs) LD adopted a high reflectivity passivation to modify the lateral optical mode distribution demonstrated low threshold current density and high conversion efficiency under a single mode operation. Compared to the conventional design of single-layer passivation, we deposited a multi-layer dielectric layer on the surface of semiconductor after completing lateral waveguide etching process. By adjusting the reflectivity of interface, we can change the near-field optical mode profile and it isn't workable to vary the far-field divergence beam but also to restrain the high order mode happening. Moreover, the corresponding threshold current was reduced obviously since the better lateral optical confinement results into a lower optical loss.

Under the same epi structure of AlGaInP visible LDs, we can reduce the horizontal far-field divergence angle from 16° to 10° by modifying the reflectivity of interface between passivation and AlGaInP epi layers from 1% to 80%. Besides, the diffraction spot of far-field pattern can also be improved obviously. Based on this design, its threshold current density can decrease from 14 A/cm2 to 10 A/cm2 at room temperature operation and LDs can be operated beyond 200mW without kink.

8816-22, Session 3

Magnetoresponse of a 15µm infrared quantum cascade detector

Simon Maëro, Louis-Anne de Vaulchier, Yves Guldner, Francesca Carosella, Robson Ferreira, Ecole Normale Supérieure (France); Laetitia Doyennette, Vincent Berger, Univ. Paris 7-Denis Diderot (France); Virginie Trinité, Mathieu Carras, III-V Lab. (France)

Quantum cascade detectors (QCD) are a photovoltaic evolution of the quantum well infrared photodetector, designed to transfer electrons through consecutives cascades of levels when under illumination. QCDs have first been presented in the 8–12 µm band1-4 and now turn to very long wave infrared (12–20 µm), with potential astronomical and metrological applications.

We report the study of a GaAs/AlGaAs QCD heterostructure with a detection wavelength of 15 µm. The application of a magnetic field in the growth direction breaks the 2D in-plane continuum into discrete Landau levels allowing the interpretation of the different contributions of the scattering mechanisms.

Current measurements have been performed with and without illumination, magnetic field being applied parallel to the growth axis. A series of strong oscillations as a function of magnetic field is observed,

for both dark current and photocurrent. Based on a previously developed model, adapted and improved for 15µm QCD, these measurements allow us to identify the intricate scattering mechanisms responsible for the different transitions in the structure. The influence of temperature is also analyzed.

These experiments show that our model allow a better understanding of those complex structures. This model could also be used for the realization of the next generation of QCD.

8816-23, Session 3

Theoretical and experimental investigation of optimized evanescent-wave absorption sensors for extreme temperature applications

Michael P. Buric, Paul R. Ohodnicki, Benjamin Chorpening, National Energy Technology Lab. (United States)

Recently, there have been significant developments in evanescent wave absorption sensors for high temperature sensing applications based upon the optical responses of advanced thin film materials. We will demonstrate how such sensors can be utilized in a mode that allows for optimized sensing capabilities starting from basic theoretical considerations. We will also present experimental high temperature sensing results for fabricated sensors. Potential applications of the sensors to be discussed include a range of high temperature systems relevant for fossil energy and combustion monitoring such as industrial combustors or reaction vessels, solid oxide fuel cells, and gas turbines. In these applications, even a small increase in operating efficiency realized via careful observation of in-process parameters and implementation of real-time process controls can result in dramatic savings across the energy industry, illustrating the necessity of pursuing such techniques. It is hoped that sensors of the type described here will allow for unprecedented measurement-access to processes which present challenging high-temperature chemically reactive environments.

8816-24, Session 4

A highly stable and conductive ordered mesoporous carbon cathode for Li-S batteries

Dennis Pleskot, Wei Wang, Robert Ionescu, Mihrimah Ozkan, Cengiz S. Ozkan, Univ. of California, Riverside (United States)

A novel ordered mesoporous carbon (OMC) material was developed as a highly conductive cathode for stable, long cycle-life Li-S batteries. The mesoporous carbon was developed using a triblock copolymer as a template, resol materials as the carbon source, and tetraethyl orthosilicate (TEOS) as the silicon source. The mesoporous carbon structure was obtained by heating and carbonizing a mixture of these ingredients. Afterwards, sulfur was impregnated into the carbon structure through a melt-diffusion process and the material was coated with an oxide layer to prevent diffusion of Li/S compounds. The resulting OMC material displayed a high pore volume with the size of individual pores on the order of nanometers. Several characterization procedures, such as SEM and TEM, were utilized to confirm the high level of porosity. Electrochemical half-cell and impedance measurements were performed on battery cathodes composed of this OMC material, with the results showing a high level of performance. Specific capacity was determined to be over 1200 mAhg-1 with good stability over 100 cycles. Impedance measurements also revealed a high conductivity for the cathode material. Thus, the OMC structure designed in this study improved upon the disadvantages of Li-S batteries, particularly the generally poor conductivity as well as cycle stability. This study therefore advances the use of Li-S batteries composed of OMC cathodes as an increasingly effective energy alternative to both contemporary Li-ion batteries and conventional fossil fuels.

8816-26, Session 4

Effects of quantum efficiency on PbSe/ PbSrSe multiple quantum well structures

Majed Khodr, American Univ. of Ras Al Khaimah (United Arab Emirates)

The effects of quantum efficiency on PbSe/Pb0.934Sr0.066 Se multiple Quantum well Structure were analyzed. We calculate and identify the critical design parameters required to optimize and study the MQW system as a function of five temperatures assuming the quantum efficiency is not equal to one and hence we include the effects of nonradiative recombination due to Auger recombination and carrier leakage over the barrier into the confinement layers. Inclusion of quantum efficiency in addition to temperature dependence increased the threshold current values by almost 10 times. Also, it was noticed that the threshold current density values dropped fast at small cavities and remained constant after some critical cavity length around 100 micro meter. When experimental quantum efficiency values were used, the threshold current values were higher than those found using the theoretical quantum efficiency values due to leakage current over the barrier.

8816-59, Session 4

Fabrication and characterization of nanostructured III-V thermoelectric materials

Clint J. Novotny, National Institute of Science and Technology (United States) and Univ. of Maryland, College Park (United States); Fred Sharifi, National Institute of Standards and Technology (United States)

Approximately two thirds of all fossil fuel used is lost as heat. Thermoelectric materials, which convert heat into electrical energy, provide a solution to recover some of this lost energy. To date, most commercial thermoelectric materials are too inefficient to be a viable option for most waste heat applications. This research proposes to investigate the fabrication and characterization of nanostructured III-V semiconductor thermoelectric materials to increase the performance of existing technology.

In order to improve thermoelectric material efficiency, either the lattice thermal conductivity must be lowered or the thermoelectric power factor must be increased. This research will focus on the latter by modifying the density of states of the semiconductor material and studying the effect of quantum confinement on the material's thermoelectric properties. Using focused ion beam milling, nanostructured cantilevers are fabricated from single crystal wafers. An all-around gate dielectric and electrode are deposited to create a depletion region along the outer core of the cantilever, thus creating an inner conductive core. The Seebeck coefficient can then be measured as a function of confinement by varying the gate voltage. This technique can be applied to various material systems to investigate the effects of confinement on their thermoelectric properties.

8816-17, Session 5

X-ray spectroscopies and linear combination analysis of electrospun polymer-carbon nanotube composites

Allen D. Winter, Bangor Univ. (United Kingdom); Faisal Alamgir, Georgia Institute of Technology (United States); Cherno Jaye, Brookhaven National Lab. (United States); Eva M. Campo, Bangor Univ. (United Kingdom)

The technological importance of PDMS drives interest towards fiber production by electrospinning. This interest is augmented by the possibility to align multiwall carbon nanotubes (MWCNTs) in electrospun fibres, to produce either structurally sound or stimuli-responsive composites. The use of PMMA as carrier polymer is effective to electrospin PDSM; providing chain entanglement towards fibre production.

This work describes the near conduction band edge structure of electrospun MWCNT-PDMS-PMMA fibres by near edge X-Ray absorption fine structure (NEXAFS) spectroscopy. The polymers were blended in a 1:1 ratio and the resulting CNT composite fraction was 0.2 wt %. NEXAFS data was collected at the C K-edge in partial electron yield mode at normal, intermediate and glancing incidence.

NEXAFS spectra were acquired with the electric field both parallel and perpendicular to the fibres to comment on the orientation of the polymer chains as a result of electrospinning. Dichroic ratios calculated from the intensities of π^* and σ^* transitions confirm that though there is a preferential fibre alignment, the polymeric chains are not uniformly oriented.

Whereas no significant difference was observed between spectra from the composite and PDMS-PMMA acquired at normal and intermediate incidences, spectra acquired at glancing incidence differ dramatically. It is this incidence angle, therefore, that reveals information on the interaction between polymer and carbon nanotubes. A modified linear combination analysis method was employed in an attempt to model this interaction and identify the chemical groups involved.

8816-28, Session 5

Optical and electrical properties of green, olivine, and amber color nanopyramid light-emitting diodes

Kuok Pan Sou, National Chiao Tung Univ. (Taiwan); Yuh-Jen Cheng, Academia Sinica (Taiwan); Jet-Rung Chang, Shih-Pang Chang, National Chiao Tung Univ. (Taiwan); Mei-Chun Liu, Academia Sinica (Taiwan); Hao-Chung Kuo, Ken-Yuh Hsu, Chun-Yen Chang, National Chiao Tung Univ. (Taiwan)

We have demonstrated electrically driven green, olivine and amber color nanopyramid LEDs. The MQWs are grown on the semipolar facets of nanopyramids by using selective area growth technique on c-plane GaN. Spatially resolved cathodoluminescent analysis shows that the quantum well emission red shifts from the bottom to apex region of pyramid facets. The temperature dependent time-resolved photoluminescent measurement shows decent internal quantum efficiency despite the high In concentration. The radiative lifetime is much faster than (0001) plane MQWs, indicating significantly improved radiative recombination efficiency. From the radiative lifetime versus temperature measurement, the power law fitting curve shows that the lifetime increases linearly with temperature at near room temperature. This indicates that the emission is mainly from a 2D MQW system and there is no significant potential localization as would normally be observed for quantum wells grown on c-plane GaN substrate. It also shows the advantage of growing MQWs on semipolar nanopyramid facets, which have better quantum well uniformity and allow high In concentration. The electrical injection of these nanopyramid LEDs were demonstrated. The emission starts from the apex region of the pyramids as injection current increases. It is due the higher In content at the apex region and can be explained by the finite element method simulation and cathodoluminescent measurement. The emission is fairly uniform across the entire LED chip area despite the corrugated nanopyramid surface. The electrical injection demonstrates the promising potential of using nanopyramid design for high In content LED applications.

8816-29, Session 5

Realization of tellurium-based all dielectric optical metamaterials using a multi-cycle deposition-etch process

Sheng Liu, Jon F. Ihlefeld, Jason Dominguez, Edward F. Gonzales, John E. Bower, Bruce D. Burckel, Michael B. Sinclair, Igal Brener, Sandia National Labs. (United States)

We develop a multi-cycle deposition-etch process for fabricating Tellurium (Te) dielectric resonator metamaterials in infrared region. Te is a suitable resonator material due to its low loss at IR wavelengths and its large refractive index. First, we attempted to fabricate Te resonators by employing common metal lift-off techniques using e-beam lithography to define cubic voids in the e-beam resist, followed by Te deposition. However, pinch-off occurs when unwanted Te also deposits near the photoresist opening and accumulates to the point where the gap closes. Therefore, we develop this robust approach to circumvent this pinch-off problem by cycling deposition and etch processes. The key to the success is to first reduce the Te deposition thickness so that pinch-off doesn't close the resist opening and then perform a brief etch to clear the pinch-off. We successfully fabricated a series of samples in which the lateral edge dimension of the resonator was gradually increased while keeping the deposition thickness the same. All the samples show two transmission minima corresponding to the lowest (magnetic dipole) and second lowest (electric dipole) resonances. We also observe spectral overlap of magnetic and electric dipole resonances for different sizes' resonators.

This work was performed, at the Center for Integrated Nanotechnologies, a U.S. Department of Energy, Office of Basic Energy Sciences user facility. Sandia National Laboratories is a multi-program laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000. #158883

8816-30, Session 5

Nano fabrication of high efficiency stacked crystal zone plate for x-ray optics

Armen V. Kuyumchyan, American NanoScience & Advanced Medical Equipment Inc. (United States); Levon A. Haroutunyan, Yerevan State Univ. (Armenia); Karapet G. Trouni, Institute of Applied Problems of Physics (Armenia); Arevik K. Truni, Ruben Z. Gabrelyan, Yerevan State Medical Univ. (Armenia); David A. Kuyumchyan, California State Univ. (United States); Andro Abramyan, University of California Irvine (United States)

The development of nanotechnology gives new possibilities for fabrication of high efficiency X-ray optical elements. The new type of stacked multilevel crystal Zone Plate (ZP) is fabricated by means of high resolution negative tone inorganic HSQ (Hydrogen Silsesquioxane or XR-1541) electron-beam resist. About 80% of the HSQ resist became SiO2 after electron beam lithography. This is a simple method to fabricate ZPs with SiO2 masks. Stacked multilevel silicon ZPs consisting of layers with bi-level zone profiles have been investigated. The composed multilevel ZP consists of two separate ZPs which have different structures. The distance between ZPs varied from 0mm up to 2mm. The efficiency of the phase ZP is 40.5%. The maximum efficiency for bi-level ZP without absorption is 68.4%. We obtain 54.6% efficiency for the stacked bi-level ZP when the distance between ZPs was 0mm. The radial distribution of intensity is determined as a convolution of the zone plate transmission function and the Kirchhoff propagator in par-axial approximation. The algorithm is based on the FFT procedure and studied by means of computer programming simulation.

8816-31, Session 6

Multi-stimuli-responsive elastomeric opal films: processing, optics, and applications
(Invited Paper)

Christian G. Schäfer, Markus Gallei, Goetz P. Hellmann, Markus Biesalski, Matthias Rehahn, Technische Univ. Darmstadt (Germany)

Synthetic opal layers and films, also referred to as photonic crystals, consist of monodisperse submicroscopic beads arranged in a face-centered cubic (fcc) lattice. They can be prepared by various techniques of deposition or spin coating from dispersions or in the melt under shear.[1] The latter technology, which takes advantage of core-shell beads consisting of a rigid core and a soft, elastomeric shell was developed in the last decade.[2,3] By this technique, large-area films can be produced, which reveal distinct iridescent colors caused by Bragg reflection from the fcc lattice as function of the viewing angle.[4,5] Based on their elastomeric properties, these films also show remarkable color changes due to a controlled lattice deformation.[6-8] Up to now, many potential applications of large-scaled elastomeric opals failed due to the presence of defects in the crystal lattice.[5] Recent developments lead to uniform samples on the multi-meter scale with monodomain bulk-ordering of the submicrometer components.[9,10] Progress in the field of tunable colloidal crystals embedded in films formed by the organization of highly monodisperse polymer-grafted beads with a responsive core-shell structure or by incorporating functional beads in a responsive polymer matrix revealed fascinating tunable materials and are promising candidates for e.g. sensing devices or as actuation systems.[11,12] By using external trigger such as the change of solvent, temperature, ionic strength, light, electrical field or mechanical stress, the lattice distance can be varied resulting in a tremendous change of optical properties.[13] Different bead architectures can be designed and many additives incorporated, for instance fluorescent dyes or inorganic nanoparticles increasing the film performance and hence expanding to even more potential applications. Here we present multi-stimuli-responsive, i.e., solvato-, pH-, iono- and mechano-responsive, elastomeric polymer opal films as promising candidates for a wide range of optical sensor applications. Highly functional elastomeric opal films combined with paper-based substrates show remarkable optical properties. Moreover, the porosity of the papers used permits the enhanced capacity of different analytes resulting in a very fast optical response due to a colloidal crystalline structure change. In combination with reproducible scale-up protocols for synthetic opals leading to industrial length scales, this approach can be used as a toolkit for tailoring a plethora of polymer-based soft sensors with a fascinating optical response. These highly functional materials have potential applications as next generation sensing devices and actuation systems, in particular when combined with inorganic nanoparticles, which are currently under investigation.

8816-32, Session 6

Silicon photonic crystal nanobeam electrooptic depletion modulator

Julian Sweet, Joshua R. Hendrickson, Air Force Research Lab. (United States); Richard Soref, Univ. of Massachusetts Boston (United States); Matthew A. Pelton, Argonne National Lab. (United States)

We theoretically investigate electrooptic modulation in silicon (Si) nanobeams produced by the depletion of electron and holes. As a silicon-on-insulator technology, the nanobeam is a single-mode Si strip channel waveguide or “photonic nanowire” that includes a resonant optical cavity at telecom wavelengths. The resonance is created by a 1D photonic crystal lattice which is a series of cylindrical air holes etched into the Si down to the buried oxide interface. In this way, a high transmission, high quality factor, waveguide-cavity system can be fabricated from a series of quadratically tapered holes on either side of a zero length cavity region.

Previous implementations of resonant nanowire electrooptic modulators consisted of a bus waveguide evanescently coupled through an air gap to a micro-ring , micro-disk, or micro-donut [1]. These designs result in a resonator that sits adjacent to the nanowire and results in a large footprint. In contrast, the resonator and optical waveguide we have devised are combined along a single nanowire. The smaller device area makes this advantageous both for fabrication considerations as well as lowering the required switching energy as compared to the micro-disk/micro-ring example.

Simulations have been performed for nanobeam structures with 8 hole pairs using a donor and acceptor concentration of 1018 cm-3 and 5 x 1017 cm-3, respectively. Initial results have shown 6 dB extinction with a 200 nm modulation length at a wavelength of 1530 nm.

Nano plasmon device fabrications using dielectrophoretic(DEP) force

Jinsik Kim, Chan-Min Kang, Seulki Kim, Korea Univ. (Korea, Republic of); Jun-Kyo F. Suh, Hyun-Joon Shin, Korea Institute of Science and Technology (Korea, Republic of); Jung Ho Park, Korea Univ. (Korea, Republic of)

Combination of nanowire and fluorescent nanoparticle which can be used as cavity-free, unidirectional plasmon guiding media and source, respectively, is an attractive material as nano-plasmonic devices. The trapping of 25nm diameter quantum dot(QD) was accomplished using the dielectrophoretic (DEP) force at nanowires which were self-grown and fabricated by e-beam lithography and lift-off. DEP force was induced around the nanowire using 3MHz sine wave. Finally, the QDs were manipulated to the nanowires and additional ‘QD on nanowire’ nanostructure was formed as a plasmonic device using DEP force.

8816-60, Session 6

Graphene/Elastomer composite based photothermal nanopositioners

Balaji Uni Panchapakesan, Univ. of Louisville (United States)

The addition of nanomaterials to polymers can result not only in significant material property improvements, but also assist in creating entirely new composite functionalities. By dispersing graphene nanoplatelets (GNPs) within a polydimethylsiloxane matrix, we show that efficient light absorption by GNPs and subsequent energy transduction to the polymeric chains can be used to controllably produce significant amounts of motion through entropic elasticity of the pre-strained composite. Using dual actuators, a two-axis sub-micron resolution stage was developed, and allowed for two-axis photo-thermal positioning (,100 mm per axis) with 120 nm resolution (feedback sensor limitation), and ,5 mm/s actuation speeds. A PID control loop automatically stabilizes the stage against thermal drift, as well as random thermal-induced position fluctuations (up to the bandwidth of the feedback and position sensor).

Maximum actuator efficiency values of 0.03% were measured, approximately 1000 times greater than recently reported for light-driven polymer systems.

8816-40, Session PWed

Nanoimprint lithography for soft and hard materials

Jae Hong Park, National Nanofab Ctr. (Korea, Republic of)

Recently, the creation, replication, and transfer technologies of nanostructures using a soft lithographic approach have received attention [1]. Many researchers and engineers have tried to materialize nanostructures, because nano-scale materials have some distinguishing characteristics from both micro- and macro-scale materials. The two main processes of engineering nanostructures are the top-down method, which is a direct engineering method for Si-type materials using photolithography or e-beam lithography, and the bottom-up method, using nano-imprinting. However, these methods are very dependent on the equipment used, and have a high process cost. They are also relatively inefficient methods in terms of processing time and energy. Therefore, some researchers have studied the replication of nano-scale patterns via the soft lithographic concept, which is more efficient and requires a lower processing cost .

In this study, accurate nanostructures with various aspect ratios are created on several types of materials. This work is highly applicable to the energy, optical, and nano-bio fields, for example. A silicon (Si) nano-mold is preserved using the method described, and target nanostructures are replicated reversibly and unlimitedly to or from various hard and soft materials. The optimum method of transferring nanostructures on polymeric materials to metallic materials using electroplating technology was also described. Optimal replication and demolding processes for nanostructures with high aspect ratios, which proved the most difficult, were suggested by controlling the surface energy between the functional materials. Relevant numerical studies and analysis were also performed. Our results showed that it was possible to realize accurate nanostructures with high depth aspect ratios of up to 1:18 on lines with widths from 100–200 nm. In addition, we were able to expand the applicability of the nanostructured mold by adopting various backing materials, including a rounded substrate. The application scope was extended further by transferring the nanostructures between different species of materials, including metallic materials as well as an identical species of material.

Highly bright and durable light-generating composite films driven by mechanical stress and its prospective application to imaging devices

Soon Moon Jeong, Seongkyu Song, Soo-Keun Lee, Daegu Gyeongbuk Institute of Science & Technology (Korea, Republic of)

Mechanically activated luminescence from solids (mechanoluminescence) is a classical optical phenomenon induced in a substance when stressed or cleaved.[1] Until now, many materials have been known to emit light by the application of stress even though scientists have not yet arrived at a clear understanding of the effect. However, no practical application has been realized because previous instances of mechanoluminescence have been weak and unrepeatable. Recently, we designed and demonstrated flexible composite films with highly bright and durable characteristics by focusing on the substance (polydimethylsiloxane; PDMS) that transfers the mechanical stress to the mechanoluminescent materials (copper-doped zinc sulfide, ZnS:Cu). By employing transparent PDMS with a high elastic modulus, we were able to realize in a simple manner a brightness of ~120 cd/m2 and durability over ~100,000 repeated motions.[2] Also, the simplicity of the fabrication process is also a strong advantage for various applications. Combined with these superior properties, in this presentation, we show the prospective application to imaging devices which uses a combination of color-tunable and patternable mechanoluminescent characteristics. We believe that the findings of this study can open a new window for developing new smart systems and opto-mechanical devices.

Signature geometry and quantum engineering

Stefan Samociuk, Penlon Cottage Trading Ltd. (United Kingdom)

Today's nano scale engineering allows us access to complex electromagnetic phenomena in the form of semiconductor chips. This paper is about how nano scale might also allow us access to the other fundamental phenomena including gravitational and the primary nuclear forces. Its not a paper full of equations and speculations but one introducing the reader to some special geometric structures, the origin of these structures and how they can be rendered to physical materials within an existing semiconductor industry. The central premise is that as we begin to manufacture forms at nano scale, geometry becomes the significant factor in defining function and this broadly corresponds with growing research in the subject of meta-materials. The recently discovered Transcendent Transcode Algorithm, a universal and absolute facet of prime numbers, provides a source of geometric design workable in many spatial dimensions and the ability to extract 2D and 3D sections from multi dimensional objects. Current string theory as used in particle physics leans more and more to considering multi dimensional concepts as constructs for basic physical phenomena. Quantum Engineering looks to resolve these two ideas into a single engineering objective: Signature Geometries – specific geometries existing on physical materials which are recognisable by fundamental physical forces. This recognition generates a reaction that can be considered a microscopic phenomena leading to the following definition for Quantum Engineering: "Take sections from an N dimensional signature geometry and render the forms to 2D or 3D nano scale materials. Select those forms that show microscopic recognition or coupling to the phenomena associated with the N space. Then create materials with billions of these rendered forms in a small space and generate macroscopic behaviour associated with the fundamental phenomena."

There are five sections to the book:

Section 1: Transcendent form and the Transcendent Transcode Algorithm(TTA).

Section 2: Signature Geometries and derivation from the TTA.

Section 3: Rendering Signature Geometries to current semi conductor production file standards.

Section 4: Quantum Engineering.

Section 5: The Philosophy.

Three-dimensional crystal structures coating on optical fibers

Wenhua Guo, Changshu Institute of Technology (China); Xia Li, School of Physics and Electronic Engineering, Changshu Institute of Technology (China); Zhijuan Lv, Jinhua Xing, Changshu Institute of Technology (China)

In this letter, the optical fiber with its smooth outer surface is selected as a substrate for the colloidal particles to self-assemble. The VD method is introduced to achieve this procedure of formation. The resulting colloidal crystals are characterized by scanning electron microscopy, which illustrate high order of the sample.

To deposit colloidal crystal films, the prepared fiber was then placed vertically in a vial with heated silica dispersion. The vial was immersed in an isothermal deposition chamber. The chamber was filled with water, placed on a rubber support. The whole experimental setup was placed into a constant-temperature, constant-humidity drying oven resting on a sturdy table.Typically, as the solvent evaporated, a uniform colloidal crystal film is formed on both the optical fiber outer surface and the vial walls.

A JEOL model JSM-5610 scanning electron microscope (SEM) operated at an accelerating voltage of 15kV was typically used for the observation of the particle arrangement in the colloidal crystal films.SEM images show that a long range ordering and highly ordered hexagonal array is produced. A continuous, uniform and highly-ordered hexagonal close-packed colloidal crystal structure with [111] crystallographic direction normal to the curved surface can be clearly observed, similar to the arrangement of the spheres on planar substrates.Square arrangement can be clearly observed, which we call the [100]-direction zones of the silica crystal films.We can also find that the dominant zones are the fcc structures with [111]- and [100]- direction zones, the regularly special coexistence pattern as well.

Predefined planar structures in semiconductor surfaces patterned by NSOM lithography

Ivana Lettrichova, Dusan Pudis, Univ. of Žilina (Slovakia); Jozef Novak, Agáta Laurenčíková, Institute of Electrical Engineering (Slovakia); Jaroslava Skriniarova, Jaroslav Kováč, Slovenska Technicka Univ. (Slovakia)

Semiconductor surface patterning is attractive and novel way how to improve properties of existing optoelectronic devices. So far, light emitting diode (LED) extraction efficiency improvement or radiation pattern modification is well described while using planar photonic structures in the surface of the device. In the meantime, there appear many applications requiring predefined structures with aperiodic or irregular design of patterned structures.

One of the promising optical technologies for planar structure fabrication is near field scanning optical microscope (NSOM) lithography. The method consists in employing the NSOM in illumination mode, where patterning of structures is done through a maskless exposure process performed by the optical near-field produced at the tip of a scanning fiber probe. Thereby, exposure of defined regions of the device on chip is performed so that different periodic and predefined arrangement can be achieved.

We demonstrate NSOM lithography as effective tool for semiconductor device surface patterning. The non-contact mode of NSOM lithography was used to pattern planar predefined structures in GaAs, AlGaAs and GaP surfaces in different two dimensional (2D) grids from 500 – 1500 nm. In this way, predefined metallic nanostructures on GaP surface were prepared which are used for organized GaP nanowire growth in solar cell applications. Predefined 2D arrangement of GaP nanowires was achieved and analyzed. Another application shows GaAs/AlGaAs-based LED with patterned structure in the emitting surface. Patterned air holes regions in the LED surface show the enhancement of radiation in comparison with the surrounding surface, what was confirmed from near- and far-field analysis.

Patterned LEDs with planar surface structures

Dusan Pudis, Ivana Lettrichova, Daniel Jandura, Univ. of Žilina (Slovakia); Jaroslava Skriniarova, Pavol Hronec, Anton Kuzma, Jaroslav Kovac, Slovenska Technicka Univ. (Slovakia); Lubos Suslik, Univ. of Žilina (Slovakia); Jozef Novak, Slovak Academy of Sciences (Slovakia)

Effect of planar structures on emission properties of light emitting diode (LED) surface is well known. Improvement of optical properties of LED such as directionality, far field profile or light extraction efficiency has been already demonstrated by implementation of planar photonic structures in LED surface. Although the effect of photonic as periodic structure on the light extraction efficiency is well documented, LEDs with predefined planar patterning have not been investigated so intensively. The predefined structure represents arbitrary planar pattern prepared in the LED surface; therefore not necessarily periodic.

From the diffraction on roughness-based effect it can be suggested, that implementation of predefined planar structure allows local enhancement of light emitting from the LED surface. Application of such structures can be attractive for local enhancement of light from defined areas of the LED surface. Also predefined structure with fresnel zone plate design is able to modify near- and far-field radiation characteristics.

We used optical techniques and focused ion beam for surface patterning of GaAs/AlGaAs based LEDs. Different predefined structures and the fresnel zone plate structures were patterned in the upper confinement AlGaAs layer. The fresnel zone plate structures were also prepared in thin polydimethylsiloxane (PDMS) layer using direct laser writing process. Patterned PDMS layer was directly applied on the surface of the LED structures. Surface of the LED structures was analyzed by employment of scanning electron microscope and atomic force microscope. The overall emission properties of prepared LEDs were investigated by near- and far-field analysis.

Nanostencil lithography for fabrication of III-V nanostructures

Kaushal D. Vora, Fouad Karouta, Jagadish Chennupati, The Australian National Univ. (Australia)

Nanostencil Lithography (NStL), while comparatively still in infant stages, is proving to be a viable option for low-cost and high resolution fabrication. An ideal stencil for NStL consists of a low-stressed silicon nitride membrane supported on a silicon chip with required patterned features in nanometer range that become apertures. The stencil is then used as a shadow mask and placed in close contact on top of a substrate/wafer. This pair is then ready for either depositing metal through the apertures in the stencil using variety of deposition techniques or etching the substrate using dry etching techniques with stencil acting as a mask. We fabricated 15 nm thick gold/chromium nanodots on III-V substrate having random distribution using a low-cost, nanoporous silicon grid (as nanostencil) having pores in the range of 10-60nm with 15% surface coverage. This grid was attached to GaAs substrate using a kapton tape in such a way that the membrane was touching the GaAs surface. Metal layers were deposited on this assembly using e-beam evaporator. We then fabricated well-ordered array of 700 nm diameter gold/chromium nanodots by fabricating nanostencil using focused ion beam on a TEM silicon nitride window/membrane. The gold nanodots (both random and ordered) can be used for vapor-liquid-solid nanowire growth (bottom-up), while the chromium nanodots can be used as a mask for reactive ion etching of III-V structures for fabricating nanowires (top-down approach). Fabrication of III-V nanowires and waveguides are ongoing using nanostencil lithography and results will be shown.

8816-50, Session PWed

Fabrication and characterization of graphene-palladium nanocomposite based hydrogen sensors

Duy-Thach Phan, Gwiy-Sang Chung, Univ. of Ulsan (Korea, Republic of)

For a future hydrogen-based economy, H2 sensors will be a critical for safety and will be widely needed in various applications. Among various sensing materials and noble metal catalysts for H2 sensors, a Pd nanostructure is a well-known and popular H2 detector. Recently, graphene has been shown to have excellent properties as a potential material to support a Pd nanoparticles (PdNP) catalyst or form Pd-graphene (Pd-Gr) nanocomposites, and has produced attractive results for H2 sensing in terms of high sensitivity and stability. Graphene oxide (GO) and reduced graphene oxide (RGO) have been widely used for various applications including photocatalysis, bio-technology, and sensing. GO is generated by oxidation of graphite and contains a wide range of functional oxygen groups such as hydroxyl and epoxy groups on the basal plane and carboxylic acid groups at the edges, which make GOs strongly hydrophilic. The hydrophilic properties created by attaching oxygen-functional groups of GOs yield a large number of advantages with respect to compatibility in MEMS/NEMS processes, biocompatibility, and producing functional graphene. In this work, we synthesized and investigated a Pd-Gr composite for resistivity H2 sensors and evaluated the influence of PdNP size in Pd-Gr composite on sensor performance. The sensors were fabricated in terms of large scale and batch process. The experimental reproducibility and working properties of sensors with respect to temperature and long period of time. Owing to good mechanical stability and high resistance to oxidation, the Pd-Gr composites exhibited good long-term stability in resistivity H2 sensors for at least six months

8816-51, Session PWed

Polydimethylsiloxane fibers for optical fiber sensor of displacement

Ivan Martincek, Dusan Pudis, Peter Gaso, Univ. of ?ilina (Slovakia)

Polydimethylsiloxane (PDMS) is a silicone elastomer with properties which make it attractive for the optical application. PDMS is highly light-transparent material in wide frequency range, chemically inert, thermally stable, permeable to gases, isotropic and homogeneous, simple to handle and manipulate and has interesting rheological properties.

We demonstrate fabrication and optical properties of PDMS fiber integrated on the conventional optical fiber and its use for optical fiber displacement sensor. Silicone elastomer Sylgard 184 (Dow Corning) was used to prepare the PDMS fiber by drawing of partially cured silicone.

Depending on the PDMS fiber elongation, the signal change in intermodal interference was documented. Optical fiber displacement sensor using PDMS fiber is based on measurement of optical signal local minimum in visible spectral range generated by intermodal interference of circularly symmetric modes. Position of the local minimum in spectral range varies with fiber elongation; stretching the PDMS fiber by 230 micrometers corresponds to the wavelength shift from 688 nm to 477 nm. Therefore, using PDMS fiber, it is possible to determine the longitudinal displacement with accuracy of 1 micrometer.

Optical properties of subwavelength patterned metal gratings for photonic device application and an alternative proposal

Hong-Kun Lyu, Sungho Woo, Daegu Gyeongbuk Institute of Science & Technology (Korea, Republic of); Sung-Hyun Jo, Jang-Kyoo Shin, Kyungpook National Univ. (Korea, Republic of)

We have investigated optical properties of subwavelength patterned metal gratings for photonic device application. It was known that optical transmittance of metal films with subwavelength periodic hole arrays can be controlled by applying a dielectric overlay to the film and the films can act as wavelength or frequency selective filters. Following advancement in lithography technology it could be applied up to complementary metal oxide semiconductor (CMOS) image sensors (CIS) by patterning metal layers placed on each pixel's photo detective device. However it is not easy to replace organic color filters applied on CIS up to date because the standard CIS structure has multi-metal layers, thick dielectric layers, and too thick metal layers for optical filters. In this work, we explore possibility to integrate the metal film into a CIS chip and present an alternative proposal by computer simulation utilizing finite-difference time-domain method. We applied aluminum (Al) for the metal film and the dispersion information associated with Al was derived from the Lorentz-Drude model. We expect that this work could contribute to search to apply subwavelength patterned metal gratings to photonic devices.

Titanium dioxide fine structures by RF magnetron sputter method deposited on an electron-beam resist mask

Hideomi Hashiba, Yuta Miyazaki, Nihon Univ. (Japan); Ondine Suavet, Ecole Nationale Supérieure de Chimie de Paris (France); Sachiko Matsushita, Tokyo Institute of Technology (Japan)

Titanium dioxide (TiO2) has been draw attention for wide range of applications from photonic crystals for visible light range by its catalytic characteristics to tera-hertz range by its high refractive index. We present an experimental study of fabrication of fine structures of TiO2 with a ZEP electron beam resist mask followed by Ti sputter deposition techniques. TiO2 thin layer of 150 nm thick is grown on ITO glass substrate with a fine patterned ZEP resist mask by a conventional RF magnetron sputter method with Ti target. The deposition was carried out with argon-oxygen gases at a pressure of 1.0 x 10 -2 Torr in a chamber. During the deposition, ratio of Ar-O2 gas was kept to 2:1 and the deposition ratio was around 0.5 A/s to ensure enough oxygen to form TiO2 and low temperature to avoid deformation of fine pattern of the ZPU resist mask. Design of the fine pattern are photonic crystal structure of periodic zigzag wires of 103 nm width, 608 nm in period[1]. TiO2 layers are white-transparent, amorphous, and those roughnesses are around 5 nm. We also studied transformation of TiO2 of the fine structures by baking at 500 degrees. XRD measurement for TiO2 shows that the amorphous form transforms to rutile and anatase forms by the baking while keeping the same profile of the fine structures. Our fabrication method can be one of a promising technique to optic devices on researches and industrial area.

Optical properties of aqueous dispersions of diamond nano-particles

Andrii B. Golovin, Ada-Simona Popescu, The City College of New York (United States); Boyan Penkov, Phoebus Optoelectronics, LLC (United States); Young Uk Jung, The City College of New York (United States); Roman Akhmechet, Phoebus Optoelectronics, LLC (United States); David T. Crouse, The City College of New York (United States) and Ctr. for Metamaterials (United States)

Metasurfaces demonstrate outstanding capabilities of modifying its optical parameters when changing its geometry at the nanoscale level. Our metasurface is an array of subwavelength apertures made in subwavelength thick metal layer. For this metasurface, we can shift transmission to shorter wavelenghts by depositing dielectric material of high permittivity into the cavities. Nanodiamonds, much smaller than the wavelength of light, can be suspended in an aqueous solution and guided into cavities by using electrophoresis. Metasurfaces are usually made from noble metals, therefore is convenient to use 2D optical array as an electrode to conduct electrophoresis of nanoparticles. The applied field controls the concentration of nanoparticles inside the apertures and on the top of the metasurface. Usually, fabrication of a metal metasurface with dielectric within apertures would require an irreversible process, e.g. sputtering, evaporation, or plasma-enhanced chemical vapor deposition. In contrast, the electrophoresis of nanoparticles is reversible by redispersing particles back in to suspensions and switching direction of the applied field. In our experiments, we deposited nanodiamonds with average diameter 3-4 nm into a 2D array of apertures with diameters of 350 nm and 200 nm made in 200 nm thick layer of gold. The accumulation of diamond nanoparticles was imaged by using scanning electron microscopy of the apertures. We also show that by increasing the concentration of nanodiamonds the effective refractive index of the aqueous suspension increases, as well as absorption and scattering. Results of material parameter characterizations at wavelength 512 nm are provided at different concentrations of nanodiamonds in suspensions.

8816-55, Session PWed

A tunable inverse-hemisphere-shaped Bragg grating sensor

Yunha Ryu, Kyoungsik Kim, Yonsei Univ. (Korea, Republic of)

Stimuli-responsive diffraction gratings have been widely studied as chemical and biological sensors. The material which consists of the diffraction gratings changes its volume or periodicity in the presence of certain stimulus such as variation of pH, ion's concentration, etc. ,which leads to a shift in diffraction wavelength. Since the color change from the shift is readily perceptible with bare human eyes, this method is one of the most simple and convenient way to detect the environmental change.

In this work, we fabricated an inverse-hemisphere-shaped grating structure using soft lithography of close-packed nanospheres. The diffraction of two-dimentional sphere arrays are usually of great interest but that of an inverse-hemisphere-shaped grating have not much exploited so far. To compare the diffraction of these two structure, we measured the intensity diffracted into the Debye ring by using 633nm He-Ne laser and calculated the diffraction efficiency.

Then, we measured the diffraction wavelength shift induced from lattice change. The periodicity of the grating was tuned by two methods; mechanical strain and swelling in liquids. Diffraction was measured at a fixed angle utilizing a UV-VIS Spectrometer, a Tungsten Halogen lamp and a fiber optic reflection probe.

Also, Finite difference time domain (FDTD) simulation program (Lumerical) was used for better understanding of the diffraction phenomenon. We calculated the power scattered into a particular grating order of the grating structure, propagation direction, and strength of the grating orders at a certain wavelength.

8816-56, Session PWed

Piezoelectricity of ZnO nano-rods array prepared by hydrothermal method

Seon Hoon Kim, Tae-Un Kim, Hyun Chul Ki, Doo Gun Kim, Ju Hyeon Choi, Hwe Jong Kim, Korea Photonics Technology Institute (Korea, Republic of); Jin Hyeok Kim, Chonnam National Univ. (Korea, Republic of)

The piezoelectricity is most suitable for a various applications, such as electronic system, molecular sensors, biological electronics, diagnosis, and so on. Nano-generators have been a dramatic increase in the number of papers related to the formation of wire-like ZnO and Schottky barrier between ZnO nanowire and electrode. The ZnO nano-wires are well aligned but random tiered. In this study, we fabricated piezoelectric devices with ZnO nano-rods and thin film. The ZnO nano-rods were grown through nano-scale 2D patterns of oriented ZnO nano-crystals using a laser interference lithography followed by hydrothermal synthesis at 90 oC. ZnO nano-rods were preferred orientation with c-axis and wurtzite structure. We measured the electrical current from a ZnO nano-rods based on nano-generators. The AC-type current and voltage behaviors are attributed to the direct compression of ZnO nano-rods by an external force (under the load of 0.8kgf). The electricity of nano-rod piezoelectric device was 8.44x10-7Wh.

A DLVO model for catalyst motion in metal-assisted chemical etching and methods to fabricate vertically aligned thin-film metallic nanostructures

Owen Hildreth, National Institute of Science and Technology (United States); C. P. Wong, The Chinese Univ. of Hong Kong (China) and Georgia Institute of Technology (United States)

Metal-assisted Chemical Etching (MaCE) is a relatively new micro and nanofabrication technique in which a catalyst is used to create a traveling galvanic etching reaction that rapidly etches the silicon substrate with feature resolutions on the order of 1 -3 nm even over aspect ratios greater than 500:1. While the chemistry of MaCE has been reasonably well established for ~10 years, the mechanism behind catalyst motion was not. This research introduces a DLVO model for catalyst motion that was validated using plastic deformation of out-of-plane rotational structures and in-situ force-displacement measurements. The new information on catalyst motion allows us to better control the etching path of the catalyst during etching and readily fabrication 3D nanostructures in a single lithography/etch cycle. The vertically align thin film metallic nanostructures utilized in this work offer interesting opportunities for switchable metamaterials over the infrared and visible spectrums.

8816-58, Session PWed

Contamination control in ion beam sputter deposited films

David I. Pearson, Sebastien Pochon, Oxford Instruments (United Kingdom)

Ion beam sputter deposition is used in a wide variety of applications where precision film control and high quality, high performance layer materials are required. However, one of the difficulties of sputtering a target material with an ion beam is the control of the beam shape and collimation so as to avoid any energetic ions following trajectories whereby they could sputter other materials than the desired target material (e.g. from the surrounding furniture and fixtures); this results in a potential contamination of the depositing film with impurity material. The effect of this on the performance of the deposited film will depend on the particular application targeted, on the levels of impurities and on the nature of the impurities.

The conventional wisdom to guarantee high purity thin films in IBD has been to use a large vacuum chamber. The chamber size was important to minimise the effect of reflected high energy particles from the target surface sputtering chamber materials onto the substrate and to allow the use of large targets to avoid beam overspill onto chamber furniture: for example, chambers in excess of 1m3 have been used for the deposition of low loss dielectric mirrors. An improved understanding of beam trajectories and re-sputtered material paths has allowed the deposition of thin films with very low metallic impurity content in a chamber volume below 0.5 m3.

Thus, by optimizing the sputter ion source, target and substrate configuration, and by arranging suitable shielding made of an appropriate material in the process chamber, the levels of contaminants in the deposited films have been reduced to a minimum. With this optimum hardware arrangement, the ion beam process parameters were then optimized with respect to the ppm levels of contaminants measured in the films by SIMS analysis.

Using the deposition of SiO2 as a standard material for SIMS composition analysis and impurity level determination, it has been shown that our IBS deposition tool is capable of depositing films with contamination levels of <50ppm for the total of all metal impurities in the deposited films.

8816-34, Session 7

Theoretical characteristics of 1.55 µm InN based quantum dot laser

Md Mottaleb Hossain, The Univ. of New Mexico (United States); Md. Abdullah Al-Humayun, Univ. Malaysia Perlis (Malaysia); Ashraful Ghani Bhuiyan, Khulna Univ. of Engineering & Technology (Bangladesh)

Quantum dot (QD) laser has recently brought the breakthrough in optoelectronics and now it has been the most research effort subject matter around the world. Recently it is reported that InN has a band gap of around 0.7eV. This is compatible to 1.55 µm because the emission energy depends in a complex way on many parameters, both on the QDs (shape, dimensions, strain, and composition) and on the confinement layers (composition, residual strain) along with ground quantized energy levels of carriers. For long-wavelength 1.55 µm operations, InN based laser is predicted to be low cost, low power consumption, long-distance transmission, high-performance light sources for optical fiber communication. Recently the design and performances of 1.55 µm laser has been reported using InN based QD and QW technology. In this abstract, we present the theoretical characteristics of photon emission at 1.55-µm wavelength considering single layer InN quantum dot in the active region. The transparency threshold has been obtained at photon energy of 0.8016 eV and at zero normalized applied transition energy. The modal gain of about 12.5 cm-1 is obtained at the threshold current density of 51 Acm-2. External differential quantum efficiency of 65% has been achieved for the cavity length of 640 µm. The proposed structure with acceptable enhanced results will create a way to fabricate InN based quantum dot laser.

8816-35, Session 7

Metal super nano-grating and surface plasmon resonance spectrometer

Junpeng Guo, Hai-Sheng Leong, The Univ. of Alabama in Huntsville (United States)

A super nano-grating is a super-period nanostructure diffraction grating. The nanostructure within each super-period grating line supports localized optical resonance. For metallic nanostructures, the optical resonance is the localized plasmon resonance. In a super nano-grating, the super-period provides optical diffractions that follow the wavelength-period relation of the classical optical diffraction of thin gratings. Optical diffraction from a super nano-grating is an optical scattering process and also a radiation process, which directly carries the information of the local optical resonance. The optical resonance spectrum can be measured by using a linear photodetector array because the optical diffraction is angularly dispersive according to the wavelength.

Surface plasmon resonance modes in super period nanohole and nanoslit gratings are investigated through device fabrications and numerical simulations. A plasmon resonance mode splitting phenomenon has been observed in super-period nanohole gratings under the transverse magnetic (TM) polarization excitation. The phenomenon is explained as the result of the coupling between the localized nanostructure mode and the diffraction grating mode. Surface plasmon spectrometers are demonstrated using super-period nanohole and nanoslit gratings. A surface plasmon spectrometer is a spectrometer that can directly measure the surface plasmon resonance in metal nanostructures without using an external optical spectrometer. Surface plasmon resonance spectrometers open a new avenue for nanostructure surface enhanced spectroscopy.

8816-36, Session 7

Observation of sharp resonance peaks from a metal-embedded GaAs microcavity

Ryo Takemoto, Nagisa Ishihara, Nahid A. Jahan, Tomoya Asano, Xiangming Liu, Hideaki Nakajima, Hidekazu Kumano, Ikuo Suemune, Hokkaido Univ. (Japan)

Generation of quantum entangled photon pairs (QEPP) from a semiconductor quantum dot (QD) has been actively studied and demonstrated with biexciton (BX)-exciton (X) cascade emissions. However the two photons has different energies and are not indistinguishable. For advanced quantum information processing such as QEPP based quantum-key distribution (QKD) and swapping of quantum entanglement to realize quantum repeaters, solid-state photon sources for generating indistinguishable photon pairs are necessary. One of the possibilities is the simultaneous generation of QEPP with the use of a cavity effect. Conventional BX-X transitions is expected to be converted into the simultaneous generation of two identical photons. Photonic crystal (PC) nano-cavities exhibit high resonance Q, but there remains compromise to extract both photons efficiently to outer photon collection optics. We have developed a fabrication method to embed a GaAs-based semiconductor nanostructure in metal and recently observed the collection of ~20% of the photons emitted from an InAs QD inside a GaAs nano-pillar from the metal-embedded nanostructure surface. In this paper, we report the observation of sharp resonance photoluminescence (PL) peaks from the GaAs nano-pillars embedded in silver (Ag). The cavity resonance modes were monitored employing weak but broad luminescence of n-type GaAs that ranges from 800 to 1600 nm. The observed sharp resonance peaks showed the high resonance Q factor up to 4000. Observation of temperature insensitivity of these sharp peaks clearly shows the origin of these peaks as the pillar nano-cavity mode.

8816-37, Session 7

Nonlinear phenomena from a PIC attached gold tip using a plasmonic-whispering gallery mode hybrid system

Fang Ren, Hideaki Takashima, Hokkaido Univ. (Japan); Yoshito Tanaka, Hokkaido Univ. (Japan) and Hokkaido Univ. (Japan); Hideki Fujiwara, Keiji Sasaki, Hokkaido Univ. (Japan)

Localized surface plasmon fields induced in metal nanostructures have recently attracted considerable attention for the efficient light-matter interaction. However, it is still a challenge to focus incident light onto single molecule with 100% coupling efficiency because of the huge scale mismatch among photons, nanostructures, and molecules. In our previous research, we have proposed a new method using a tapered-fiber coupled microsphere in which we have succeeded in high coupling efficiency (~100%) by controlling the distance between a gold tip and microsphere, and have achieved second harmonic generation from the top of the gold tip using this plasmonic-whispering gallery mode (WGM) hybrid system. In this paper, nonlinear fluorescence was observed from Pseudoisocyanine(PIC)-terminated mercaptopropionic acid self-assembled monolayers formed on the surface of a gold tip via a tapered-fiber coupled microsphere resonator. The nonlinear fluorescence signal shows a quadratic dependence for the average incident power, which proves two-photon fluorescence from the PIC attached gold tip. Moreover, we also confirmed that the emission intensity from the PIC attached gold tip depends on the coupling efficiency between the PIC attached gold tip and microsphere exponentially. These results suggest the possibility that the efficient plasmon excitation via a tapered-fiber coupled microsphere resonator induces the strong light-matter interaction at the top of the gold tip and open up a possibility of inducing optical nonlinearities within a plasmonic-WGM hybrid system with high Q factor.

8816-38, Session 7

Generation and performance of localised surface plasmons utilising nano-scale structured multi-layered thin films deposited upon D-shaped optical fiber

Thomas D. Allsop, Aston Univ. (United Kingdom); Ron Neal, Plymouth Univ. (United Kingdom); Martin Dvorak, Aston Univ. (United Kingdom) and Brno Univ. of Technology (Czech Republic); Chengbo Mou, Aston Univ (United Kingdom); Kyriacos Kalli, Cyprus Univ. of Technology (Cyprus); Alex Rozhin, Aston Univ (United Kingdom); David J. Webb, Aston Univ. (United Kingdom)

A new generation of surface plasmonic optical fibre sensors is fabricated using multiple coatings deposited on a lapped section of a single mode fibre. Post deposition UV laser irradiation using a phase mask produces a nano-scaled surface relief grating structure, resembling nano-wires. The overall length of the individual corrugations is approximately 14 µm with an average full width half maximum of 100 nm. Evidence is presented to show that these surface structures result from material compaction created by the silicon dioxide and germanium layers in the multi-layered coating and the surface topology is capable of supporting localised surface plasmons. The coating compaction induces a strain gradient into the D-shaped optical fibre that generates an asymmetric refractive index profile which enhances the coupling of the light from the core of the fibre to plasmons on the surface of the coating. Experimental data are presented that show changes in spectral characteristics after UV processing and that the performance of the sensors increased from that of their pre-UV irradiation state. The enhanced performance is illustrated with regards to change in external refractive index and demonstrates high spectral sensitivities in gaseous and aqueous index regimes ranging up to 4000 nm/RIU for wavelength and 800 dB/RIU for intensity. The devices generate surface plasmons over a very large wavelength range, (visible to 2 µm) depending on the polarization state of the illuminating light.

8816-39, Session 7

Nano-imaging photolithography for plasmonic device applications

Alireza Bonakdar, Sung Jun Jang, Hooman Mohseni,
Northwestern Univ. (United States)

Low cost, large area and high throughput fabrication of sub-micron periodic optical nanoantennae is pivotal for commercializing surface plasmon enhanced devices such as solar cell, photodetector, metamaterial, molecular sensor, and optical communication. Here, we propose the nano-imaging photolithography method which can address these demands. Surface plasmon squeezes optical energy and shrinks the optical wavelength to deeply sub-diffraction limit resulting in resonance feature size on the scale of sub-micron in the visible and infrared region of light spectrum. Although, conventional photolithography in air is the well established, relatively low cost method to fabricate large area of optical elements with high throughput, sub-micron feature size of plasmonic antenna is not feasible as the imperfection physical contact between macroscopic mask and sample imposes sub-micron fuzzy features. As the alternatives, electron beam lithography and ion beam milling are fully capable to produce the state of the art devices with nanoscale feature sizes. However, they are relatively costly and time consuming specifically for large area applications.
The proposed nano-imaging photolithography method can transfer an arbitrary single macroscopic pattern to a micron/sub-micron feature scale. We are fabricating arrays of optical antenna such as nanorod and Bowtie antennas. Our homemade set up is low cost, very fast and is robust against the variation of UV source lamp and accurately adjustable for optimum operating point where the features as small as 100 to 200 nm are achievable. This method is based on our previous highly cited microsphere nanolithography which was limited to hexagonal closed packed array of nanoholes.

Self-assembled nanoparticle vesicles for optical and bio applications *(Invited Paper)*

Kuniharu Ijiro, Hokkaido Univ. (Japan)

A simple approach to the creation of colloidal assemblies from heterogenous nanoparticles is in high demand for the development of functional devices. The interparticle plasmonic coupling in the assemblies can produce collective properties different from those of dispersed particles, therefore metal and semiconductor nanoparticle assemblies are of considerable interest in many fields, such as material, analytical and medical sciences. Particularly, vesicular assembly of nanoparticles (nanoparticle vesicles) will propose new applications of nanoparticles facilitating the inner space, such as drug delivery, catalyst carrier, surface-enhanced Raman scattering (SERS) sensing platforms. Herein we demonstrated that surface modification with a semifluorinated ligand (SFL) efficiently produced sub-100 nm nanoparticle vesicles (-60 nm in diameter). We applied these nanoparticle vesicles for sensing system based on SERS, which gave largely increased Raman signals compared with general Raman signals. And photoinduced dr ug release from the nanoparticle vesicles was performed.

8817-3, Session 1

Hybrid gold nanocarriers with ultra-high chromophore loading for fluorescent imaging and photodynamic therapy *(Invited Paper)*

Patrice L. Baldeck, Univ. Joseph Fourier (France)

We will review our work on hybrid Gold nanoparticles (GNP) that are coated with polymers bearing photoactive molecules optimised for their fluorescence or PDT activity. Our first goal in using GNP is to load a large density of photoactive molecules onto a biocompatible nanoplatform. Our second goal is to optimize the molecule GNP interaction to improve the photoactive properties.

In this project GNP have typical dimensions in the 50-100 nm that are suitable for in vivo imaging and therapy. Their geometrical shapes included spheres, rods, bipyramids and stars. The spherical shape is efficient only when a spacer is used to maintain a minimum distance between the photoactive molecule and the metallic surface. However, more elongated shapes, or tipped shapes can be used for a direct grafting of photoactive molecules if their transition dipole moments are maintained perpendicular to the surface (J-aggregate type of interaction between the GNP and molecules). We will report on optical spectroscopy, fluorescence imaging, cell uptake, cytotoxity, and PDT action of several type of polymers coatings and photoactive dye loading.

Grating formation in bi-layered DNA-complex devices: application to thin-film tunable dye lasers *(Invited Paper)*

Yutaka Kawabe, Toshifumi Chida, Toshinori Matsuoka, Kodai Fukuzawa, Kazuhiro Tada, Chitose Institute of Science and Technology (Japan)

Interaction of some organic dyes with DNA induces fluorescence enhancement through intercalation or groove binding, stimulating the development of compact tunable thin-film dye lasers. We have demonstrated amplified spontaneous emission, laser emission and its tuning via distributed feedback from a dynamic grating formed in DNA-surfactant complexes doped with cyanine or hemicyanine dyes.[1,2]

The formation of semi-persistent (or quasi-dynamic) grating is more preferable in order to realize stable and tunable laser oscillation, so we designed bi-layered laser devices composed of a DNA-CTMA layer doped with pyridine 1 and an PMMA layer including an azo dye, DR1. Under the excitation of the azo layer with interfering two beams for grating formation and the pumping of the emission layer with another beam, we observed laser emission from the device. The temporal behavior of the induced grating was controllable by varying the excitation energy and polarization allowing the optimization of grating properties suitable to applications. We achieved laser emission with semi-persistent grating and its switching by choosing an adequate energy of excitation.

Furthermore, monolithic DNA device having two functions as lasing and grating formation would be more promising. DNA-CTMA complex had been considered to be a poor matrix for grating inscription, but we found that doping of an azo-carbazole compound made it possible to inscribe gratings with high diffraction efficiency and moderately long lifetime which can be applicable to monolithic tunable laser devices.

Lasing and random lasing in bio-polymeric dye doped systems *(Invited Paper)*

Jaroslaw Mysliwiec, Lech Sznitko, Adam Szukalski, Pawel Karpinski, Andrzej Miniewicz, Wroclaw Univ. of Technology (Poland)

The potential for photonic application of modified deoxyribonucleic acid with cationic surfactant cetyltrimethylammonium chloride, has been shown in many recent fields. Here we present results of detailed studies on lasing achieved in a double-layer system consisted of a biopolymer based matrix loaded with luminescent dye together with photochromic polymer and random lasing emission (RL). The laser action was achieved via distributed feedback configuration with third order of Bragg scattering on surface relief grating generated in photochromic polymer. The RL originates due to the scattering induced by the high surface roughness coming from the dye doped biopolymer. We show that lasing parameters for bio-polymeric system can be comparable with similar systems based on standard or pi-conjugated polymers and may contribute to commercialization of polymeric lasers.

Grating inscription in DR1: DNA-CTMA thin film: simple models and experiment *(Invited Paper)*

Antoni C. Mitus, Grzegorz Pawlik, Wojciech Radosz, Jaroslaw Mysliwiec, Andrzej Miniewicz, Wroclaw Univ. of Technology (Poland); François Kajzar, Ileana Rau, Univ. Politehnica of Bucharest (Romania)

Recent experimental results indicate that the inscription of gratings in DR1:DNA-CTMA thin films displays some features of non-exponential grating amplitude growth with time [1]. We provide new experimental data and analyze them using a simple modeling based on semi-intercalation hypothesis [2] put forward for the interpretation of experimental data [3] and on computer-based analysis of local free volume in bond-fluctuating model of a polymeric matrix.

Deoxyribonucleic acid (DNA): a new nanomaterial for applications in electronics and in photonics *(Invited Paper)*

Ileana Rau, Univ. Politehnica of Bucharest (Romania)

Biopolymers in general, and the deoxyribonucleic acid (DNA) in particular, appear to be the choice materials for the next generation photonic and electronic devices. There are several arguments for the practical use of these materials, such as their origin from renewable resources, abundance, biodegradability, versatility and ease of processing. The DNA biopolymer can be extracted from the waste of food processing industry, thus can be cheap and is ecofriendly. Although the pure DNA represents a limited interest for practical applications (water solubility only, weak electron conjugation, low ionic conductivity) it can be functionalized with surfactants and with active molecules, providing desired optical and electrical properties. Some of these properties, like fluorescence, are enhanced due to the specific environment it offers. The DNA-surfactant complexes are insoluble in water and soluble in a number of organic solvents, offering large possibilities for functionalization. They form high optical quality thin films, which can be obtained by spin coating. In this talk the different doping mechanisms will be described and discussed. Different physico-chemical properties of obtained complexes, such as the photo-thermal stability, thin film processability, photoluminescence, linear and nonlinear optical properties will be reviewed and discusses. The observed nonlinear optical (NLO) molecules properties of thin films doped with some active molecules will be reviewed and discussed. Some practical applications of these materials will be also presented and discussed.

Dielectric properties of BaTiO3 doped DNA at microwave frequencies *(Invited Paper)*

Guru Subramanyam, Eunsung Shin, Hailing Yue, Univ. of Dayton (United States); Fahima Ouchen, Roberto S. Aga, Carrie M. Bartsch, James G. Grote, Air Force Research Lab. (United States)

Nanoparticles of $BaTiO_3$ were introduced in to DNA for enhancing the dielectric properties of DNA films in this study. Different compositions of $BaTiO_3$ doped DNA thin films were studied using our patented capacitive test structure. Swept frequency scattering parameters were experimentally obtained for the devices in an inert atmosphere at room temperature. Our measurement results show increasing effective dielectric constant of the $BaTiO_3$ doped DNA as a function of the $BaTiO_3$ dopant concentration, with dielectric loss-tangent maintained relatively low. The presentation will discuss the processing of the films, the experimental results obtained, and the conclusions from this study.

Improving energy transfer in QD-DNA photonic networks

Susan Buckhout-White, U.S. Naval Research Lab. (United States) and George Mason Univ. (United States); Christopher M. Spillmann, Mario G. Ancona, U.S. Naval Research Lab. (United States); W. Russ Algar, The Univ. of British Columbia (Canada); Michael Stewart, Kimihiro Susumu, Alan Huston, Ellen Goldman, Igor Medintz, U.S. Naval Research Lab. (United States)

There is considerable research in the area of manipulating light below the diffraction limit, with potential applications ranging from information processing to light-harvesting. In such work, a common problem is a lack of efficiency associated with non-radiative losses, e.g., ohmic loss in plasmonic structures. From this point of view, one attractive method for sub-wavelength light manipulation is to use fluorescence resonance energy transfer (FRET) between chromophores. Although most current work does not show high efficiency, biology suggests that this approach could achieve very high efficiency. In order to achieve this goal, the geometry and spacing of the chromophores must be optimized.

For this, DNA provides an easy means for the self-assembly of these complex structures. With well established ligation chemistries, it is possible to create facile hierarchical assemblies of quantum dots and organic dyes using DNA as the platform. These nanostructures range from simple linear wires to complex 3-dimensional structures all of which can be self-assembled around a central quantum dot (QD). The efficiency of the system can then be tuned by changing the spacing between chromophores, changing the DNA geometry such that the donor to acceptor ratio changes, or changing the number of DNA structures that are self-assembled around the central QD. By exploring these variables we have developed a flexible optical system for which the efficiency can be both controlled and optimized.

SHardonnay: the first fluorescent protein rationally designed for improved second-harmonic generation *(Invited Paper)*

Evelien De Meulenaere, Ngan Nguyen Bich, Katholieke Univ. Leuven (Belgium); Kristof Van Hecke, Univ. Gent (Belgium); Luc Van Meervelt, Jozef Vanderleyden, Koen Clays, Katholieke Univ. Leuven (Belgium)

Nonlinear imaging is steadily drawing more scientists' attention because of a number of advantages it has for application on live samples, and the additional molecular information that can be extracted from data based on second-harmonic generation (SHG) or coherent anti-Stokes Raman scattering (CARS). We set out to investigate the applicability of fluorescent proteins in simultaneous two-photon fluorescence and SHG imaging. For this purpose, we measured the second-order nonlinear optical properties of a small rainbow of fluorescent proteins, ranging from green to red, by means of hyper-Rayleigh scattering. A trend was observed showing an increasing first hyperpolarizability (β) for more red-shifted proteins. Only the yellow fluorescent protein, eYFP, exhibits a surprisingly low β. We hypothesized that this could be explained by centrosymmetric stacking of the chromophoric Tyr66 and the neighboring Tyr203 residues. We have removed the inversion center by mutating Tyr203 into Phe203, which resulted in a new yellow fluorescent protein with comparable linear optical properties, and an improved β. Based on the specific function (Second-Harmonic generation), the color of its emission, and in analogy with the "mFruit" names, we have named our mutant SHardonnay.

It is the first time that a fluorescent protein has been rationally altered for this purpose. SHardonnay exhibits an improved fluorescence quantum yield, and a 2-3 nm hypsochromic shift in its linear spectral properties. Structure determination by X-ray crystallography as well as linear optical characterization corroborate a correct folding and maturation. This study

can eventually lead to improved red fluorescent proteins for even better performance.

Second harmonic generation from tyrosine containing peptides *(Invited Paper)*

Mehmet N. Nasir, E. Bergmann, Emmanuel Benichou, Isabelle Russier-Antoine, Noelle Lascoux, Christian Jonin, Françoise Besson, Pierre-François Brevet, Univ. Claude Bernard Lyon 1 (France)

The Second Harmonic Generation (SHG) response at the air-water interface from Tryptophan and Tyrosine-containing peptides at the air-liquid interface is presented. First, the quadratic hyperpolarizability of these aromatic amino acids is reported and compared to other amino acids, in particular the non aromatic ones. Then, the quadratic hyperpolarizability of short peptides is discussed with a particular emphasis on current models aiming at predicting this hyperpolarizability in terms of the hyperpolarizability of the amino acids themselves.

Based on these results, the properties of short peptides at the air-water interface are investigated. In particular, the light polarization analysis of the SHG response provides critical information on the kinetics of adsorption and re-arrangements at the interface. These results show that tryptophan and tyrosine can be used as endogenous molecular probes for peptides and proteins, paving the way for interface studies of biomolecules.

8817-22, Session 6

Bacteriorhodopsin-based bipolar photosensor for biomimetic sensing *(Invited Paper)*

Katsuyuki Kasai, Yoshihiro Haruyama, Toshiki Yamada, Makoto Akiba, Yukihiro Tominari, Takahiro Kaji, Toshifumi Terui, Ferdinand Peper, Shukichi Tanaka, Yoshitada Katagiri, Akira Otomo, National Institute of Information and Communications Technology (Japan); Hiroshi Kikuchi, NHK Science & Technical Research Labs. (Japan); Yoshiko Okada-Shudo, The Univ. of Electro-Communications (Japan)

Bacteriorhodopsin (bR) is a promising material for several applications. Biomimetic artificial retinas could be realized by using bR, since it is similar in its function to visual pigment rhodopsin. Optical excitation of bR at an electrode-electrolyte interface generates differential photocurrents while an incident light is turned on and off. The optical bipolar response offers the suitable sensing for vision applications such as motion detection and edge enhancement. This unique functional response is applicable to biomimetic sensing. We take notice of the functional vision system of an insect. It is known that the insect has realized the quick motion controlled by the optical flow sensing function, i.e., motion field detection. We are aiming to apply such insect-mimetic sensing based on the light-sensitive retinal protein bR to the autonomous mobile robot vision. The bipolar photosensor which consists of the bR dip-coated thin films patterned on two ITO plates and the electrolyte solution. This bipolar photocell will function as a biomimetic photoreceptor cell, i.e., the artificial visual receptive field. The bipolar structure has made the excitatory region and inhibitory region, since generation of the photocurrent is rectified in the cathodic direction. The experimental result of the edge detection, and the zero-cross character of the bipolar photosensor cell is similar to the feature of the ganglion cell receptive field. This result shows our bipolar cell acts as a basic unit of edge detection. We will also show the novel scheme for an insect-mimetic optical flow sensing function in the presentation.

Enhancing molecular logic and enzyme kinetics through modulation of temporal and spatial constraints of quantum dot-based systems that use fluorescent (förster) resonance energy transfer

Jonathan C. Claussen, U.S. Naval Research Lab. (United States)

Luminescent semiconductor nanocrystals or quantum dots (QDs) contain favorable photonic properties (e.g., resistance to photobleaching, size-tunable PL, and large effective Stokes shifts) that make them well-suited for fluorescence resonance energy transfer (FRET) based applications including monitoring proteolytic activity, elucidating the effects of nanoparticles-mediated drug delivery, and analyzing the spatial and temporal dynamics of cellular biochemical processes. Herein, we demonstrate how unique considerations of temporal and spatial constraints can be used in conjunction with QD-FRET systems to open up new avenues of scientific discovery in molecular logic circuitry and enzyme kinetics. For example, by conjugating both long lifetime luminescent terbium(III) complexes (Tb) and fluorescent dyes (A647) to a single QD, we can create multiple FRET lanes that change temporally as the QD acts as both an acceptor and donor at distinct time intervals. Such temporal FRET modulation creates multi-step FRET cascades that produce a wealth of unique photoluminescence (PL) spectra that are well-suited for the construction of molecular logic gates. We also demonstrate how QD-enzyme conjugate efficiencies can change with spatial constraints. In particular we analyze how enzyme density and QD size can regulate enzyme efficiency. These research advances in molecular logic and enzyme-QD efficiency open the door to future applications including multiplexed in vivo biodetection and biosensing for disease diagnostics and treatment.

SFG characterization of a cationic ONLO dye in biological thin films

Lewis E. Johnson, Pomona College (United States); Michael T. Casford, Paul B. Davies, Univ. of Cambridge (United Kingdom); Malkiat S. Johal, Pomona College (United States)

Biopolymer-based thin films, such as those composed of CTMA-DNA, can be used as a host material for NLO-active dyes for applications such as electro-optic (EO) switching and second harmonic generation. Previous work by Heckman et al. (Proc. SPIE 6401, 640108-2) has demonstrated functioning DNA-based EO modulators. Improved performance requires optimization of both the first hyperpolarizabilities (β) and degree of acentric ordering exhibited by the chromophores. The cationic dye DANPY-1 (Proc. SPIE 8464, 846409-D) has a high affinity for DNA and a substantial hyperpolarizability; however, its macroscopic ordering has not been previously characterized. We have characterized the acentric ordering of the dye using sum-frequency generation (SFG) spectroscopy and microscopy in surface-immobilized DNA and other biologically relevant thin films.

8817-25, Session 6

Integration of biological photonic crystals in dye-sensitized solar cells for enhanced photocurrent generation

Jeremy Campbell, Oregon State Univ. (United States)

Dye-sensitized solar cells (DSSCs) have been investigated as a low-cost alternative to silicon-based photovoltaics. Relying on a network of titanium dioxide nanoparticles for electron transport, these devices must balance photon capture with carrier collection. Adding photonic structures may increase light capture within these devices without undermining electron transport.

The recognition of photonic structures in nature has renewed interest in a class of single-celled photosynthetic algae called diatoms, which are abundant in all aquatic ecosystems. Diatoms biologically fabricate silicon dioxide cell walls (frustules) that contain intricate sub-micron pore arrays with length scales comparable to the wavelengths of visible light. We hypothesize that diatom biosilica may function as photonic crystal slabs to enhance light capture within DSSCs without increasing device thickness.

We have identified a broad optical resonance (>100nm) within the visible spectrum of diatom biosilica films in air. Additionally, a fabrication approach has been developed that allows for controlled and uniform placement of biosilica within DSSCs. Two strategies were investigated for diatom biosilica integration: as a discrete optical layer and as a distributed optical material within the bulk titanium dioxide. Characterization of the optical effects of biosilica integration throughout device assembly reveals a significant reduction in photoanode transmittance with biosilica addition (20-30%). The optical effect is lost when the liquid electrolyte is added due to the similar refractive indexes of the electrolyte and the biosilica. Functionalization of the diatom biosilica with titanium dioxide preserves refractive index contrast and restores the optical effects, resulting in photocurrent enhancements of 10-20%.

8817-26, Session PWed

Protein ‘smart’ micro/nano-biooptics via femtosecond laser direct writing

Yun-Lu Sun, Wen-Fei Dong, Hong-Bo Sun, Jilin Univ. (China)

Here, the proof-of-concept protein (Bovine Serum Albumin) microlenses were fabricated by femtosecond laser direct writing (FsLDW) system mainly composed of a nano-precision piezo stage and a two-galvano-mirror set respectively for the horizontal and vertical scanning movements. The laser beam from a femtosecond titanium:sapphire laser (80 MHz repetition rate, 120 fs pulse width, 780 nm central wavelength) was ightly focused by a high-numerical-aperture (NA=1.35) objective for 3D scanning to photocrosslink protein molecules within the focal spot and directly write out protein micro/nanostructures on the matrix. Here, kinds of microlenses (including refractive, diffractive and hybrid microlenses, etc.) as well as microlens arrays were conducted using protein aqueous ink. By carefully optimization, the single-line width of protein FsLDW could be tailored by changing the processing parameters and was as low as ~200 nm. Smooth surface with roughness average (Ra) of ~ 5-10 nm and outstanding 3D geometry were assured by optimized laser finishing resulting in excellent optical performances. PH value was chosen as the main environmental signal to tune the protein microlens in consideration of the possible operating environment, for example, microfluidic chips. The microlenses were fabricated in neutral protein aqueous ink, and swelled both in acidic and basic environment leading to the change of the curvature radius and hydrogel’s refractive index which then resulted into the adjustment of imaging and focusing. The microlenses performed well in an aqueous mixture of rabbit serum and red blood cells, which experimentally proved the good biocompatibility and ability of anti-biofouling of protein-based microelements.

8817-27, Session PWed

An efficiency method of synthesis to study the effect of annealing temperature on formation of calcium phosphates ceramics

Geovana D. Webler, Univ. Federal de Alagoas (Brazil); Maximiliano M. J. Zapata, Federal Univ. of Rio Grande do Sul (Brazil); Eduardo J. da Silva Fonseca, Jandir M. Hickmann, Univ. Federal de Alagoas (Brazil)

In recent years, there has been growing interest in studies of ceramic based on calcium phosphates, such as hydroxyapatite [(HAP) - $Ca10(PO4)6(OH)2$)] together with the β-tricalcium phosphate [(β-TCP) - $Ca3(PO4)2$]. In this work, biphasic calcium phosphate ceramics HAP/β-TCP was synthesized by solid state reaction, starting from calcium carbonate and ammonium phosphate monobasic for 10 h, with the goal of evaluating the influence of annealing temperature on the formation of ceramic materials. Samples synthesized at five different temperatures, 700, 800, 900, 1000 and 1100°C were investigated using the techniques of Fourier transform infrared spectroscopy (FTIR), Raman spectroscopy, Scanning electron microscopy (SEM), X-Ray Diffraction (XRD) and Rietveld refinement. From FTIR and Raman spectra, the presence of functional groups corresponding to phosphate (PO4)3- in all samples were observed. SEM measurements showed the presence of pores, important for potential biomedical applications, consequently favoring osseointegration. While, the XRD analyzes of the crystalline structures of these materials revealed the phases related to HAP and β-TCP. Finally, the quantification of phases obtained in x-ray difractograms was made using the Rietveld refinement. Our results indicate that increasing the annealing temperature leads to decrease in the percentage of phosphate β - tricalcium phosphate, and, therefore, according to the literature, the sample synthesized at 1100°C, with the proportions of HAP of 63.17% and 36.83% β-TCP, showed the better performance to applications. In addition, the method showed compares favourably to the current methods by its versatile, due to its simplicity of synthesis, and a short period of time to the heat treatment.

8817-29, Session PWed

Processing and nano-mechanical characterization of gold-chitosan nanocomposites for biomedical applications

Philip A. Yuya, Nimitt G. Patel, Clarkson Univ. (United States)

Gold nanoparticle reinforced chitosan bionanocomposite is excellent material for biosensors and certain implants. Nano-sized particle reinforcement into chitosan matrix enhances the materials properties and alters the microstructure. Naturally derived chitosan from shrimp shells was processed through acetic acid treatment to make the matrix of nanocomposites. Gold nanoparticles (~30 nm) were synthesized via citrate reduction method from HAuCl4 and incorporated in chitosan matrix. The bionanocomposite films were then prepared through solution casting with varying concentration of gold nanoparticles. Uniform distribution of gold nanoparticles was achieved throughout the chitosan matrix. Synthesis outcomes and prepared nanocomposites were characterized through SEM, TEM, EDS, UV-vis, zeta potential and FT-IR for their physical, morphological and structural properties. Materials response under the influence of temperature, frequency and indentation depth was characterized through various nanoindentation techniques. Quasi-static nanoindentation was used to determine elastic properties such as hardness and reduced modulus while dynamic nanoindentation was used for viscoelastic properties such as storage modulus, loss modulus, viscoelastic creep and relaxation of the nanocomposites. High temperature nanoindentation technique was used to investigate glass transition temperature of the nanocomposites. Through quasi-static nanoindentation, it was observed that the hardness and reduced modulus of nanocomposites increased significantly with direct proportion of gold nanoparticles concentration. Gold nanoparticles concentration showed positive impact on storage modulus and glass transition temperature of the materials. Lower storage modulus at higher indentation depth was recorded in all nanocomposites. In summary, the results show enhanced mechanical properties with increase in gold nanoparticles concentration and provide better understanding of structure-property relationships of such biocompatible materials for biomedical applications.

8817-30, Session PWed

Mesenchymal stem cells are differentiated by PEDF to osteoblasts in alginate microbeads

Crispin R. Dass, Curtin Univ. (Australia); Mina Elahy, Swati Baindur-Hudson, Victoria Univ. (Australia)

Stem cell encapsulation has become a promising tool in the bone tissue engineering field. However, the major challenge of this technique is in the timing of cell differentiation and cell release into the desired bone defect area. In this study, we used the anti-angiogenic protein, pigment epithelium-derived factor (PEDF), as an osteogenic supplement to differentiate mesenchymal stem cells (MSCs) to osteoblasts in monolayer cell culture and encapsulated within alginate microbeads. We show that PEDF has osteogenic differentiation potential, using qualitative and quantitative methods (such as viability assay, immunocytochemistry, assays for mineralisation and immunoblotting). Alginate microbeads containing MSCs and PEDF degraded significantly more compared to alginate microbeads with MSCs alone, signifying that PEDF differentiates MSCs into osteoblasts that are capable of being released from entrapment within the bead matrix. Thus, stem cells encapsulated with PEDF within alginate microbeads are released as differentiated osteoblasts as assessed by immunostaining for alkaline phosphatase, collagen-1, osteopontin, and osteocalcin (major osteogenic biomarkers). PEDF is a promising protein candidate for supporting osteoblastic differentiation in enhancing bone tissue engineering.

8817-31, Session PWed

Effect of the surface plasmon on second harmonic generation from tyrosine

E. Bergman, Emmanuel Benichou, Isabelle Russier-Antoine, Noelle Lascoux, Christian Jonin, Pierre-François Brevet, Univ. Claude Bernard Lyon 1 (France)

The Second Harmonic response from biomaterials is at the focus of current fundamental studies. One of the reasons for this recent interest stems from the potential use of Second Harmonic for optical imaging of biological tissues. Aromatic as well as non aromatic amino acids have therefore been investigated in detail. In particular, their first hyperpolarizability has been determined by hyper Rayleigh scattering. Tryptophan and Tyrosine have thus been shown to potentially be interesting targets in peptides and proteins owing to their rather large first hyperpolarizability.

However, recent studies have also provided hints on the sensitivity of the first hyperpolarizability of these aromatic amino acids to perturbations, in particular to the complexation with metallic salts, like silver or gold salts. Besides, it is also known that metallic nanoparticles can provide large enhancement of electromagnetic fields in their immediate vicinity under Surface Plasmon excitation.

This work therefore reports the use of hyper Rayleigh scattering to measure the first hyperpolarizability of tryptophan and tyrosine in the close vicinity of small gold or silver metallic nanoparticles. A wavelength analysis in particular is helpful in determining the role of the Surface Plasmon resonance in the observed changes of the first hyperpolarizability of tryptophan and tyrosine.

8818-1, Session 1

Bioinspired superhydrophobic, self-cleaning and low drag surfaces *(Keynote Presentation)*

Bharat Bhushan, The Ohio State Univ. (United States)

Nature has developed materials, objects, and processes which function from the macroscale to the nanoscale. These have gone through evolution over 3.8 billion years. The emerging field of biomimetics allows one to mimic biology or nature to develop nanomaterials, nanodevices, and processes [1-3]. Properties of biological materials and surfaces result from a complex interplay between surface morphology and physical and chemical properties. Hierarchical structures with dimensions of features ranging from macroscale to the nanoscale are extremely common in nature to provide properties of interest. Molecular scale devices, superhydrophobicity, self-cleaning/anti-fouling, drag reduction in fluid flow, energy conversion and conservation, high adhesion, reversible adhesion, aerodynamic lift, materials and fibers with high mechanical strength, biological self-assembly, anti-reflection, structural coloration, thermal insulation, self-healing, and sensory aid mechanisms are some of the examples found in nature which are of commercial interest. This talk will provide a broad overview of four selected objects of interest found in nature and applications under development or available in the marketplace. These will include (1) Lotus Effect used to develop superhydrophobic and self-cleaning/anti-fouling surfaces with low adhesion [3-5], (2) Shark Skin to develop surfaces with low fluid drag and anti-fouling characteristics [3,6], and (3-4) Rice Leaf and Butterfly Wing Effect to develop superhydrophobic and self-cleaning/anti-fouling surfaces with low drag [7-8]. Rice leaf and Butterfly Wings combine the Shark Skin and Lotus Effect.

Imprinted and injection moulded nano structured optical surfaces *(Invited Paper)*

Anders Kristensen, Alexander B. Christiansen, Jeppe Clausen, Emil Højlund-Nielsen, Claus H. Nielsen, Technical Univ. of Denmark (Denmark); Claus F. Hansen, Tommy Kristiansen, Erik L. Simonsen, Per Høvsgaard, LEGO Group (Denmark); N. Asger Mortensen, Technical Univ. of Denmark (Denmark)

Within the past decades, nano-structured surfaces, or sub-wavelength structures (SWS) have attracted much attention as a cost-efficient (non-vacuum) alternative to multi-layer thin film deposition for obtaining anti-reflective optical surfaces. In this paper, nanostructured polymer surfaces are fabricated by up-scalable polymer replication methods: imprinting/embossing and injection moulding. A Black Silicon (BSi) random nanostructure surface is used as master original. The optical transmission at normal incidence was measured for wavelengths from 400 nm to 900 nm. For samples with optimized nanostructures, the transmission was increased by 2% compared to samples with planar surfaces.

8818-3, Session 2

Use of modulated pulse power magnetron sputtering for the systematic variation of film stoichiometry at static reactive gas flow rates

Neil R. Murphy, Lirong Sun, John T. Grant, John G. Jones, Rachel Jakubiak, Air Force Research Lab. (United States)

Reactive modulated pulse power magnetron sputtering (MPPMS) was used in the deposition of multilayer metal-dielectric stacks from a single transition metal sputtering source under a static flow rate of reactive gas. The MPPMS technique allows the user to have precise control over the magnitude and frequency of the voltage pulses applied to the cathode. At the foundation of this method is the ability to form a dielectric compound on the surface on a metallic sputtering target in a low frequency regime and dynamically reduce it by applying a more aggressive, higher frequency voltage pulse.

Switching between dielectric and metallic target surfaces created alternating metal – dielectric layers without varying the flow rate of the oxygen and argon gases. Oxide impurity concentrations within the metallic layers were not large enough to inhibit the absorptive properties of the base metal. Material systems explored include oxides of molybdenum and tantalum. Optical characterization of the films was conducted using UV-visible spectroscopy and in situ spectroscopic ellipsometry. Experimentally obtained values for the wavelength dispersion of refractive index and extinction coefficient values were used in the design and prediction of the performance of multilayer interference filters.

8818-4, Session 2

Two-dimensional nanostructures on optical glass via nanosphere lithography and vapor HF etching

Elmer Wang, Wayne State Univ. (United States) and Visotek, Inc. (United States); Yang Zhao, Wayne State Univ. (United States)

It is desired to have artificial optical materials with controllable optical properties. One approach is to create composite materials with nanomachining and nanostructures. In this research, two-dimensional (2D) nanostructures were created on the surface of optical glass using nanosphere lithography. The effective refractive index of the artificial layer is smaller than the refractive index of the substrate and can be varied by changing the size of the nanoparticles and depth of etching. In comparison with conventional techniques, this approach is more efficient and cost-effective for the creation of large areas of thin surface layers as an artificial material. A uniform monolayer of 200 µm polystyrene nanospheres was deposited on soda-lime glass slides. Deposition was performed via a slide-coating technique to take advantage of capillary forces. The slides were etched with vapor-phase hydrofluoric acid (HF) to create 2D structures. Vapor-phase etching was selected in order to etch the substrate without disturbing the monolayer nanoparticle mask. The etching rate of nanostructures was studied. An atomic force microscope (AFM) was used to monitor the nanosphere monolayers and etching analysis. It was shown that the nanoparticle pattern was successfully transferred to the surface of the substrate. The resultant thin-layer of modified substrate serves as an artificial material with a desired refractive index which modifies the surface reflection and transmission properties. The substrate with the created artificial material layer demonstrated reduced reflectivity in optical wavelengths.

8818-5, Session 2

Tunable stoichiometry of SiOx-BaOy-BOz fabricated by multi-target PLD

John G. Jones, Chad M. Holbrook, Jonathan T. Goldstein, Air Force Research Lab. (United States); Lirong Sun, General Dynamics Information Technology (United States); Neil R. Murphy, Rachel Jakubiak, Charles E. Stutz, Air Force Research Lab. (United States)

Nanostructured thin-films of multiple oxide materials were obtained by using pulsed laser deposition (PLD) with independent targets consisting of SiO_2, Ba, and B. At a power of 300 mJ per pulse, island growth occurred on a per pulse basis with some 150 pulses required to deposit 1 nm of material. Programmable stoichiometry of multi-component or nanostructured thin-films was achieved by using a 248 nm KrF excimer laser, a galvanometer mirror system, and three independent target materials. The number of pulses on each target can be programmed with a high degree of precision. Trends in material properties were identified by systematically varying the stoichiometries of multiple nanostructured thin-films and comparing the resulting properties measured using in-situ spectroscopic ellipsometry, x-ray diffraction (XRD), and energy dispersive spectroscopy (EDS)(reliable with ~ 1 um of material thickness). Typically thin-films deposited by PLD at temperatures below 300 C are amorphous, however, crystallinity was obtained with post growth heat treatment and verified with XRD.

8818-6, Session 2

SiC multi-layer protective coating on carbon obtained by thermionic vacuum arc method

Victor Ciupina, Univ. Ovidius Constanta (Romania); Cristian P. Lungu, National Institute for Lasers, Plasma and Radiation Physics (Romania); Rodica Vladoiu, Danut Tiberius Epure, Gabriel Prodan, Univ. Ovidius Constanta (Romania); Corneliu Porosnicu, Ionut Jepu, National Institute for Lasers, Plasma and Radiation Physics (Romania); Marius Belc, Madalina Prodan, Cosmin Rosca, Iuliana M. Stanescu, Constanta Stefanov, Mirela Contulov, Aurelia Mandes, Virginia Dinca, Univ. Ovidius Constanta (Romania); Eugenia Vasile, S.C. Metav-Cercetare Dezvoltare S.A. (Romania); Valer Zaroschi, National Institute for Lasers, Plasma and Radiation Physics (Romania); Virginia Nicolescu, Ceronav (Romania)

SiC single-layer or multi-layer on C used to improve the oxidation resistance and tribological properties of C have been obtained by Thermionic Vacuum Arc (TVA) method. The 200nm thickness carbon thin films was deposed on glass or Si substrate and then 100÷500 nm thickness SiC successively layers on carbon thin film was deposed. The microstructure and mechanical characteristics of as-prepared SiC coating were investigated by Transmission Electron Microscopy (TEM), Energy Dispersive X-Ray Spectroscopy (EDS), Scanning Electron Microscopy (SEM), X-Ray Diffraction (XRD) and tribological techniques.

Samples containing SiC single-layer or multi-layer coating on carbon were investigated up to 1000oC. The results of thermal treatments reveals the increase of oxidation resistance with increase of the number of SiC layers. The mechanism of oxidation protection is based on the reaction between SiC and elemental oxygen resulting SiO_2 and CO.

The tribological behavior of SiC coatings was evaluated with a tribometer with ball-on-disk configuration from CSM device with 6mm diameter sapphire ball, sliding speed in dry conditions being 0.1m/s, with normal contact loads of 1N, 3N and 10N, under unlubricated conditions. The friction coefficient on SiC was compared with the friction coefficient on uncoated carbon layer.

Electrical conductivity of SIC coating on carbon was measured comparing the potential drop on the sample with potential drop on a series standard resistance in constant current mode. The electrical conductivity of SiC coatings was monitoring relative to the uncoated carbon layers at different temperatures.

8818-7, Session 3

Homogenization of a lattice of resonant scatterers

Didier Felbacq, Univ. Montpellier 2 (France); Emmanuel Kling, Sagem (France)

Metamaterials are artificial composite objects that are considered for their “effective behavior” that is hardly encountered in natural materials and to some extend tailorable. The effective behavior is the one that emerges in the limit where the wavelength is “much larger” than the period of the cell upon which the metamaterial is built. Typically, the order parameter is $\eta=d/\lambda$. One of the main issue in defining the effective parameters is that the size of the cell in current metamaterials is not that small as compared to the wavelength. This makes necessary to go beyond the usual 0th order of homogenization theory (in the small parameter η). Unfortunately, it is not always clearly stated in the physical literature that homogenization only makes sense as an expansion in power of η, which results in claims that an effective permittivity could match the Bloch spectrum for any frequency. In this work, we address a simple situation where a layer of point-like scatterers is considered. A complete asymptotic analysis is given that allows a clear delimitation of the homogenization regime. It is also shown that, in that situation, the effect of spatial dispersion are limited and are not a clue to the description of the effective scattering behavior of the structure.

8818-8, Session 3

Modes of interaction between nanostructured metal and a conducting mirror as a function of separation and incident polarization

Fadi Bonnie, Matthew D. Arnold, Geoffrey B. Smith, Angus R. Gentle, Univ. of Technology, Sydney (Australia)

The optical resonances that occur in nanostructured metal layers are modulated in thin film stacks if the nanostructured layer is separated from a reflecting conducting layer by various thicknesses of thin dielectric. We have measured and modeled the optical response of interacting silver layers, with alumina spacer thickness ranging from a few nm to 50 nm, for s- and p-polarized incident light, and a range of incident angles. Standard thin film models, including standard effective medium models for the nanostructured layer, break down for spacer thickness below a critical threshold. For example with polarisation in the film plane in this material combination it occurs at around 10 nm of Al_2O_3. This arises from onset of hybrid modes between the two plasmonic layers. Three types of new modes are possible (a) a two-particle mode involving a particle and its mirror image (b) A Fano resonance from hybridisation of localized and de-localised plasmon modes(c) a Babinet’s core-(partial) shell particle with metal core-dielectric shell in metal [1,2]. For larger spacings thin film and effective medium models do apply. Variations in peak intensity arise then from spacing dependent phase modulation.

8818-9, Session 3

An investigation into Voigt wave propagation for optical sensing

Tom G. Mackay, The Univ. of Edinburgh (United Kingdom)

In the nonsingular case of optical propagation in a linear, homogeneous, anisotropic, dielectric material, two independent plane waves, with orthogonal polarizations and different phase speeds, can propagate in a given direction. However, in certain dissipative biaxial materials there are particular directions along which these two waves coalesce to form a single plane wave. This coalescent Voigt wave represents the singular case. Most notably, the amplitude of Voigt waves are linearly dependent upon propagation direction. A porous nanostructured material is envisaged which does not itself support Voigt wave propagation. But when this porous material is infiltrated with a fluid containing an agent to be detected, the resulting homogenized composite material does support Voigt wave propagation. Furthermore, the directions along which Voigt waves propagate may be sensitive to the concentration of the agent to be detected. This sensitivity is explored theoretically, in order to establish the feasibility of an Voigt-wave based optical sensor.

8818-10, Session 4

Robust and durable polyhedral oligomeric silsesquioxane-based anti-reflective coatings with broadband quasi-omnidirectional properties

Hemant K. Raut, Saman S. Dinachali, National Univ. of Singapore (Singapore); Ai Y. He, A*STAR Institute of Materials Research and Engineering (Singapore); Anand G. Venkatesan, National Univ. of Singapore (Singapore); Mohammad S. M. Saifullah, Jaslyn B. K. Law, A*STAR Institute of Materials Research and Engineering (Singapore); Seeram Ramakrishna, National Univ. of Singapore (Singapore)

Polymer-based anti-reflective coatings on glass pose major challenges for outdoor applications due to their incompatible mechanical and thermal properties. Here we demonstrate a durable, chemically and thermally stable polyhedral oligomeric silsesquioxane-based (POSS) anti-reflective moth's eye nanostructures on glass fabricated by double-sided nanoimprint lithography (NIL). These anti-reflective nanostructures exhibited excellent broadband and quasi-omnidirectional antireflective properties. An optimum POSS resist composition for nanoimprinting was formulated. Thermal free radical co-polymerization during nanoimprint lithography produced a uniform array of moth's eye nanostructures on both sides of a glass substrate with yields ~90-100%. The measured elastic modulus of the POSS thin-films is higher than or equal to the average elastic modulus of polymers used to fabricate anti-reflective coatings such as polydimethylsiloxane, polycarbonate, polystyrene, polyethylene terephthalate etc. The transmittance of the plane glass increased from 91.8% to 98.2% the POSS-based moth's eye anti-reflective nanostructures on both sides of the glass. A minimum reflectance of 1.2% as compared to 8.2% in case of plane glass was observed in the POSS-based moth's eye ARC glass. The Weighted Average Transmittance (WAT), that is indicative of the broad-band property of anti-reflection, showed that the WAT for the POSS-based moth's eye ARC glass was 96% as compared to 90.5% for plane glass. A quasi-omnidirectional transmittance is also observed from -50° to +50° of angles of incidence for the POSS-based moth's eye ARC glass. Furthermore, a series of ASTM-based tests on the imprinted structure showed strong adherence to glass, better hardness and mechanical strength with superior chemical and thermal stability.

8818-11, Session 4

Titania nano rice: a robust superamphiphobic film

Anand G. Venkatesan, Saman S. Dinachali, National Univ. of Singapore (Singapore) and A*STAR Institute of Materials Research and Engineering (Singapore); Sreekumaran Nair, Amrita Institute of Medical Science (India); Seeram Ramakrishna, National Univ. of Singapore (Singapore)

Rice-shaped TiO2 nanostructures are fabricated by electrospinning for creating a robust superamphiphobic coating on glass substrates. The as-fabricated TiO2 nanostructures (sintered at 500 ºC) are superhydrophilic in nature which upon silanization turn into superamphiphobic surface with surface contact angle (SCA) values achieved using water (surface tension, γ = 72.1 mN/m) and hexadecane (surface tension, γ = 27.5 mN/m) being 166° and 138.5°, respectively. The contact angle hysteresis for the droplet of water and hexadecane are measured to be 2° and 12°, respectively. Thus, we have successfully fabricated superior self-cleaning coatings that possess exceptional superamphiphobic property by employing a simple, cost-effective and scalable technique called electrospinning. Furthermore, the coating showed good mechanical and thermal stability with strong adherence to glass surface thus revealing the potential for real applications.

8818-12, Session 4

Optical simulations of biomimetic nanostructures and applications in energy and toxic sensing

Surojit Chattopadhyay, National Yang-Ming Univ. (Taiwan)

Many natural surfaces are texturized in the nano-scale to impart certain optical properties, such as anti-reflection, and wetting properties, such as superhydrophobicity in lotus. The cornea of the moths or wings of Cicada has tiny conical burls that reduce reflection (in moths) and increase transmission (in Cicada) of the surfaces. We have fabricated nano-tip (NT) structures on semiconductor (Si, GaAs, GaP, GaN) surfaces by a top-down type self masked plasma etching process involving a plasma of silane, methane, hydrogen and argon. We simulate and compare the optical properties of these nanotips against simple geometrical structures as single and dual diameter nanorods using FDTD. The anti-reflection properties are explained on the basis of gradient refractive index (GRIN) profiles of these structures. The plasma etching can be tuned with respect to substrate properties to arrive at superior surface designs meeting the application needs.

We have used the silicon nanotips (SiNTs) with a thin atomic layer deposited oxide coating to obtain thin film capacitors with the highest (till date) equivalent planar capacitance. The structure could be used as super-capacitors in energy-related devices.

Another application of these nanotips is in molecular sensing via surface enhanced Raman scattering (SERS). Optical sensing of DNA has been demonstrated at the sub-picomole level using self assembled silver nanoparticle (AgNPs) decorated gold nanotip (AuNT) arrays. We show how AgNP coated SiNTs can detect toxic molecules used as insecticides in agricultural products.

8818-13, Session 5

Liquid crystal optical fibers for sensing applications *(Invited Paper)*

Pankaj K. Choudhury, Univ. Kebangsaan Malaysia (Malaysia)

Propagation characteristics of optical fibers are greatly dependent on the material which the fiber is comprised of. Varieties of materials have been developed, and investigated for their usage in fabricating optical fibers

for specific applications. Within the context, a liquid crystal medium is both inhomogeneous and optically anisotropic, and fibers made of such mediums are greatly useful. Also, liquid crystals exhibit strong electro-optic behavior, which allows alternation in their optical properties under the influence of external electric field. These features make liquid crystal fibers to be of prudent use in the area of optics and photonics.

The present communication is aimed at providing a glimpse of the efficacy of liquid crystal fibers followed by the analytical investigation of wave propagation through such guides. Generally, transverse electric and transverse magnetic are the two types of modes that can be sustained in such guides; both of these modes are individually tackled to explore the propagation characteristics. The investigations reveal the novelty of the usage of liquid crystal fibers for optical sensing and/or field coupling under the situation when the transverse electric modes are excited in the guide. The case of tapered liquid crystal fibers is also discussed, and it is found that the tapering of the geometry greatly improves the propagation features so that these would be highly efficient for aforesaid applications. A control on the dispersion characteristics of such fibers may also be imposed by making the guide even more complex. The possibility of devising such options is also touched upon.

8818-14, Session 5

Waveguide core integrated nanostructured SERS sensor platform

Stuart J. Pearce, Swezin Oo, Michael E. Pollard, Ruiqi Y. Chen, Sumit Kalsi, Martin D. B. Charlton, Univ. of Southampton (United Kingdom)

The intensity of Raman scattering can be enhanced by a factor of 106 using Surface Enhanced Raman Spectroscopy (SERS). In this method, molecules are placed within a few nm of a rough/nanostructured metal surface. In this paper we show fabrication and characterisation of an integrated optical waveguide beneath a nano-structured precious metal coated surface. By using a waveguide core, the excitation field comes from underneath and enters the nanostructures at the base. This allows the emission to reach the discrete sensing areas effectively and should provide ideal parameters for maximum Raman interactions. The nanostructured geometry projects the Plasmon field into free space, thus increasing the cross section of interaction between the analyte molecules and optical fields, thereby increasing device sensitivity. Thin films of silicon oxynitride were deposited using PECVD on to thermal oxide coated 4 inch wafers and annealed at various temperatures to obtain low loss layers suitable for the waveguide core material. Based on the results from our simulations, nanostructured features of various diameters/feature lengths and pitch were etched into the low loss silicon oxynitride layer. The sensor area was coated with a thin layer of gold (25nm) and a variety of optical measurements were completed for many of the processed test chips including broadband reflectrometry, normal incident Raman spectroscopy and waveguide Raman spectroscopy using a Raman probe above the sensor area. The results showed that detection of a Raman active molecule (Benzyl Mercaptan) was possible when excited from the underlying waveguide core with 104 sensitivity.

8818-15, Session 5

Surface-plasmonic-polaritonic sensor using a dielectric columnar thin film

Stephen E. Swiontek, Akhlesh Lakhtakia, The Pennsylvania State Univ. (United States)

Surface-plasmon-polariton (SPP) waves are electromagnetic surface waves exploited for real-time and label-free optical sensing of biochemical and chemical species in research and industrial settings. SPP waves are guided by the interface of a thin metal film and a substantially thicker dielectric material.

Theory shows that a SPP wave can be launched at the interface of a thin metal film and a dielectric columnar thin film (CTF) in the Turbadar-Kretschmann-Raether configuration. The CTF is an assembly of parallel and tilted nanowires grown by physical vapor deposition. A collimated vapor flux is generated and directed towards a substrate which is held at a fixed orientation in relation to the vapor flux. The CTF contains void regions which can be infiltrated with a fluid. The angular location of the SPP wave in the Turbadar-Kretschmann-Raether configuration will shift upon infiltration of the CTF by the fluid, and the device can behave like an optical sensor.

Therefore, a 30-nm-thick aluminum film was deposited onto an SF-11 glass substrate, followed by a partnering lanthanum-fluoride CTF. The sample was affixed to an SF-11 right-angle prism and the reflected intensities of a p-polarized plane wave at different angles of incidence were recorded. The angular location of the SPP wave was recorded in relation to: (i) the deposition parameters, (ii) the orientation of the CTF, and (iii) the refractive index of the infiltrant fluid.

8818-16, Session 5

Waveguide-mode sensors with sculptured porous waveguide

Motofumi Suzuki, Munehito Takagaki, Shohei Kuriyama, Kaoru Nakajima, Kenji Kimura, Kyoto Univ. (Japan)

Recently, so-called waveguide-mode sensors, which consist of multilayer of dielectric/absorptive/glass substrate, are attracting much attention from viewpoints of applications to the molecular detection. In order to enhance the sensitivity, open pores much smaller than the wavelength are introduced into the waveguide layers so that their effective refractive index changes depending on that of the surrounding fluid. The cost effective processes to create nanopores with high uniformity and reproducibility are strongly required. In this work, obliquely deposited thin films with nanocolumnar structures have been introduced to the waveguide layer in the waveguide-mode sensors. The multilayers including the porous SiO2 waveguide layer were prepared by dynamic oblique deposition technique. On a glass substrate, a Si layer as the absorptive layer was deposited by e-beam evaporation up to 240 nm thick from surface normal. A nanocolumnar SiO2 layer was deposited at a deposition angle of 70 degree by e-beam evaporation up to a thickness of 700 nm. The substrate was rotated rapidly during the deposition. The reflectance measured in the different fluid as a function of angle of incidence shows sharp minima. The angles of the reflectance minima depend strongly on the surrounding fluids of air, H2O and C2H5OH. Consequently, the nanocolumnar thin films are quite useful for the waveguide layer in the waveguide-mode sensors.

8818-17, Session 5

Influence of structural, morphological, and compositional aspects on NO2-sensing ability of TiO2-NTs

Bilge Saruhan-Brings, Yakup Goenuellue, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany)

In this work, nano-tubular TiO2 sensing-layers were synthesized through the anodization method. In order to improve the sensor ability (i.e. sensitivity, selectivity or response-recovery time) of TiO2-NTs, Cr-doping process was achieved by chemically-wall wetting route. The sensor properties (selectivity, sensitivity or response and recovery time) of un-doped and doped TiO2-NTs were carried out by DC-resistance measurement towards, NO2 and CO varied temperature of 300°C to 500°C. Moreover, the morphology (i.e thickness of TiO2-NTs), measurement temperature and doping effect on sensor behaviours were figured out by Electrochemical Impedance Spectroscopy (IES) with equivalent circuit model fitting

8818-18, Session 5

Enhancement in electrogenerated chemiluminescence technique using nano particles-thin film

Ali Shokuhi Rad, Islamic Azad Univ., Qaemshahr (Iran, Islamic Republic of); Mohsen Jahanshahi, Babol Univ. of Technology (Iran, Islamic Republic of)

Simply put ECL or Electrogenerated chemiluminescence involves applying electric potential to a chemical reaction, resulting in the oxidation or reduction of the substance which reacts to produce light. The amount of analyte is ideally proportional to the amount of light detected so ECL can be used to measure the amount of a given chemical in solution. One of the important ways is based on modification of electrode surface using nano materials which enhance ECL signals compared to the unmodified electrode. In general, with regarding to works done in this topic, the nano particles can be immobilized on a appropriate support, such as nafion film or sol–gel film which were immobilized on the surface of electrode. Compared to the bare electrode, the modified electrode incorporating nano particles significantly enhanced the response of the ECL sensor due to the enhanced specificity of the modified electrode. As an example we used silver nanoparticles as part of modifier layers to enhance the sensitivity of obtained biosensor toward glucose determination. Compared to nanoparticles free biosensor, nanoparticles included biosensor shows huge sensitivity as well as more stability toward determination of glucose.

8818-37, Session PWed

Evolution of optical and plasmonic properties of aluminum/porous alumina thin films during anodization and etching processes

Mykola Biednov, National Taras Shevchenko Univ. of Kyiv (Ukraine); Tetiana Lebedeva, Institute of Cybernetics (Ukraine)

Devices, based on surface plasmon resonance phenomena have a variety of sensing applications. Aluminum/ porous alumina based sensors attract much interest due to coupling of surface plasmon to waveguide modes, enhanced surface area of porous alumina, chemical and mechanical stability and ability to precisely control properties of the film by selecting anodization and etching conditions. In this work we carried out ellipsometry, SEM, and reflectometry measurements to study evolution of effective refraction index, thicknesses of the aluminum and porous alumina layers, porosity, reflectivity curves and surface plasmon resonance angle during anodization and etching and built theoretical models of these processes. Theoretical models along with Bruggeman approximation and Fresnel equations were used to calculate evolution of reflectivity curves and sensitivity. Results of calculations agree well with experimental measurements at all stages of the film manufacturing. Using theoretical modeling we determined optimal manufacturing conditions and film parameters that would guarantee maximal sensitivity at fixed wavelength.

8818-38, Session PWed

FDTD modelling of waveguide core integrated etched nanostructures

Stuart J. Pearce, Michael E. Pollard, SweZin Oo, Martin D. B. Charlton, Univ. of Southampton (United Kingdom)

Surface Enhanced Raman Spectroscopy (SERS) allows the intensity of Raman scattering to be enhanced by a factor of 106 by placing molecules within a few nm of a rough metal surface. In this paper we continue our investigation into a completely different configuration for a SERS sensor platform, incorporating an optical waveguide beneath a nano-structured precious metal coated surface. The nanostructured geometry projects the Plasmon field into free space, thus increasing the cross section of interaction between the analyte molecules and optical fields, thereby increasing device sensitivity. In this arrangement the excitation field comes from underneath and enters the nanostructures at the base. This allows the emission to reach the discrete sensing areas effectively and should provide ideal parameters for maximum Raman interactions. Using Finite Difference Time Domain (FDTD) modeling methods the waveguide coupled SERS nanostructures were fully analyzed and their theoretical performance simulated by using frequency domain power monitors around the nanostructures. The model investigates efficiency of coupling between the waveguide and surface plasmons, but also investigates spatial localization around sharp features of the geometry. Simulations were completed using different types of etched nanostructures (pryamidal, circular, square) and dimensions to determine a suitable sensor area which would allow for maximum field intensity within the features when excited from underneath. The simulations suggested that a pitch of 2500nm, a circular or square diameter/feature length of 500nm and an etch depth of 400nm showed more field intensity within the nanostructured pits.

8818-40, Session PWed

Self-organising formation of super layer Structure in PbBr-based layered perovskite superlatice materials by mixing of bulky chromophore-linked ammonium bromide and alkyl ammonium bromide

Masanao Era, Koich Sakaguchi, Saga Univ. (Japan)

A family of lead-bromide based layered perivskite [(RNH3)2PbX4] is a self-organized organic-inorganic surper lattce material, in which organic dielectric (RNH3) layer and tow-dimensional lead halide semiconductor layer consisting of cornar-sharing PbX6 ocatahedra are alternately piled up. Based on their low dimensional semicondctor nature (quatum well), they form stable exciton, and exhibit attractive optical properties, efficient photoluminescence, electroluminescence and efficient optical nonlinearity owing to the stable exciton. In this work, we found that the supuer lattice structure is albe to be modified by the ratio of chromophore-linked alkyl ammonium bromide, alkyl ammonium bromide and lead bromide PbBr2, which is dissolved in the solution employed for a simple spin-coating.

Propyl ammonium bromide 1, carbazole-linked and naphthalen-linked ammonium bromides 2 and 3, and PbBr2 4 were dissolved in dimethylformamide (DMF) at the molar ratio of 1:2:4 and 1:3:4 = 2:0:1, 4:2:3, 1:1:1, 2:4:3, and 0:2:1. The thin films were prepared on fused quartz substrates by spin-coating from the DMF solutions.

Super layer structure, where organic dielectric layer, inorganic semiconductor layer, and organic semiconductor are assembled in order, was successfully constructed by a simple spin-coating with the solution in which propyl ammonium bromide 1, carbazole-linked propyl ammonium bromide 2 and PbBr2 3 (the molar ratio; 1:2 :4 and 1:3:4=4:2:3) were dissolved. Detailed results will be presented in this presentation.

8818-41, Session PWed

IGZO oxide thin film transistors with 3-layer gate insulator

Sang Chul Lim, Ji-Young Oh, Jae Bon Koo, Chang-Woo Park, Soon-Won Jung, Bock Soon Na, Electronics and Telecommunications Research Institute (Korea, Republic of)

In this study, we applied the 3 layer gate dielectrics to a-IGZO TFTs in order to display panel performance improvement, and also semiconductor active layer with protection layer (PL). The electrical measurements of the ZnO TFT devices were performed in ambient air

(room temperature and 20% relative humidity) without passivation using a Keithley 4200 semiconductor parameter analyzer. The device fabrication process involves a series of thin film deposition and photolithographic patterning steps. In order to minimize contamination, the substrates usually undergo a cleaning procedure using deionized water, before and after the growth of thin films by sputtering methods. The devices structure were fabricated top-contact gate TFTs using the a-IGZO films on the plastic substrates. The channel width and length were 80 and 20 um, respectively. The source and drain electrode regions were defined by photolithography and wet etching process. The electrodes consisting of Ti(15 nm)/Al(120 nm)/Ti(15nm) trilayers were deposited by direct current sputtering. The 30 nm thickness active IGZO layer deposited by rf magnetron sputtering at room temperature. The deposition condition is as follows: a rf power 200 W, a pressure of 5 mtorr, 10 % of oxygen [O2/(O2+Ar)=0.1], and room temperature. A 9-nm-thick Al2O3 layer was formed as a first, third gate insulator by ALD deposition. A 290-nm-thick SS6908 organic dielectrics formed as second gate insulator by spin-coating. The TFTs device has a channel width (W) of 80 µm and a channel length (L) of 20 µm. The IDS-VDS curves showed well-defined transistor characteristics with saturation effects at VG>-10 V and VDS>-20 V for the inkjet printing IGZO device. The carrier charge mobility was determined to be 15.18 cm^2 V-1s-1 with FET threshold voltage of -3 V and on/off current ratio 10^9

8818-42, Session PWed

Studies on nonlinear optical absorption of indium gallium zinc oxide (IGZO) thin films

Sanal K. Kozhiparambil, Vishnu Kavungal, Majeesh M. Mangalasseril, Madambi K. Jayaraj, Cochin Univ. of Science & Technology (India)

Amorphous oxide semiconductors (AOS)are of considerable interest for next generation optoelectronic device applications. One of the most promising AOS materials is indium–gallium–zinc–oxide (IGZO) which is being used as a channel layer in transparent thin film transistors.

N-type transparent conducting indium gallium zinc oxide (IGZO) films were successfully grown on glass substrates at room temperature by rf magnetron sputtering using a powder target. Structural, optical, morphological and electrical properties of IGZO films were investigated. Structural studies by X-ray diffraction showed that all IGZO films were amorphous in nature. The surface morphology of IGZO films analyzed by scanning electron microscope (SEM) and atomic forced microscopy, revealed that all the films are uniform and film deposited at 40W rf power have an average roughness of 0.75nm. Composition of the film was confirmed by EDAX measurement which shows that percentage of Zn increased with the increase of rf power. The average transmission in the visible range was greater than 80% and the transmission in the higher wavelength region decreased with increase in rf power. Refractive index in the visible region of IGZO film calculated by Swanepoel technique was found to be 1.92. The carrier concentration in IGZO films can be controlled by controlling rf power due to the increase of Zn/(Ga+In+Zn) ratio. Hall measurement shows a carrier concentration of 2.5e18 cm ?3 and conductivity 87.52S/cm for the films deposited at 100W rf power . The nonlinear optical absorption in IGZO thin films and its dependence on the free-carrier density using Z-scan technique has been investigated. It was observed that nonlinear absorption coefficient decreases with increasing carrier concentration.

8818-43, Session PWed

GaN-based light-emitting diodes by laser lift-off with Ag nanoparticles

Wun Wei Lin, Lung-Chien Chen, National Taipei Univ. of Technology (Taiwan)

This study presents a GaN thin film light-emitting diode (TF-LED) on an electroplated flexible copper substrate to improve thermal conduction effect of the LED. The optoelectronic characteristics and stress effect of the GaN TF-LEDs on the electroplated flexible copper prepared by laser lift-off technique was examined.

The surface of the peeled GaN TF-LED after laser lift-off process demonstrated a pore array. The GaN pore array surface was etched by photo-electrochemical method to form hexagonal pyramid hillocks on the surface using KOH solution. Then, freestanding peeled GaN TF-LEDs with the front surface protected by wax were immersed into 3M KOH solution at room temperature for 30min under ultraviolet illuminations to perform the photo-electrochemical etching. A single-layer Ag film was deposited on a N-face GaN with pore array surface by RF magnetron sputtering. After 300 oC annealing, the Ag nanoparticles was formed on the roughened N-face GaN as a reflective layer for achieving an improved light extraction in GaN-based LEDs.

Surface morphologies with and without photo-electrochemical etching were observed by field emission scanning electron microscope (FESEM) (LEO 1530).

8818-44, Session PWed

Optimizing absorptance in nanostructured thin films

Tom H. Anderson, Dominykas Gustas, Tom G. Mackay, The Univ. of Edinburgh (United Kingdom)

Nanostructured thin films, such as chiral sculptured thin films (CSTFs) and columnar thin films (CTFs), are promising for a host of applications because their porosities and optical properties can be fine-tuned to order, at least up to a certain useful degree. One possible application lies in the area of dye-sensitized solar cells, wherein such nanostructured thin films may provide a scaffold to support light-absorbing dyes. A theoretical study is presented wherein CSTFs and CTFs are infiltrated with light-absorbing dyes. The structural parameters of the CSTFs and CTFs are varied in order to optimize absorptance. Results are compared against those for a simple porous isotropic dielectric material infiltrated with light-absorbing dyes. Conclusions are drawn about the feasibility of CSTFs and CTFs for applications requiring high absorptance, such as dye-sensitized solar cells.

8818-45, Session PWed

Size effect on negative refractive indexes of aluminum/silicon-dioxide/aluminum nanosandwich films

Yi-Jun Jen, Hung-Sheng Liao, Meng-Jie Lin, National Taipei Univ. of Technology (Taiwan)

In this study, three different thicknesses of aluminum (Al) / silicon-dioxide (SiO2) / aluminum (Al) nanosandwich films (SWFs) are deposited using glancing angle deposition (GLAD) technique with continuous azimuthal rotation. The SWF comprises the SiO2 layer sandwiched between Al nanopillars. The thicknesses d of top and bottom Al nanopillar increase from 188nm to 233nm. The thickness of SiO2 is fixed at 45nm. Each SWF is measured the reflection coefficients and transmission coefficients from its both sides by walk-off and polarization interferometers. By considering the bianisotropic parameter, the equivalent electromagnetic parameters of each film are derived from the four coefficients. The analysis of measured reflection and transmission coefficients of the SWF showed that it presents a negative-real equivalent permittivity as well as a negative-real equivalent permeability. Base on the analysis of measurement, the size effect of Al / SiO2 / Al SWFs is demonstrated for the optical properties. As the thickness d increase from 188nm to 233nm, the equivalent refractive index is negative and its average magnitude decrease from -1.703 to -1.247. The same trend can be found for the real part of equivalent permittivity varied from -1.193 to -0.824 with increasing thickness. Furthermore, the SWFs are also simulated to analyze the magnetic field in the SiO2 layer by finite-difference time-domain (FDTD). The result of simulation demonstrates the negative permeability comes from the reversed magnetic resonance within the SiO2 layer. The reversed magnetic field decreases with increasing thickness d.

Success with an approach for computer-based numerical simulations

Diana Khashimova, Technische Univ. Hamburg-Harburg (Germany)

Zeolites are crystalline oxides with uniform, molecular-pore diameters of 3-14Å. Significant developments since 1950 made production of synthetic zeolites with high purity and controlled chemical composition possible. In powder-form, zeolites are major role-players in high-tech, industrial catalysis, adsorption, and ion exchange applications.

Understanding properties of thin-film zeolites has been a focus of recent research. The ability to fine-tune desired macroscopic properties by controlled alteration at the molecular level is paramount. The relationships between macroscopic and molecular-level properties are established by experimental research. Because generating macroscopic, experimental data in a controlled laboratory can be prohibitively costly and time-consuming, reliable numerical simulations, which remove such difficulties, are an attractive alternative.

Numerical models were developed for pure component and subsequently multicomponent adsorption processes. Using a Configurational Biased Monte Carlo (CBMC) approach in grand canonical ensemble, both process types were simulated numerically, replicating benchmark experimental data. Classical theoretical models using ideal (IAST) and real adsorbed solution theory (RAST) to predict mixture adsorption in nanopores, are also presented for comparison.

Reported are computer simulations for the adsorption of alkanes in the all-silica MFI (channel) and DDR (cage) type zeolites matching experimental data on adsorption of light hydrocarbons - alkanes- such as methane, ethane and butane. Included are binary and ternary mixtures.

The numerical approach developed can be a powerful, cost and time saving tool to predict process characteristics for different molecular-structure configurations. The approach used here for simulating adsorption properties of nanopore materials including process characteristics, may have great potential for other properties of interest.

8818-19, Session 6

Tailoring optical complex fields with nanostructured metallic thin film *(Invited Paper)*

Qiwen Zhan, Univ. of Dayton (United States)

Polarization of light plays an important role in optical science and engineering. Recently there is an increasing interest in complex optical fields with spatially inhomogeneous state of polarizations and optical singularities. New effects and phenomena have been predicted and observed for light beams with these unconventional states. In this talk, I will first review the recent developments in complex optical fields and their potential applications. A summary of methods for the generation of these fields will be provided. Among various generation techniques, nanostructured metallic thin film offers unique advantages due to its compactness and flexibility. Furthermore, strong interactions of nanostructured metallic film with vectorial optical fields enable the development of unique functional devices and systems. As examples, the design and fabrication of nanostructured metal thin film that can produce complex vector fields for focal field engineering (specifically for optical needle field generation) will be presented. Beaming and steering of photons emitted from nano-emitters integrated with nanostructured metal thin film will be demonstrated. The design of a plasmonic metal-insulator-metal (MIM) device that integrates several functions will also be illustrated.

8818-20, Session 6

Collective phenomena in plasmonic nanostructures and photonic metamaterials *(Invited Paper)*

Stefan Linden, Rheinische Friedrich-Wilhelms-Univ. Bonn (Germany)

Metamaterials have added new and fascinating effects to optics, e.g., magnetism at optical frequencies, negative index materials, and strong chirality. For most photonic metamaterials, the mesoscopic origin of these phenomena is the excitation of plasmonic modes in its metallic metaatoms. Thus, a qualitative first understanding of the features of a given metamaterial can often be obtained by considering the plasmonic resonances of an isolated metaatom. However, electromagnetic interactions between the metaatoms can have a significant impact on the properties of the metamaterial.

In this presentation, we will present recent experiments which underline the importance of collective phenomena in photonic metamaterials.

8818-21, Session 6

Multiply stacked ZnO nanoflowers by atmospheric plasma surface modification for flexible electronics

Do Yeob Kim, Jae Young Kim, Clemson Univ. (United States); Hyuk Chang, Youngjun Park, Samsung Advanced Institute of Technology (Korea, Republic of); Min Su Kim, Jae-Young Leem, Inje Univ. (Korea, Republic of); John Ballato, Sung-O Kim, Clemson Univ. (United States)

ZnO nanostructures with high surface area to volume ratio have shown great promise for sensors and energy harvesting applications. Here we demonstrate a simple approach for morphology-controlled bilayer ZnO nanostructures on plastic substrates derived from the surface modification of ZnO seed layers using an atmospheric pressure plasma jet (APPJ) treatment. Several advantages are expected from the plasma treatment on ZnO seed layers: (i) the surface wettability of the seed layers changes from hydrophobic to hydrophilic, resulting in higher surface energies for the growth of high-density ZnO nanostructures, (ii) the nucleation sites increase due to the increased surface roughness by the plasma etching, and (iii) there is no thermal damage to the plastic substrate by plasma treatment due to its low temperature weakly-ionized discharge. The obtained ZnO nanostructures consisted of a two-layered structure with nanorod arrays on the bottom layer and nanoflower arrays on the top layer. The individual nanoflower structure was composed of a number of hexagonal nanorods, which grew radially in many directions. Multiple-stacks of nanoflowers were grown continuously on the nanorods in the plasma-treated sample whereas only one stack of nanoflowers was grown on the nanorods in the as-prepared sample. It was confirmed that the plasma treatment induced a significant increase in the height and density of the ZnO nanoflowers/nanorods while the crystal shape and size of the ZnO nanoflowers/nanorods were barely affected. The multiply-stacked high-density ZnO nanoflowers/nanorods are easily obtained through a simple plasma treatment of the seed layer during conventional hydrothermal synthetic procedures making APPJ a very useful enhancement for flexible electronics on plastic substrates.

8818-22, Session 6

Nanostructured composite thin films with tailored resistivity by atomic layer deposition

Anil U. Mane, Jeffrey W. Elam, Argonne National Lab. (United States)

We have developed a new type of nanostructured composite material comprised of M:Al2O3 (where M= W or Mo) consisting of conducting metal nanoclusters embedded in an insulating Al2O3 matrix. These nanocomposite thin films were prepared by atomic layer deposition (ALD). Quartz crystal microbalance (QCM) measurements performed using various M cycle percentages revealed that the M ALD inhibits the Al2O3 ALD and vice versa. Despite this inhibition, the relationship between M content and M cycle percentage was close to expectations. Depth profiling X-ray photoelectron spectroscopy (XPS) showed that the (M:Al2O3) films were uniform in composition and contained Al, O, and metallic M as expected, but also included significant F and C. Cross sectional TEM revealed the composite film structure to be metallic nanoparticles (1-3 nm) embedded in an amorphous insulating matrix. The resistivity of these composite films could be tailored in the range of 1012-104 Ohm-cm by adjusting the M ALD cycle percentage. We have used these nanocomposite films as resistive coatings in microchannel plates (MCPs) fabricated from borosilicate glass micro-capillary capillary arrays manufactured by Incom, Inc. We have successfully demonstrated ALD MCPs up to 8” x 8” in size. These devices have application as image-preserving electron multipliers in a wide variety of applications. We have also utilized our M:Al2O3 nanostructured composite films as charge-drain coatings on the insulating components of electron- and ion-optics devices. Some of these applications will be highlighted in the presentation.

8818-23, Session 6

Optimization of a 2D-photonic crytal structure for light extraction in luminescent TiO2 thin films

Lucie Devys, Géraldine Dantelle, Ecole Polytechnique (France); Henri Benisty, Institut d’Optique Graduate School (France); Thierry Gacoin, Ecole Polytechnique (France)

Optimization of light propagation in optically active devices is the subject of large amount of works, motivated by applications in the field of photocatalysis, solar cells, OLEDs …The objective of our work is to characterize and optimize the extraction of a guided light in a high index luminescent thin film, using a 2D-photonic crystal imprinted on the film surface. For that purpose, we investigate a model system made up of two successive TiO2 layers obtained by sol-gel chemistry: the first one contains a dispersed luminescent non-scattering europium molecular complex, chosen for its large Stokes shift. The second TiO2 layer, deposited on top of the first one, is patterned on its surface by nanoimprint lithography. The patterning has a square geometry with a period of 400 nm and variable depth controlled by the viscosity of the TiO2 sol. The patterned area shows a 8-fold extraction enhancement compared with the unpatterned one. However, a key parameter to control extraction issues is the extraction length, corresponding to the length of light propagation in the film before being extracted. Using an optical microscope, we measure the extraction length with different depths of the surface structure: 20, 40 and 60 nm. By fitting the experimental results with the corresponding simulation, the extraction length is deduced, confirming that, in this range, the deeper the surface structure, the shorter the light extraction. Moreover the contributions of the extraction due to the crystal photonic and to the isotropic scattering linked to the imperfections of the layer are estimated.

8818-24, Session 6

Electrochemical deposition p-CdS nanowires

Maarif A. Jafarov, Baku State Univ. (Azerbaijan)

One-dimensional (1D) semiconductor nanostructures have received much attention due to their novel properties and potential applications in nanoscale electronics and optoelectronics. It is evident that the p-CdS nanowires with a smooth surface and a high aspect ratio still inside the nanochannels of anodic alumina substrate (AAS) can be clearly seen. The diameters of the nanowires are uniform and equal to the pore size of the AAS used.

One can see that the nanowire is dense and uniform in diameter corresponding to the pore size of the AAS. It is noticed that there are some contrast variations along the nanowires. The electrochemical deposition was carried out at a constant current density of 10 mA/cm2 at 330 K. During the pulsed time, species were reduced on the pore ground. The delayed time provided time for the recovery of the ion concentration. Here both the pulsed time and delayed time were 100 ms. The electrolyte was prepared by dissolving 1,0 mM CdCl2, 3.07 mM Na2S2O3, 0.15 M C6H8O7?H2O, and 0.05 M Na3C6H5O7x2H2O in water. The pH of the final electrolyte was adjusted to 5 with H2SO4.

Power X-ray diffraction (XRD), scanning electron microscopy (SEM), transmission electron microscopy (TEM, H-800) and high-resolution transmission electron microscopy (JEOL-2010) were used to study the crystalline structure and morphology of nanowire arrays. The chemical compositions of the nanowires were determined by energy dispersive spectrometer (EDS). The band structure of the nanowires was obtained by measuring the optical absorption spectra on UV-visible spectrophotometer. For XRD and optical absorption measurements, the overfilled nanowires on the surface of the AAS and the back Au film were mechanically polished away using Al2O3 nanopowders.

It can be seen that the absorption spectrum of the p-CdS nanowires/AAS assembly system is quite different from that of the blank AAS, which is due to the absorption of p-CdS nanowires. The band gap of nanowires with diameters of 60 and 40 nm is about 3.4 and 3.5 eV, respectively. The shift of 40 nm nanowires is higher than that of 60 nm nanowires. This result indicates that the optical band edge of the p-CdS nanowires embedded in AAS exhibits a marked blue shift with respect to that of the bulk and thin-film p-CdS (2.4-2.5 eV). The blue shift could be attributed to the quantum size effect, which has also been observed in other semiconductor nanosystems. To obtain a high-filling, uniform, and single-crystalline p-CdS nanowire array by the electrochemical deposition into the nanochannels of the AAS, several factors should be considered. First, before electrodeposition the AAS should be ultrasonicated in water for a few minutes to remove the impurities and air bubble inside the nanochannels, because the p-CdS ions will preferentially nucleate and grow at the sites of the impurities, causing the inhomogeneous growth of nanowires, and the air bubbles will hinder the ions to diffuse into the nanopores of the AAS, causing the electrodeposition on the surface of the AAS. Second, a suitable deposition rate is critical to obtain dense, ordered, and single-crystalline nanowires. To avoid the rapid nucleation and growth and inhomogeneous concentration gradient in the nanopores, the pulsed electrodeposition technique is employed, which allows a better control over the deposition parameters, such as deposition rate and ion concentration at the deposition interface, as compared with the direct and alternating current deposition. The delayed time (100 ms) provided enough time for the concentration of the metal ions at the pore tips to achieve steady state through diffusion. No evident concentration gradient near the reaction interface exists during the deposition, and the pulsed time controls the atom-by-atom deposition of nanowires, which improves the homogeneity of the deposition and makes the deposited nanowires have a highly preferential orientation and good crystallization. Proper choice of the pH value of the electrolyte and deposition potential is also important.

8818-25, Session 7

Light-harvesting scheme employing nanostructured thin films for solar cells

Hsin-Ping Wang, Jr-Hau He, National Taiwan Univ. (Taiwan)

It is of current interest to develop the photon management with nanostructures since the ability to suppress the reflection and light trapping over a broad range of wavelengths and incident angles plays an important role in the performance of optoelectronic devices, such as photodetectors, light-emitting diodes, optical components, or photovoltaic systems. Superior light-trapping characteristics of nanostructured thin films, including polarization-insensitivity, omnidirectionality, and broadband working ranges are demonstrated in this study. These advantages are mainly attributed to the subwavelength dimensions of the nanowires, which makes the nanostructures behave like an effective homogeneous medium with continuous gradient of

refraction index, significantly reducing the reflection through destructive interferences. The relation between the geometrical configurations of nanostructures and the light-trapping characteristics is discussed. We also demonstrated their applications in a variety of solar cells. This report paves the way to optimize the nanostructured optoelectronic devices with efficient light management by controlling structure profile of nanostructures.

8818-26, Session 7

Modeling and comparison of light trapping caused by textured interfaces and nanoparticles in thin film solar cells

Birhanu Tamene Abebe, Erlangen Graduate School in Advanced Optical Technologies (Germany) and Friedrich-Alexander Univ. Erlangen-Nürnberg (Germany); Kai Hertel, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany) and Erlangen Graduate School in Advanced Optical Technologies (Germany); Christoph Pflaum, Erlangen Graduate School in Advanced Optical Technologies (Germany) and Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany)

The efficiency of thin film solar cells can be improved by various known and extensively studied light trapping techniques such as textured interfaces, nanoparticles, and so on. All these methods are expected to differ in the amount by which they improve the efficiency of the solar cells. In this paper, textured interfaces and nanoparticles are simulated and their respective effect on the absorption of the active layer, aSi:H in this case, is observed. The nanoparticles are silver nanoparticles, and for the interface simulations, a number of different AFM scans is used. For the nanoparticle simulations, different sizes, shapes and positions are simulated. To achieve this, Maxwell's equations are solved with a Finite Difference Method (FDM) and the Finite Integration Techniques (FIT) using a special scheme that accounts for the negative permitivity of silver. To accurately simulate the silver nanoparticles, the simulation is done with a very fine spatial discretization and run on high performance machines with a highly parallel iterative scheme. Before the two light trapping methods are implemented on the solar cells, their respective scattering behavior is determined by implementing the nearfield to farfield transformation using Fourier analysis.

8818-27, Session 7

High effective carrier lifetime of hierarchical structures by defect-removal etching for silicon heterojunction solar cells

Hsin-Ping Wang, Tzu-Yin Lin, National Taiwan Univ. (Taiwan); Ming-Yi Huang, AU Optronics Corp. (Taiwan); Jr-Hau He, National Taiwan Univ. (Taiwan)

Surface passivation is an important issue in a-Si:H/c-Si based heterojunction solar cells. To obtain desirable surface passivation, the surface area should be as small as possible (e.g., flat surface). However, because of the high reflective index of Si, the flat surface of Si causes up to 40 % of the incident light reflected, which severely limits device performances. Fabricating nanostructure is an effective way to reduce the reflection of light for solar cells but also aggravates the surface recombination by increasing the surface area. Therefore, a crucial challenge in heterojunction solar cell is to break the balance between surface recombination and light absorption losses.

In this work, the uniform compound structures were performed using metal-assisted chemical etching technique. Combined with defect removal etching (DRE), the reflectance was measured and the defect or contamination on the surfaces was monitored through the minority carries lifetime measurements and XPS measurement. The results shows that the reflectance is significantly suppressed, and the carrier lifetime would slightly reduce by controlling the morphology of nanostructures.

8818-28, Session 8

Roughness, optical, and wetting properties of nanostructured thin films *(Invited Paper)*

Angela Duparré, Sven Schroeder, Fraunhofer-Institut für Angewandte Optik und Feinmechanik (Germany)

The talk will provide an overview on our measurement and analysis methodology to investigate the properties of thin film coatings related to their nanostructures and roughness. It will be shown that an unambiguous, comprehensive, yet handy assessment of nanoroughness can be accomplished on the basis of Power Spectral Density functions (PSD) and rms roughness parameters relevant for the specific function of the thin film component. Atomic force microscopy data of the film and substrate surface structures are combined with white light interferometry as well as light scattering techniques. Even though light scattering from thin film nanostructures is typically seen as an unwanted effect, it also carries valuable information about its origins. Compared to other characterization methods, scattering techniques are at the same time non-destructive, fast, and capable of investigating even large sample areas. The talk will also demonstrate how nanostructures that are essential for superhydrophobic and hydrophilic thin films can be predicted, characterized, and related to their functional properties. Examples of application comprise optical and non-optical thin films with different material compositions, designs, and nanostructures.

8818-29, Session 8

Optical property of obliquely deposited dielectric films upon a metamaterial thin film

Yi-Jun Jen, Meng-Jie Lin, Jia-Wei Dai, National Taipei Univ. of Technology (Taiwan)

The equivalent electromagnetic parameters of a silver nanorod array (Ag NRA) fabricated by glancing angle deposition are rederived by considering the bianisotropic parameter in additional to permittivity and permeability. The corresponding optical constants including refractive index, forward impedance and backward impedance are derived to present the wave propagating through the film. In measurement, the reflection coefficients and transmission coefficients from both sides of the Air/Ag NRA/ BK7 glass system are detected via walk-off interferometer. The equivalent optical constants are adopted to estimate the optical performance when additional films are deposited upon the NRA.

The Ag NRA is deposited at a deposition angle of 89deg first. A SiO2 NRA is then deposited at a deposition angle of -89deg. Finally a Ta2O5 NRA is deposited upon the SiO2 NRA at a deposition angle of 80deg. The reflectance and transmittance of the three-layered system Air/ Ta2O5 NRA (165nm)/ SiO2 NRA (133nm)/ Ag NRA(130nm) /BK7 glass are measured and compared with theoretical estimation of reflectance. At a wavelength of 568nm, the theoretical estimated the p-polarization reflectance is 21.75% that is close to the measured reflectance of 20.3%. On the other hand, it is demonstrated that suitable arrangement of dielectric thin films upon a metamaterial thin film can induce the p-polarized transmission.

8818-30, Session 8

Morphological and structural investigation of alpha-sexithiophene grown on KCl (100)

Guenther Schwabegger, Johannes Kepler Univ. Linz (Austria); Tatjana Djuric, Technische Univ. Graz (Austria); Helmut Sitter, Johannes Kepler Univ. Linz (Austria); Roland Resel, Technische Univ. Graz (Austria); Clemens Simbrunner, Johannes Kepler Univ. Linz (Austria)

Alpha-sexithiophene was deposited on KCl (100) by hot wall epitaxy technique [1] at different substrate temperatures (60°C – 135°C).

The morphological investigation was performed by AFM and optical microscopy, revealing terraced islands and needle-like anisotropic structures. It could be shown that needle formation is a thermally activated behaviour.

Structural investigations were performed by specular XRD scans. Upright standing molecules have been detected, which could be related to the terraced islands ((001) crystal contact plane). Furthermore, (010) and (-411) crystal planes have been observed, which explains the observed nano-needles (flat lying molecules).

The texture was investigated by XRD pole figures, showing that all three crystal types exhibit a well defined azimuthal alignment with respect to KCl high symmetry directions. Interestingly, the epitaxial orientation of the islands could be explained by "ledge directed epitaxy" [2], which describes the nucleation of crystallites on existing topographic features on the substrate (nano-needles).

A real space model of the crystallites was developed with the help of XRD pole figures and single crystal data. Surprisingly, the azimuthal orientation of the molecules is exactly the same for needles with (010) and (-411) contact planes. This observation represents a hint that the adsorption geometry of single molecules seems to be decisive for the organic crystal nucleation. Additionally, the substrate surface symmetry is nicely reflected by the multiplicity of formed needle orientations.

8818-31, Session 8

Broadband and wide angle light absorption for an aluminum nanorod array in a prism-coupling system

Yi-Jun Jen, Jia-Wei Dai, Jung-Hui Chao, National Taipei Univ. of Technology (Taiwan)

Traditional optical thin films exhibit low absorption when light is incident obliquely because the optical path decreases with increasing angle of incidence. A thin light absorber is also a challenge to perform high absorption at oblique incidence. Under the condition of total reflection, a thin silver film with thickness around 40nm in a Kretschmann configuration (prism / metal film/ air) enables to absorb light at an extremely small angle range by exciting surface plasmon at interface of metal/air. In this work, a metamaerial thin film composed of aluminum nanorods is fabricated and used to absorb light in high efficiency.

Al NRA is 184nm thick and tilted at an angle of 40 with respect to surface normal. The deposition plane defined by the directions of rod and surface normal is orientated at angles of a=0 deg, a=90 deg, and a=180 deg with respect to the plane of incidence to measure the reflectance versus incident angles from 40 deg to 70 deg and wavelengths from 400nm to 700nm.

When the deposition plane is the same with plane of incidece, the reflectance spectra indicate that Al NRA exhibits strong absorptance over 80% at angles of incidence from 40 deg to 55 deg for both p-polarization and s-polarization. The enhanced p-polarized absorbtance is extended from 40 deg to 70 deg. At a=90 deg, the absroptance is weaker at angles of incidence from 55 deg to 70 deg compared with other two cases measured at a=0 deg and a=180 deg.

8818-32, Session 8

In situ stress evolution of the silver films on different seeding layers

Lirong Sun, Neil R. Murphy, John G. Jones, John T. Grant, Rachel Jakubiak, Air Force Research Lab. (United States)

The in situ stress evolution of the thin silver films prepared using DC magnetron sputtering (DCMS) and modulated pulse power magnetron sputtering (MPPMS) techniques was measured in real time during the film growth using a high resolution multi-beam optical sensor (MOS). Simultaneously, in situ spectroscopic ellipsometry data was collected and correlated with the MOS data. The MOS is an extremely sensitive and non-destructive tool to measure thin film stress and interface effects during film growth. During deposition of silver on a Si substrate the compressive stress decreased from 7.2 GPa at 10 nm thickness to 2.5 GPa when the film thickness reached 20 nm. When silver was deposited on a ZnO film compressive stress was present initially, but switched to tensile stress around 7 nm indicating coalescence of the silver film. Earlier onset of coalescence of the thin silver films deposited on ZnO can be attributed to smaller and more prevalent nucleation sites that decreased the probability for large island growth compared to the Si. The in situ results were further correlated with the surface roughness, grain sizes and morphology by the XRD, XRR, XPS, AFM and SEM measurements for various seeding layers.

8818-33, Session 9

Thermal infrared emitters by plasmonic metasurface *(Invited Paper)*

Junichi Takahara, Yosuke Ueba, Osaka Univ. (Japan)

Recent progress of our study about thermal radiation from periodic microstructures on metal surface "metasurface" is reviewed. Modification of thermal radiation spectra is observed by resonant electromagnetic modes inside single micro-cavity fabricated on tungsten. In addition, new types of narrow-band thermal emitter using spoof-surface plasmon mode on a periodic array of micro-cavity is proposed. Finally, thermal radiation from metasurface composed in sprit-ring resonators is reported. These emitters are tunable on resonant frequency by structural parameters and can be applied to wide-range of emitting device from THz to IR range.

8818-34, Session 9

Gap surface plasmon resonators, antennas, and structures for plasmon nanofocusing *(Invited Paper)*

Dmitri K. Gramotnev, Nanophotonics Pty Ltd. (Australia); Anders Pors, Michael G. Nielsen, Sergey I. Bozhevolyi, Univ. of Southern Denmark (Denmark)

Plasmonic antennas and resonators, i.e., metal nanostructures exhibiting efficient (resonant) scattering of radiation and strongly enhanced local electromagnetic fields, offer unique opportunities for potential applications as plasmonic nanosensors, nanomanipulation and near-field trapping techniques, high-resolution probes for nanoimaging, improved photovoltaics, nanoscale photodetectors with significantly enhanced signal-to-noise ratio, catalysis applications, etc. This paper will analyze a new type of nanoantennas and resonators using gap surface plasmons (GSPs) in metal-insulator-metal configurations where only the top metal layer is structured. The analyzed configurations include circular GSP bowtie structures with large bow angles and strip-like continuous layer GSP resonators. The excitation of the plasmonic resonators is achieved through their illumination by the linearly polarized incident light. The analysis is based on rigorous numerical simulations and determination of the local field enhancements and scattering/absorption cross-sections. Spectral characteristics of the GSP bowtie structures are studied, demonstrating the existence of two distinct types of resonant modes with the domination of the dipole and quadrupole moments resulting in low- and high-Q resonances, respectively. The continuous layer GSP resonators in the form of metal stripes on a dielectric-metal layered structure are investigated numerically and experimentally, demonstrating good agreement between the experimental and theoretical results, excellent resonant characteristics, and significant levels of local field enhancement. The opportunities for a combination of nanoantenna resonant effects with plasmon nanofocusing in bowtie-like structures is also discussed and analyzed. The considered structures offer significant new potentials for the design of photovoltaic applications, nano-optical sensors, and devices with enhanced imaging, photodetection and nanomanipulation opportunities.

8818-35, Session 9

Large scale and low-cost fabrication of Fano-resonant plasmonic and photonic nanostructures for sensing

Benjamin Gallinet, Laurent Davoine, Guillaume Basset, Marc Schnieper, Ctr. Suisse d'Electronique et de Microtechnique SA (Switzerland)

Nanostructuring of surfaces has recently become the cornerstone of many growing fields of nanoscience and technology, such as nanoelectronics, nano-electromechanical systems, plasmonics, and metamaterials. New patterning techniques are required to fulfil their meticulous fabrication requirements in terms of resolution, complexity, cost-efficiency, and throughput. We report on the fabrication by nanoimprint lithography of large-area plasmonic and photonic sensing platforms. Resonant gratings are obtained by patterning a sol-gel material and evaporating a high refractive index semiconductor. A chemically sensitive dye layer is deposited, which acts as the transducer. By exposition to a liquid or an invisible gas such as ammonium, the change in absorption is detected optically. An analytical model is introduced to explain the enhancement of the signal by the resonant grating, which can be detected with the naked eye from a color change of the reflected light. The sensors are compatible with environments where electricity cannot be used such as hospitals, industries, with explosives, and in traffic. The same fabrication procedure is used for metallic subwavelength structures supporting localized surface plasmons. The near-field and far-field optical properties of the system are investigated with an analytical model together with numerical calculations. The strong coupling between the different metallic layers leads to the formation of subradiant and superradiant modes, with the spectral signature of Fano resonances. Fano-resonant systems combine strong nanoscale light confinement with a narrow spectral line width, which makes them very promising for biochemical sensing and immunoassays, towards the label--free detection of single molecules in real time.

8819-1, Session 1

Controlling high-throughput manufacturing at the nano-scale *(Invited Paper)*

Khershed P. Cooper, U.S. Naval Research Lab. (United States)

Interest in nano-scale manufacturing R&D is growing. The reason is to accelerate the translation of discoveries and inventions of nanoscience and nanotechnology into products that would benefit industry, economy and society. Ongoing research in nanomanufacturing is focused primarily on developing novel nanofabrication techniques for a variety of applications—materials, energy, electronics, biomedical, etc. Our goal is to foster the development of high-throughput methods of fabricating nano-enabled products. Large-area parallel processing and continuous processing are high-throughput means for mass production. An example of large-area processing is step-and-repeat nanoimprinting, by which nanostructures are reproduced again and again over a large area, such as a 12 in wafer. Roll-to-roll processing is an example of continuous processing. By this means it is possible to print and imprint multi-level nanostructures and nanodevices on a moving flexible substrate. The big pay-off is reduced unit cost. However, the anticipated cost benefits can only be realized if the increased production rate is accompanied by high yields of high quality products. To ensure product quality, we need to design manufacturing systems such that the processes can be closely monitored and controlled. One approach is to bring cyber-physical systems (CPS) concepts to nanomanufacturing. CPS involves the control of a physical system such as manufacturing through modeling, computation and communication. Such a closely coupled system will involve in-situ metrology and closed-loop control of the physical processes guided by physics-based models, driven by appropriate instrumentation. This paper will discuss these ideas in the context of controlling high-throughput manufacturing at the nano-scale.

8819-2, Session 1

Inkjet-printed zinc tin oxide transport layers in inverted organic solar cells

Eric Danielson, The Univ. of Texas at Austin (United States); Harish Subbaraman, Omega Optics, Inc. (United States); Ananth Dodabalapur, The Univ. of Texas at Austin (United States)

Inverted organic solar cells, which utilize a transparent cathode and a high work function metal anode, have been the subject of extensive research. Their advantages over conventional organic solar cells include increased resistance to environmental degradation and compatibility with large area fabrication techniques. Carrier transport layers are essential for achieving high power conversion efficiencies in inverted organic solar cells and therefore need to be compatible with large area fabrication techniques. Inkjet printing is one such technique that can be integrated into the low cost, mass production of these cells via roll to roll fabrication. N-type metal oxides such as ZnO or zinc tin oxide (ZTO) have been used as electron transport layers for inverted cells, but only as spin coated films. We have developed inkjet printable ZnO and ZTO solutions for use as electron transport layers in inverted organic solar cells and achieved power conversion efficiencies of over 3% in inverted P3HT:PCBM solar cells with inkjet printed ZTO layers. We characterize these inkjet printed films using n-FET measurements and a variety of metrology techniques including AFM and ellipsometry. Printed ZTO film characteristics are compared with the resulting inverted solar cell performance and an optimal printing methodology is presented. We also incorporate inkjet printed PEDOT:PSS as a hole transport layer using previously established techniques to demonstrate the feasibility of large area inverted solar cell fabrication.

High precision dynamic gap control for optical nano-lithography using interferometeric-spatial-phase-imaging

Xiaolei Wen, Purdue Univ. (United States) and Univ. of Science and Technology of China (China); Luis Traverso, Purdue Univ. (United States); Pornsak Srisungsitthisunti, King Mongkut's Institute of Technology (Thailand); Euclid E. Moon, Massachusetts Institute of Technology (United States); Xianfan Xu, Purdue Univ. (United States)

In optical near-field nano-lithography, it is essential to achieve a high precision dynamic control over the distance between the optical mask and the substrate, which is about 10 nm. For this reason, we demonstrate the use of interferometeric-spatial-phase-imaging (ISPI) to control the gap distance. The ISPI technique creates interference fringes from checkerboard gratings fabricated on an optical mask, which are used to determine the value of the gap between the mask and the substrate surfaces. By comparing the gap value on different positions of the mask, we are able to align the mask and the substrate to a high degree of parallelism which stabilizes the gap distance. Moreover, with the use of ISPI technique and dynamic feedback, we can precisely track in real-time the gap distance during the nanolithography process and maintain it with a nanometer level precision. The effect of the gap distance and scanning speed on lithography results is discussed, in order to find out optimal operating parameters which can both avoid friction between surfaces and also obtain narrowest lithography line-width. We demonstrate parallel lithography results with the use of a 5x5 array of bowtie aperture antennas as focusing elements, which produce feature line-width below 90 nm.

8819-4, Session 1

Detection limits for nanoparticles in solution with classical turbidity spectra

Gilles Le Blevennec, Théo Chevallier, Commissariat à l'Énergie Atomique (France)

Detection of nanoparticles in solution is required to manage safety and environmental risks. Spectral transmission turbidity method has now been known for a long time. It is derived from the Mie Theory and can be applied to any number of spheres, randomly distributed and separated by large distance compared to wavelength. Here, we describe a method for the determination of size, distribution and concentration of nanoparticles in solution using UV-Vis transmission measurements. The method combines Mie and Beer Lambert computation integrated in a best fit approximation. In a first step, a validation of the approach is completed on silver nanoparticles solution. Validation of results is done with Transmission Electronic Microscopy measurements for the size distribution and an Inductively Coupled Plasma Mass Spectrometry for the concentration. In view of the good agreement obtained, a second step of work focuses on how to manage the concentration to be the most accurate on the size distribution. Those efficient conditions are determined by simple computation. As we are dealing with nanoparticles, one of the key points is to know what the size limits reachable are with that kind of approach based on classical electromagnetism. Taking into account the transmission spectrometer accuracy limit we determine for several types of materials (metals, dielectrics, semiconductors) the particle size limit detectable by such a turbidity method. These surprising results are situated at the quantum physics frontier.

8819-5, Session 1

Graphene metrology: investigating CVD-graphene microstructure changes with growth pressure using fluorescence quenching microscopy

Hamed Hosseini Bay, Paige Romero, Zafer Mutlu, Isaac Ruiz, Mihrimah Ozkan, Cengiz S. Ozkan, Univ. of California, Riverside (United States)

The exceptional structure and properties of graphene made it an interesting and remarkable topic for research in recent years. Many applications including flexible electrodes for rechargeable batteries and supercapacitors, solar cells, electronic circuitry, sensing platforms and drug delivery have been foreseen for graphene and graphene-based sheets. Accordingly, chemical vapor deposition (CVD) is believed to be the most promising method for industrial-scale synthesis of graphene. In the past few years, a method based on fluorescence quenching of fluorescent dyes by graphene have been developed by our group as a high-throughput non-invasive quality control method for metrology of CVD-graphene sheets. In this method, a thin layer of fluorescent dye is applied on graphene and the energy transfer from dye molecules to graphene makes it possible to observe graphene sheets on arbitrary substrates. There are several parameters in a CVD system, which define the microstructure of graphene, chief among which is the growth pressure. Herein, we investigate the changes of graphene microstructure in different pressures implementing this method. Our results suggest that at lower pressures, graphene growth domains (grains) are significantly larger but there would be more defects in the subsequent graphene sheets. Moreover, results indicate that Fluorescence quenching microscopy (FQM) yields more insight about the dramatic change of the microstructure and quality of the sheets compared to scanning electron microscopy (SEM) and atomic force microscopy (AFM). Furthermore, Nucleation and growth of the graphene layers have been investigated as well.

8819-6, Session 2

New generation CMOS camera for semiconductor defect inspection applications *(Invited Paper)*

Wei Zhou, Darcy Hart, Rudolph Technologies, Inc. (United States)

Semiconductor defect inspection industry is always driven by defect detection rate and through-put. With semiconductor fabrication technology node advances to 2X ~1Xnm range, wafer processing critical macro defect size reduces to a few microns, approaching to typical silicon area scan camera pixel size range. Higher resolution image utilizes more detector pixels to represent the 2D defect, corresponding to smaller field of view on wafer, which fundamentally limits inspection throughput. Instead of recognizing defect shape, most of time detecting the existence of defect is more critical for high throughput volume production; therefore single pixel defect detection becomes more and more essential, which is fundamentally constrained by camera performance.

There are a numerous CMOS detectors based on different generation of CMOS technologies. Unfortunately, most of the time the vendor's data sheet cannot be easily converted into camera performance description for the end user due to different emphasis. This paper presents a model to describe camera performance for semiconductor machine vision. Most of performance items descried in camera industrial general protocols like EMVA1288 are condensed into two complex charts: dynamic range and noise profile, which address all critical factors for low defect contrast high speed semiconductor machine vision applications.

Current mainline cameras and high-end OEM cameras are evaluated with this model. Camera performances are clearly differentiated among CMOS technology generations and integration vendors, which will facilitate application-driven camera selection and operation optimization. The new challenges for CMOS detectors are discussed for semiconductor inspection applications.

8819-7, Session 2

Novel LED coupling design for semiconductor inspection illumination and application extensions *(Invited Paper)*

Wei Zhou, Rudolph Technologies, Inc. (United States)

High speed strobe based illumination scheme is one of the most critical factors for high throughput semiconductor defect inspection applications. HB LEDs are always the first and best option for such applications due to excellent flash-to-flash spatial and temporal stability, fast responding time, larger linear intensity range and no heat issue for - extremely low duty cycle applications. For some applications where a large area is required to be illuminated simultaneously, it remains a great challenge to efficiently package a large amount of HB-LEDs in a highly confined 3D space, to generate a seamless illuminated area with high luminance efficiency and spatial uniformity.

Traditional circular shaped TIR lens can be optimized for better luminance control, but inherently introduce spatial non-uniformity due to air gaps between lens channels. A novel 3D structured TIR lens is presented in this paper. The non-circular edge shape fundamentally reduces the intensity drop at the channel boundaries, while positive curvatures on the TIR lens's top surface efficiently guide the light into desired angular space. Number of edges and radius of top surface curvature are control parameters for system level performance and manufacture cost trade-off. With the novel advantages, the proposed 3D structured TIR lens also maintains the benefits of traditional TIR lens such as coupling efficiency and mold manufacture capability.

The applications can be extended into other non-illumination area like parallelism measurement and solar panel efficiency enhancement.

8819-8, Session 2

6-DOF displacement and angle measurements using heterodyne laser encoder

Ssu-Wen Pan, Hung-Lin Hsieh, National Taiwan Univ. of Science and Technology (Taiwan)

A novel heterodyne laser encoder for 6-DOF displacement and angle measurements is proposed. The system configuration is simple and easy to perform. It combines the advantages of heterodyne interferometry, grating shearing interferometry, and Michelson interferometry.

A heterodyne light beam is generated by using an Electro-Optic modulating technique for amplitude modulation. When the expanded heterodyne beam with four orthogonally polarized beams is focused on a two-dimensional semi-transmission grating, two detection configurations for in-plane (x and y directions) and out-of-plane (z direction) will be obtained. The zeroth and first order diffraction beams of x and y axes partially overlap and interfere with each other. By means of measuring the phase variations of the interfering signals from the moving grating, the grating movement in x and y directions can be acquired. Besides, the grating movement in z direction can be obtained by detecting the optical-path difference between the reference beam and the reflection beam from the semi-transmission grating. Furthermore, by using the beam dividing method, the angle information (θx, θY, θZ) can be measured without changing the original optical configuration.

Feasibility and performances of the proposed laser encoder have been addressed and demonstrated by using displacement and angle measurement experiments. The experimental results show that our proposed method has the ability to measure 6-DOF displacements and angles information with high system stability. The measurement resolutions of displacement and angle are about 2 nm and 0.01. Comparing with other commercial measurement instructions, this laser encoder has the advantages of high resolution, high repeatability, and high flexibility.

8819-9, Session 3

Nanomanufacturing concerns about measurements made in the SEM I: imaging and its measurement *(Invited Paper)*

Michael T. Postek, András E. Vladár, National Institute of Standards and Technology (United States)

The high resolution of the SEM is especially useful for qualitative and quantitative applications for both nanotechnology and nanomanufacturing. But, should users be concerned about the imaging and measurements made with this instrument? Perhaps one should or, at a minimum, understand some of the uncertainties associated with those measurements. It is likely that one of the first questions asked when the first scanning electron micrograph was ever taken was: "...how big is that?" The quality of that answer has improved a great deal over the past few years, especially since SEMs are being used as a primary tool on semiconductor processing lines to monitor the manufacturing processes. These needs prompted a rapid evolution of the instrument and its capabilities. Over the past 20 years or so, instrument manufacturers, through this substantial semiconductor industry investment of research and development (R&D) money, have vastly improved the performance of these instruments. All users have benefitted from this investment, especially where metrology with an SEM is concerned. But, how good are these data? This presentation will discuss a sub-set of the most important aspects and larger issues associated with imaging and metrology with the SEM. Every user should know, and understand these issues before any critical quantitative work is attempted.

8819-11, Session 3

Stability requirements for repeatable scanning probe nano-metrology *(Invited Paper)*

Ndubuisi G. Orji, Ronald G. Dixson, National Institute of Standards and Technology (United States)

The requirements necessary to obtain stable and repeatable scanning probe dimensional measurements are continually becoming more stringent. This is due to the needs of industries such as semiconductor lithography (patterned features) and chemicals (nanoparticles) where the measurands could be less than 10 nm in size. In addition to the challenging dimensions being measured, the uncertainty requirements are even smaller.

When designing highly repeatable and traceable scanning probe microscopes, it is essential to consider environmental requirements such as temperature and vibration, in addition to following accepted precision engineering principles such as symmetric design, separation of metrology and force loops, and elastic averaging. The environmental factors determine if a well-designed instrument can achieve stable and repeatable results. We present work and results on temperature, vibration, and acoustic requirements for a stable and highly repeatable atomic force microscope. The test case for our work has a temperature stability of below 5 mK over 48 hours, and a vibration reading of below 0.025 micrometers per second for $1 \leq f \leq 200$ Hz (integrated over one third octave). We also look at some of the key requirements needed to obtain repeatable probe based dimensional measurements in ambient environments.

8819-12, Session 3

Advance in dimensional measurements of nano-objects based on defocusing of the electron probe of a scanning electron microscope

Mikhail N. Filippov, N.S. Kurnakov Institute of General and Inorganic Chemistry (Russian Federation) and JSC Ctr. for Surface and Vacuum Research (Russian Federation) and Moscow Institute of Physics and Technology (Russian Federation); Valeriy Gavrilenko, JSC Ctr. for Surface and Vacuum Research (Russian Federation) and Moscow Institute of Physics and Technology (Russian Federation); Vitaliy B. Mityukhlyaev, Alexander V. Rakov, JSC Ctr. for Surface and Vacuum Research (Russian Federation); Pavel A. Todua, JSC Ctr. for Surface and Vacuum Research (Russian Federation) and Moscow Institute of Physics and Technology (Russian Federation)

Measurement of geometrical parameters of nano-objects with the help of a scanning electron microscope (SEM) is based on analysis of video-signal curves obtained when the SEM operates in the low-energy secondary electron imaging mode. The SEM video-signal curve represents a convolution of the actual profile of the nano-object and the instrumental function which depends on many parameters including the electron probe diameter. The electron probe diameter can be relatively easily varied during the experiment by means of defocusing of the electron probe. In the present paper, we study the dependence of the profile of the video-signal curves versus the electron probe diameter for various types of nano-objects including spherical nanoparticles, protrusions located on a flat surface, etc. We found out that the distance between certain points located on the video signal curve is a linear function of the diameter of the electron probe. Using such linear dependence in the limiting case when the probe diameter goes to zero, one can deduce the actual size of the nano-object.

8819-18, Session 3

NSF nanomanufacturing program and its implications for measurement and control *(Invited Paper)*

Khershed P. Cooper, National Science Foundation (United States)

The NSF Nanomanufacturing Program supports fundamental research in novel methods and techniques for batch and continuous processes, and top-down and bottom-up processes leading to the formation of complex nanostructures, nanodevices and nanosystems. The program leverages advances in the understanding of nano-scale phenomena and processes, nanomaterials discovery, novel nanostructure architectures, innovative nanodevice and nanosystem design. It seeks to address issues such as quality, efficiency, scalability, reliability, safety and affordability. The program encourages research in the development of new nano-scale processes and production systems based on computation, modeling and simulation and use of process sensing, monitoring, and control. Research in instrumentation and metrology is an integral part of the program. Additionally, the program supports education of the next generation of researchers, and encourages building a workforce trained in nanomanufacturing systems. It is also interested in understanding long-term societal implications of large-scale production and use of nano-scale materials. For this, it encourages the development of standards. This paper will describe the program philosophy.

8819-10, Session 4

Nanomanufacturing concerns about measurements made in the SEM II: specimen contamination

Michael T. Postek, András E. Vladár, Purushotham P. Kavuri, National Institute of Standards and Technology (United States)

The scanning electron microscope (SEM) has gone through a tremendous evolution to become a critical tool for many and diverse scientific and industrial applications. The improvements that have been made have significantly improved the overall SEM performance and have made

the instrument far easier to operate. But, ease of operation also fosters operator complacency. In addition, the user friendliness has reduced the "apparent" need for more thorough operator training for using of these instruments. Therefore, this overall attitude has fostered the concept that the SEM is just another expensive digital camera or another peripheral device for a computer. Hence, a person using the instrument may be lulled into thinking that all of the potential pitfalls have been eliminated and they believe everything they see on the micrograph is always correct. But, this may not be the case. The first paper in this series, discussed some of the issues related to signal generation in the SEM, instrument calibration, electron beam interactions and the need for physics-based modelling to accurately understand the actual image formation mechanisms. All these were summed together in a discussion of how these issues effect measurements made with the instrument. This second paper, discusses another major issue confronting the microscopist: specimen contamination. Over the years, NIST has done a great deal of research into the issue of sample contamination and its removal and elimination and some of this work is reviewed and discussed here.

8819-13, Session 4

Quantitative microscope characterization for sub-nm parametric uncertainties of sub-10 nm CD arrays *(Invited Paper)*

Bryan M. Barnes, Jing Qin, Martin Y. Sohn, Hui Zhou, Richard M. Silver, National Institute of Standards and Technology (United States)

We have recently reported [1] the parametric fitting, with uncertainties, of 30-line and 100-line arrays with sub-20 nm nominal critical dimensions. Although these arrays have a 60 nm nominal pitch and are measured using 450 nm light, the arrays do not fill the field of view and a continuum of high-frequency content is present in the measured images. The inherent difficulty in accurate measurement of such finite arrays is the characterization of the optical platform. Each scattered angle traverses the collection path differently, which confounds direct simulation-to-experiment fitting. In addition, the intensity at each angle of incidence may also vary, requiring characterization of the illumination path.

To enable these parametric measurements, the transmissivity of the illumination and collection paths must be known as functions of polarization and angle. The collection path tool function must be applied to each scattering order from the simulation in the Fourier domain. Upon recombination of these orders, a more faithful reproduction of the image is achieved and rigorous, quantitative fits are then performed. Techniques for tool characterization will be presented for visible and deep-ultraviolet microscopes with practical examples based on measurements of several targets.

8819-14, Session 4

Pulse-to-pulse stability analysis in a frequency-doubled, q-switched Nd:YAG rod-laser

Matheus A. Tunes, Brazilian Navy (Brazil); Cláudio Geraldo Schön, Escola Politecnica da Univ. de São Paulo (Brazil); Niklaus U. Wetter, Instituto de Pesquisas Energéticas e Nucleares (Brazil)

The Nd:YAG Laser, Q-switched and side-pumped by diode lasers, is widely studied in the scientific area since it is an excellent source of short and high-energy pulses that are attractive to many physical applications like LIBS and LIDAR systems, medical surgery, industrial applications like cutting, drilling and many others.

Although this Laser system is used in many applications because of its efficiency, small size and low cost, the experimental setup has many difficulties regarding pulse-to-pulse stability. Specifically when passively Q-switched and wavelength-doubled to 532 nm, using a non-linear crystal for second harmonic generation (KTP), this instability may greatly hamper the application of the resonator. The main reason for this amplitude jitter is the non-linear birefringence of YAG and the fact that plane-plane resonators are normally used in conjunction with high-power solid-state lasers.

A widely accepted scientific analysis of this pulse-to-pulse instability is the monitoring of the output power as a function of time in a y-t diagram, that goes either over a series of pulses or, in other cases, takes a couple of hours [1-3].

Our work shows a fast and efficient comparative methodology to estimate the degree of power stability of a Laser resonator operating in the Q-switched regime observing statistical fluctuations of the pulse area. Additionally we perform a Monte-Carlo simulation in the solution of the Q-switching rate equations that reproduces the experimental data in some aspects.

To confirm the validity of our method, we performed a characterization of a plane-parallel Nd:YAG Laser operating at 532 nm. This characterization was conducted in two parts: first without a polarization-stabilizing, quarter-wave plate, and then, with the plate. As optimization mechanism, the quarter-wave plate is a widely explored issue in scientific papers [4]. The standard deviation of the pulse area histogram with the quarter-wave plate exhibits and order of magnitude smaller jitter and this fact can be used as a stability criterion in pulsed Laser systems.

Piezoelectricity and its effect monitoring seismicity

Umesh P. Verma, BIT Sindri (India); Amitabh Sharma, M.J.K. Girls Inter College (India)

Piezoelectricity for the first time defined by Madam Curie (1880 in UK) and explained in detail by Jacuous curie in France was the generation of electricity and voltage due applied by mechanical stress on the piezoelectric material like quartz, tourmaline, zirconium, benitoite, lead, belemnite like ceramic material are sensitive to mechanical stress which are responding the stress and strain in form of generated voltage. Voltage direction depends on the polarization of the crystal and actuation stress .At temperature below Curie point, however, each crystal has tetrahedral or rhombohedra symmetric and dipole moment. The domain in the ceramic element is aligned by exposing the element to a strong direct current or electric power. the electromechanical coupling factor K and indicator of the effectiveness with which a piezoelectric material converts mechanical energy electrical energy depends on mode of vibration, shape of the ceramic material etc. Stress may be in nature geothermal energy {mantle's convective current (kogeanou2007)}, hydrostatic pressure, directed pressure in the incumbent rock (M.P.Billings), A. Holmes (1962) ,tectonic moment stored in the form of strain in the epicentres' zone of fault blocks.

Voltage or current generated corresponds to the in surged stress by the equation:

E=-(g33T) ---------------- (1) and Q=-(d33F) --------------------- (2)

Where, E=electric field,g33=piezoelectric voltage constant=stress on ceramic charge, Q=generated charge=applied force,d33=piezoelectric charge constant.

The stress strain relationship are in corporatized in dealing with the amount of voltage and direction of current generation in the piezoelectric substances that subject to predictable rupture in amount &direction and in approximation. Circuit and block diagram devised by the author in the paper explains inthe Principle and Mechanism section for decvice to be used for sensing the stress in terms of piezoelectricity developed due to impending seismic stress on situ.

8819-16, Session PWed

Study of ion beam damage in magnetic tunnel junction on FIB prepared samples

Kwangho Park, SAMSUNG Electronics Co., Ltd. (Korea, Republic of); Cheolwoong Yang, Sungkyunkwan Univ. (Korea, Republic of); Dongwoo Nam, Kyuman Hwang, Junsoo Bae, Juhyeon Ahn, Jin Choi, Samsung Electronics Co., Ltd. (Korea, Republic of); Sangsup Jeong, Hanku Cho, Samsung Electronics Co., Ltd. (Korea, Republic of)

Magnetic Random Access Memory (MRAM) has emerged as the leading candidate for future universal memory due to its non-volatility, excellent endurance and read/write performance [1]. The magnetic tunnel junction (MTJ) is a data storage element in MRAM and is basically composed of two ferromagnetic layers separated by the magnesium oxide (MgO) tunnel barrier. MgO between two ferromagnetic layers was adopted to enlarge the resistance difference between two kinds of magnetic arrangements by tunneling current through MgO. Like this, it is important to understand Characterization of MgO for developing Mram. Due to thin thickness of MgO, FIB milling should be used for the preparation of TEM specimens in Mram. The major problem in MgO sampling by FIB milling is the transform of MgO between two ferromagnetic due to FIB induced damage, which leads to high tunnel current through MgO and high resistance difference between two kinds of magnetic arrangements. An understanding of FIB generated artifact on MgO is important to analysis Mram and to optimize the sample preparation process. The normal ion beam damage are compared with low-kV FIB ion beam damage on blanket MgO wafer. Experiments were performed using Helios 450 FIB(FEI) and XV-200TBs(SII) with gallium ion sources operated at 30kV to 1kV, respectively. As a preliminary, the thicknesses of all specimens were fixed at 100nm for the final ion beam milling currents of 210pA(30kV) by Helios 450 FIB(FEI). Specimens of 100nm were transferred to low-kV FIB (Helios 450/XV-200TBs) to do the low-kV ion milling. Now each specimen has a 2kV cleaned surface and a 30kV FIB prepared surface. In this paper, we understand the normal ion beam damage on blanket MgO through changing beam current and beam voltage. Then we present the optimized recipe and which equipment is better to analysis

8819-17, Session PWed

Development of standard operating protocol for the nanoparticle size measurement and analysis by using a scanning electron microscopy

Hyuksang Kwon, Eun Ji Noh, Soo Jin Kim, Nam Woong Song, Korea Research Institute of Standards and Science (Korea, Republic of)

The multi-functional nanoparticles are promising for various applications such as biocompatible nanobio sensors and nanomedicines for diagnostics. However, the potential hazardous effects of the nanoparticles on the living bodies have been reported to be dependent on their size in some articles. It is prerequisite to provide an accurate size measurement technique for the correlation of toxicity and the size of nanoparticles as well as to prepare the size selected nanoparticles with narrow distribution. Since a scanning electron microscopy (SEM) is an easily accessible method to characterize nanostructures, we developed a standard operating protocol for the nanoparticle size measurement and analysis by using an SEM.

SEM images of more than 100 nanoparticles were analyzed using the image J 1.45s software. Smaller sizes of nanoparticles appeared with the increase of the accelerating voltage and the decrease of the filament current. The signal to noise ratio of image analysis and the image resolution were also observed with varying the accelerating voltage and the filament current. Then the size change with repeated e-beam irradiations was observed. It was noted that the e-beam irradiation for 1 min, comparable with the time required for the best alignment, makes the size increase of ca. 1 ~ 2 nm compared with the pre-irradiation condition. It means that the alignment time before the image acquisition should be minimized as short as possible under the mild imaging condition. Now, we are developing the standard operating protocols for the SEM measurement with a certified reference material to secure the traceability chain.

8820-1, Session 1

Fabrication of ambipolar gate-all-around field-effect transistors using silicon nanobridge arrays

Jin Yong Oh, M. Saif Islam, Univ. of California, Davis (United States)

In this work, we present simple methods for creating silicon nanobridge (NB) arrays with repeatability and demonstrate the fabrication of gate-all-around field-effect transistors (GAA-FETs) using NB arrays. P-type NBs of a low doping concentration were synthesized using SiH4, B2H6, HCl gases via the VLS technique directly on the arrays of silicon electrode-pairs. By depositing citrated gold colloids (diameter 200 nm, 7.0x10^8 / cm^3) with 7 % hydrofluoric (HF) acid for 2 min, NB arrays were achieved with a yield of up to 97 %. Subsequently, GAA-FETs were fabricated based on NB arrays. Regardless of the number of NB channels, GAA-FETs exhibited ambipolar transfer-characteristics that are typically observed in Schottky barrier FETs. Although effectively suppressed by a surround gate for a low drain bias of -50 mV, drain leakage current substantially increased from 0.1 pA to to 20 nA as a drain bias increases from -50 mV to -2 V. The significant increase of leakage current is attributable to reduction of the Schottky barrier width by the increase of drain bias. The unexpected ambipolar behaviors of our GAA-FETs suggest that gold impurities presumably cause Schottky barriers at the interface between NBs and silicon electrodes.

8820-2, Session 1

Nanostructured metal-insulator-semiconductor (MIS) devices for photoelectrochemical applications *(Invited Paper)*

Daniel V. Esposito, Thomas P. Moffat, National Institute of Standards and Technology (United States); A. Alec Talin, Sandia National Labs., California (United States)

Using photoelectrochemical cells (PECs) to produce H2 from the electrolysis of water is a promising approach to harvest solar energy. However, the performance of PEC devices is often limited by low conversion efficiencies or poor stability of semiconducting photoelectrodes. In order to overcome these issues, we have explored a metal-insulator-semiconductor (MIS) photoelectrode architecture that decouples the stability of a semiconductor from its ability to efficiently absorb visible light. The critical component of the MIS design is a thin (1-3 nm) oxide layer that protects the photon-harvesting semiconductor from the corrosive electrolyte while facilitating tunneling of minority carriers between the semiconductor and metallic collector structures.

In this presentation, two nano-scale modifications to Si-based MIS devices are described that lead to substantial improvement in their performance. These include the implementation of high-quality, thermally-grown oxide layers and bilayer metallic collectors. These two modifications have enabled greatly improved photoelectrode performance through control of interfacial properties and engineering of the MIS barrier heights. Central to these studies are the use of in-situ, micro-scale scanning probe techniques (scanning photocurrent microscopy and scanning electrochemical microscopy) that allow for simultaneous evaluation of optical, electronic, and catalytic properties. It is shown that knowledge gained from these techniques can be invaluable in elucidating observations made from macro-scale measurements. In the final portion of this talk, efforts to achieve further improvement in MIS photoelectrode operation through the use of 3D MIS structures will be presented.

8820-3, Session 1

Electronic effects of defects in one-dimensional channels *(Invited Paper)*

Elliot J. Fuller, Deng Pan, Brad L. Corso, O. Tolga Gul, Philip G. Collins, Univ. of California, Irvine (United States)

As electronic devices squeeze down to the one-dimensional limit, unusual device physics can result, even at room temperature. Nanoscale conductors like single-walled carbon nanotubes (SWNTs) are particularly useful tools for experimentally investigating these effects. This talk will focus on our characterization of point defects in SWNTs and their electronic consequences. A single scattering site in an otherwise ballistic SWNT can dominate two-terminal device characteristics [1] and provide the amplification to observe single electron events at room temperature. Defect contributions have been investigated using scanning probe methods [2] and exploited in single-molecule sensing experiments [3].

8820-4, Session 2

Role of materials, geometry, and process conditions in tantalum oxide memristor performance *(Invited Paper)*

Andrew J. Lohn, Patrick R. Mickel, James E. Stevens, Michael T. Brumbach, Matthew Marinella, Sandia National Labs. (United States)

Memristors, also referred to as resistive memory or ReRAM, are nanoscale circuit elements that are gaining widespread interest as possible Flash or DRAM replacements and also as passive non-linear circuit elements in analog applications such as neural networks. These two-terminal devices are able to change their resistance such that binary, multi-level cell, or analog values can be stored. In tantalum oxide based memristors, which have shown excellent performance in terms of speed, endurance and power consumption and which are currently being developed by several memory manufacturers as Flash replacement, the internal structure of the device and switching mechanism are not well understood. At Sandia, we have fabricated a large number of tantalum oxide based devices by systematically varying a wide range of parameters including electrode materials, stoichiometry, deposition system and post-growth temperatures. Extensive characterization of the subsequent materials and devices has revealed structure that we have correlated to specific performance parameters. The correlation between material properties and device performance has shed light on the impact of geometry on TaOx memristors and guided us toward a clearer understanding of their operating mechanisms. With these insights we explain the origin of the desirable features exhibited in our devices and provide a path forward toward developing devices with unique and sought-after traits.

Development of dual-gated bilayer graphene device structures *(Invited Paper)*

Stephen W. Howell, Thomas E. Beechem III, Taisuke Ohta, Khalid M. Hattar, Allister B. Hamilton, Sandia National Labs. (United States)

We will present our efforts to fabricate chip-scale Bernal-stacked bilayer graphene (BLG) device structures using an epitaxial growth process with a semi-insulating 6H-SiC substrate. Bernal stacked bilayer graphene has a bandstructure that can be modified via the application of a transverse electric field. Importantly, this field creates a bandgap having a magnitude commensurate with the field thereby providing a pathway to tunable electronics. This is unique to Bernal bilayer and is not found in monolayer graphene. To leverage this bandgap, a dual-gated (top and bottom gates) structure is needed not only to create the bandgap but also to place the Fermi level within it. Realizing such a dual-gated structure is, however, complicated in epitaxial-BLG on SiC, since there is not an appreciable oxide for the back-gate dielectric as is the case when graphene rests on silicon. Furthermore, to take full advantage of BLG's unique properties for electronic and optical applications, synthesis and fabrication techniques must be developed to produce gated BLG device structures over a large area with sufficient yield. In response, we will present methods that demonstrate: 1) chip-scale BLG synthesis on SiC(0001), 2) creation of a back-gate using ion implantation, 3) synthesis of quasi-free standing BLG on SiC(0001) after implantation, and 4) bandgap control using a dual gated structure.

Recently, we have successfully demonstrated chip-scale BLG synthesis on SiC that was of reasonable electronic quality. The as grown graphene was Bernal stacked with a mobility of 2,600-4,000 cm2/Vs (verified by low temperature magneto transport measurements and Raman Spectroscopy/Lee et al. Nanoletters (11) 3624 2011). Ion implantation of nitrogen was then utilized to create a conductive backplane buried in the SiC as verified by capacitance and current leakage measurements. We successfully synthesized quasi-freestanding BLG on SiC(0001) after implantation. The quality of this graphene film was verified using Raman spectroscopy. Finally, we have successfully fabricated back-gated BLG FETs, where the implant serves as the back-gate.

Sandia National Laboratories is a multi-program laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000. This work is supported by Sandia LDRD Program.

Growth kinetics of monolayer graphene on Pd(111) *(Invited Paper)*

Suneel Kodambaka, Univ. of California, Los Angeles (United States)

In this talk, we present in situ low energy electron microscopy (LEEM) observations and density functional theory (DFT) calculations focused on understanding the growth kinetics of monolayer graphene on single-crystalline Pd(111). In our experiments, carbon-containing Pd(111) samples were heated to temperatures around 900 oC and cooled to lower temperatures to promote surface segregation of carbon in the form of graphene. LEEM images and electron reflectivity data are acquired from the sample during graphene growth at a constant temperature as a function of incident electron energy and annealing time. We find that the area of graphene increases linearly with time. Interestingly, the work functions of graphene-free regions decrease (increase) during the growth (dissolution) of graphene. DFT calculations show that Pd work function can change due to the formation of metastable carbides and due to precipitation of C adatoms on the surface. Based upon our results, we suggest that attachment-limited kinetics govern the growth of graphene on Pd(111).

Growth and intentional doping of Si nanowires using Si-Cl-H growth chemistry *(Invited Paper)*

Joan M. Redwing, Sarah M. Eichfeld, Chito E. Kendrick, Haoting Shen, Meng-Wei Kuo, Theresa S. Mayer, The Pennsylvania State Univ. (United States)

The growth of silicon nanowires by the vapor-liquid-solid (VLS) method is of significant fundamental interest driven by practical applications in nanoelectronics, sensing and energy harvesting. The use of silicon tetrachloride (SiCl4) in combination with gold-catalyzed VLS has long been employed for the synthesis of Si whiskers and more recently for Si nano/microwire growth. The high temperatures (~1000oC) required for growth with SiCl4 combined with the Cl-based chemistry are advantageous for producing epitaxial Si wire arrays. Our studies have focused on investigating the mechanisms of Si nanowire growth with SiCl4 and the incorporation of intentional dopants. This work has revealed that the growth rate of Si nanowires with SiCl4 is controlled by gas phase chemistry and transport of reactant species to the growth surface under atmospheric pressure conditions. Si nanowires grown by VLS typically exhibit a <111> or <112> growth direction, however, Si nanowires with a <110> growth direction can be obtained with SiCl4 under conditions which promote stable {111} sidewall facets. Intentional boron doping of the Si nanowires using trimethylboron was also examined in order to investigate the mechanism of dopant incorporation in the wires. Multi-point resistance measurements carried out on single nanowires demonstrate uniform resistivity along the axial and radial directions of the nanowire. The results indicate that the primary route to dopant incorporation occurs via the liquid catalyst with negligible vapor-solid deposition and diffusion of dopants through the sidewalls of the nanowire.

Plasma-enhanced atomic layer deposition of aluminum oxide coating for photo emission wavelength tuning of indium phosphide nanowires

David M. Fryauf, Univ. of California, Santa Cruz (United States) and NASA Ames Research Ctr. (United States); Andrew J. Lohn, Sandia National Labs. (United States); Byung Joon Choi, Steven J. Barcelo, Hewlett-Packard Labs. (United States); Kate J. Norris, Junce Zhang, Nobuhiko P. Kobayashi, Univ. of California, Santa Cruz (United States) and NASA Ames Research Ctr. (United States)

Semiconductor-oxide nanostructure (SON) devices can be a very intriguing material platform if optoelectronic properties of the original semiconductor nanostructures can be tuned by explicitly controlling properties of the oxide coating. This paper describes our finding that optical properties of semiconductor nanowires can be tuned

by depositing a thin layer of metal oxide. In this experiment, indium phosphide (InP) nanowires were grown by low-pressure metal organic chemical vapor deposition on silicon substrates with gold catalyst. InP nanowires formed three-dimensional nanowire networks from which collective optical properties were obtained. The InP nanowire network was coated with an aluminum oxide (AlOx) thin film deposited by plasma-enhanced atomic layer deposition (PEALD) using trimethylaluminum (TMA) as a metal precursor and oxygen (O2) as an oxidant gas activated by remote plasma. We focus on how several key optical characteristics of the InP nanowire network, such as peak wavelength of photoluminescence spectra, change as physical properties, for instance thickness, of the AlOx coating vary. We observed continuous blue shift in photoluminescence spectra when the thickness of the AlOx coating was increased. Possible causes for the blue shift include quantum confinement associated with the AlOx coating that contains fixed charges and confines photo generated electron-hole pairs within an area smaller than the Bohr radius in InP. Temperature dependence of PEALD AlOx coating density and carbon impurity level was also studied. Samples were further characterized by scanning electron microscopy, x-ray diffractometry, and energy dispersive x-ray spectroscopy in an attempt to explain the physical mechanisms for the blue shift.

Size-controlled InAs quantum nanostructures in InP nanowire grown via the Au-free vapor-liquid-solid mode *(Invited Paper)*

Guoqiang Zhang, Danang Birowosuto, Nippon Telegraph and Telephone Corp. (Japan); Kouta Tateno, Hideki Gotoh, Tetsuomi Sogawa, NTT Basic Research Labs. (Japan)

We report on the first in-situ tuning of the InP/InAs hetero-nanowire (NW) diameter. The tuning ability enables us to freely engineer the size of the InAs segment in InP nanowire by varying the thickness and the diameter. Thus we could tune the bandgap in a wide range including the telecommunication window.

Semiconductor nanowires (NWs) have been expected as the next-generation build blocks in optoelectronics and electronics. The vapor-liquid-solid (VLS) mode has been widely used for the growth of the NWs due to its high controllability. The self-assisted VLS mode has been developed to avoid the incorporation of foreign catalyst materials like Au. InP NWs have been grown by the In-particle-assisted VLS mode. It has been found out that the In particle size at the tip could be increased or decreased during growth by modifying the III source flow rate [G. Zhang, et al: Appl. Phys. Exp. 5 (2012) 055201.]. This provides a new way to tune the NW diameter during the growth, a new controllable dimension in the NW synthesis.

The InP/InAs hetero-NWs were grown via the self-assisted vapor-liquid-solid (VLS) growth mode. We tuned the size of the In particle at the NW tip by modulating the In source flow rate, and then the NW diameter also changed during the growth. When the flow rate of TMIn is decreased, the In particle size decreases with growing because the supply of the In source becomes insufficient. This enables us to freely engineer the size of InAs segment in InP NW. Consequently, by studying the photoluminescence of the InAs segment in individual NWs at 4K, we could tune the bandgap in a wide range including the telecommunication window (1.3μm - 1.5μm).

Improvement in efficiency droop of GaN-based LEDs by optimization of active regions *(Invited Paper)*

Hao-Chung Kuo, Da-Wei Lin, Shih-Pang Chang, B. C. Lin, Chien-Chung Lin, Gou-Chung Chi, National Chiao Tung Univ. (Taiwan)

GaN-based light-emitting-diodes (LEDs) have been developed in various applications due to its widely tunable wavelength from ultraviolet to blue/green. Nevertheless, the most expected application, solid-state lighting, is still developing. Although the light-extraction efficiency has been significantly improved by different techniques, the internal quantum efficiency (IQE) still suffers a major obstacle. This efficiency droop behavior strongly limits the development of many specific applications which require the operation current of the InGaN/GaN LEDs under high injection levels.

Carrier overflow out of the active region as well as inefficient injection and transportation of holes have been identified to be the major reasons of efficiency droop. Conventional GaN-based c-plane quantum wells suffer from the quantum-confined Stark effect (QCSE) and electron overflow as a result of a spontaneous and piezoelectric polarization field parallel to the [0001] direction. On the other hand, the low hole mobility causes their feebleness in transportation along active region, such as insufficient transportation across the electron blocking layer (EBL) and accumulation of holes at the quantum wells near p-GaN.

In this paper, we first introduce the physical mechanisms of efficiency droop in GaN-based LEDs and its origin. Then we propose several methods to reduce this effect, such as alternative substrates, semi-polar (1-101) MQWs, low temperature insertion layer between n-GaN and MQWs, graded-thickness MQWs (GQWs), and graded-composition EBL (GEBLs). The results show that by reducing the polarization field in MQWS, enhancing hole transportation in MQWs, and enhancing hole injection across EBL, the efficiency droop behavior could be successfully reduced.

Guest adsorbate induced switching of electrical conduction in a metal-organic framework

A. Alec Talin, Sandia National Labs. (United States); Andrea Centrone, Paul M. Haney, National Institute of Standards and Technology (United States); Vitalie Savila, Michael E. Foster, Sandia National Labs., California (United States); Robert A. Kinney, Veronika A. Szalai, Heayoung Yoon, Dmitry Ruzmetov, National Institute of Standards and Technology (United States); Mark Allendorf, Sandia National Labs., California (United States)

Metal-organic frameworks (MOFs) are extended, crystalline compounds consisting of metal ions interconnected by organic ligands and characterized by permanent porosity that makes these materials highly attractive for gas storage, separations, and many other related applications. Electrically conducting or semiconducting MOFs would present a whole new class of electronic materials, with combined advantages of traditional inorganic semiconductors (crystallinity, relative thermal stability, and demonstrated epitaxial growth) with those of molecular electronics (low cost synthesis and control of electronic structure through chemistry). However, the largely ionic character of the ligand- to- metal center bonding and the lack of long-range delocalized orbitals render most MOFs electrical insulators. We describe a new approach wherein insertion of guest molecular specie (7,7,8,8-tetracyanoquinododimethane) that strongly interacts with the framework (Cu3BTC2) switches the MOF conductivity from insulating to Ohmic, while preserving its crystal structure. This method exploits the MOF structure as an active template and potentially allows conductivity to be tuned by modulating the MOF-guest's interactions with the MOF building blocks.

Ultrasensitive biomolecular assays with amplifying nanowire FET biosensors *(Invited Paper)*

Chi On Chui, Univ. of California, Los Angeles (United States)

In this talk, we will review our recent development and validation of the ultrasensitive electronic biomolecular assays enabled by our novel amplifying nanowire field-effect transistor (nwFET) biosensors. Our semiconductor nwFET biosensor platform technology performs low parasitics signal amplification in the electrical domain that requires neither labeling, enzymes, nor optics. We have designed and fabricated the biomolecular assay prototypes as well as the corresponding analytical procedures. We have also validated the assays' analytical performance in detecting key protein biomarkers in buffer and serum, and compared the results against the state-of-the-art nwFET bioassays.

Using tobacco mosaic virus template for the fabrication of three-dimensional hierarchical microbattery electrodes with high energy and high power density *(Invited Paper)*

Ekaterina Pomerantseva, Konstantinos Gerasopoulos, Markus Gnerlich, Philipp Odenwald, James Culver, Reza Ghodssi, Univ. of Maryland, College Park (United States)

We present a novel approach for the fabrication of lithium-ion microbattery electrodes which deliver high energy and high power density. The key enabling technology is the use of self-assembled Tobacco mosaic virus (TMV) nanoforests as a template for active battery materials. The self-assembling TMV is a genetically modified biological nanorod with increased chemical binding properties for enhanced manufacturability. High energy density is achieved due to the active surface area increase within a given footprint by combining TMV with three-dimensional (3D) microfabrication processes. The TMV nanostructure enables high power density through larger electrode/electrolyte contact area and faster charge transport.

The electrodes consist of an array of electroplated gold micropillars with an aspect ratio of three (60 µm high, 20 µm in diameter). The pillars are coated with the self-assembled nanoscale TMV template and subsequently metalized in-place. Active battery material (V2O5) is conformally deposited using atomic layer deposition (ALD) on the hierarchical micro/nano network. Electrochemical testing of these electrodes indicates a 3-fold increase in energy density, compared to the TMV-templated electrodes without micropillars, without increasing footprint area or reducing rate performance. Further increase in energy density can be achieved by increasing surface area of 3D microelements as demonstrated by fabrication and electrochemical testing of the electrodes with hollow gold micropillars. Scaling up energy density by increasing active material thickness beyond 100 nm revealed some loss in surface area which highlighted the importance of nanoscale engineering for achieving maximum energy and power density in energy storage systems.

Difference in formation of ferromagnetic MnAs nanoclusters on III-V semiconducting nanowire templates *(Invited Paper)*

Shinjiro Hara, Hiromu Fujimagari, Shinya Sakita, Masatoshi Yatago, Hokkaido Univ. (Japan)

Recent activities for semiconducting nanowires have gained much attention in the potential application to future electronic and photonic devices. However, there are less numbers of the reports of magneto nano-electronic, or spintronic, device applications, such as magnetic sensors and spin-polarized light-emitting diodes, utilizing vertical free-standing nanowires. The authors have realized many varieties of nanowires, e.g. GaAs, InP, and InAs nanowires, and GaAs/AlGaAs and GaAs/GaAsP core-shell ones, by catalyst-free selective-area metal-organic vapor phase epitaxy (SA-MOVPE) on partially SiO2-masked wafers of GaAs(111)B, Si(111), etc. We report here on the differences in ferromagnetic MnAs nanocluster formation on GaAs, GaAs/GaAsP, and InAs nanowire templates by SA-MOVPE, because there is not much information on dependence of the nanocluster formation on materials of the nanowire templates. GaAs and GaAs/GaAsP nanowires were grown at 750C, while InAs nanowires were grown at 580C. MnAs nanoclusters are formed commonly at six ridges between two {0-11} crystal facets on hexagonal prisms of III-V semiconducting nanowires presumably because many atomic steps exist between the crystal facets. Here, MnAs nanoclusters were grown "into" the nanowires, as a result of the phenomenon of endotaxy, because manganese source and hydrogen were supplied, i.e. no arsenic source supply. In the case of GaAs/GaAsP and InAs nanowires, however, MnAs nanoclusters were formed on the top {111}B surfaces of the nanowires, as well as at six ridges of the hexagonal prisms. The results obtained here possibly show that the

endotaxy of MnAs depends on the strength of atomic bonds in the host materials of nanowires.

Moisture barrier and chemical corrosion protection of silver-based telescope mirrors using aluminum oxide films by plasma-enhanced atomic layer deposition

David M. Fryauf, Univ. of California, Santa Cruz (United States) and NECTAR (United States); Andrew C. Phillips, Univ. of California (United States); Junce Zhang, Kate J. Norris, Nobuhiko P. Kobayashi, Univ. of California, Santa Cruz (United States) and NASA Ames Research Ctr. (United States)

An urgent demand remains in astronomy for high-reflectivity silver mirrors that can withstand years of exposure in observatory environments. The University of California Observatories Astronomical Coatings Lab has undertaken development of protected silver coatings suitable for telescope mirrors that maintain high reflectivity at wavelengths above 340 nm and into the mid-infrared spectrum. We present initial results of an experiment showing that plasma-enhanced atomic layer deposition (PEALD) can produce superior protective layers of transparent dielectrics.

Several novel coating recipes have been developed with ion-assisted electron beam deposition (IAEBD) of materials including yttrium fluoride, and oxides of yttrium, hafnium, titanium and tantalum. Samples of these mirror coatings were covered with conformal layers of aluminum oxide (AlOx) deposited by PEALD using trimethylaluminum as a metal precursor and oxygen as an oxidant gas activated by remote plasma. Samples of coating recipes with and without PEALD oxide undergo aggressive environmental testing, including high temperature/high humidity (HTHH), hydrogen sulfide (H2S) exposure, and abrasion/adhesion resistance. Samples were exposed to an environment of 80% humidity at 80°C for ten days in a simple test set-up, and tarnishing endurance was tested by exposure to H2S concentrations of 10-20 ppm for several days. H2S exposure and HTHH testing show visible results confirming that the PEALD oxide offers enhanced robust protection against chemical corrosion and moisture from an accelerated aging environment. Mirror samples are further characterized by reflectivity/absorption, ellipsometry, atomic force microscopy, and X-ray diffractometry before and after deposition of oxide coatings. AlOx is suitable for many applications and has been the initial material choice for this study. We are planning further experiment with other materials, particularly tantalum and titanium oxides, and silicon nitride.

8820-34, Session 10

Optical filters and antireflection coatings for high performance detectors *(Invited Paper)*

April D. Jewell, John Hennessy, Jet Propulsion Lab. (United States); Erika T. Hamden, Columbia Univ. (United States); Timothy M. Goodsall, Todd J. Jones, Alexander G. Carver, Michael E. Hoenk, Shouleh Nikzad, Jet Propulsion Lab. (United States)

Here we describe the development of optical coatings for silicon-based detectors for astronomy, planetary and terrestrial applications. At the Jet Propulsion Laboratory, thin-film optical filters are incorporated with existing detector technologies. We have used atomic layer deposition (ALD) to grow filters on silicon substrates. ALD is a technique whereby thin films are grown a monolayer at a time through a series of self-limiting chemical reactions at a substrate surface; thus, ALD offers nanometer-scale control over film thickness. We have characterized the nucleation and growth behavior of a variety of ALD films with materials characterization techniques such as spectroscopic ellipsometry and transmission electron microscopy as well as examined the interfacial chemistry of stacked layers. Based on this work we are able to achieve precision growth of multilayer films and provide tailored, repeatable performance targeted for specific applications. The behavior of these films matches that predicted by model-based designs of multilayer bandpass filters. A five layer film structure optimized to maximize transmission over a narrow band centered at 200 nm was deposited onto live CCDs. Quantum efficiency (QE) measurements match modeled film behavior remarkably well, showing improved performance at the target wavelength of 200 nm. Also under development are ALD coatings to enhance QE for a variety of spectral ranges. Broadband targets include 100-300 nm, 300-1000 nm, and 200-1000 nm; while narrower band benchmarks focus on improved QE for 100-200 nm, 200-235nm and 240-300 nm. The work described marks a significant advancement in detector technology and capability.

8820-35, Session 10

Surface modification of the PEALD Al2O3/GaSb interface for enhanced electrical performance *(Invited Paper)*

Erin R. Cleveland, Laura Ruppalt, Brian K. Bennett, Sharka M. Prokes, U.S. Naval Research Lab. (United States)

The integration of high-k dielectrics with high moblility III-V semiconductor materials is attracting widespread attention as an alternative to Si-based complementary-metal-oxide-semiconductor (CMOS) applications. Among the III-V's, GaSb is a promising as the channel material in high speed, low power metal-oxide-semiconductor-field-effect-transistors (MOSFETs) due to its high electron and hole mobilities, as well as a relatively narrow badgap. However, poor quality of the gate-oxide/GaSb interface has limited its use in microelectronics. A significant effort has been focused on surface preparations prior to ALD that removes the native oxide in order to ensure the best possible interface. Current approaches typically rely upon wet-chemical etches; however, this technique typically suffers from a lack of reproducibility, as well as potential contamination. Recently, we demonstrated the use of hydrogen plasma prior to plasma-enhanced-atomic-layer-deposition (PEALD) of Al2O3 on GaSb. Samples demonstrating good electrical characteristics correlated to elimination of Sb-oxide, decrease in elemental Sb, and increase in Ga2O3. Therefore, we compared the effectiveness of wet and dry surface treatments for improving the electrical properties of the PEALD Al2O3/GaSb interface. We evaluated the effectiveness of TMA as a standalone process to remove the native oxides from GaSb substrates that have undergone no additional wet chemical treatment and those dipped in HCl prior to TMA exposure. Furthermore, we investigated the use of hydrogen plasma prior to PEALD as a means to produce a suitable electrical interface. XPS and TEM were used to characterize composition and structure, while C-V measurements

were performed to evaluate the electrical integrity of the resulting surfaces.

8820-36, Session 10

Different intermixing regimes of metal-oxide and metal-sulfide multilayers synthesized by atomic layer deposition *(Invited Paper)*

Sergey V Baryshev, Argonne National Lab. (United States) and Euclid TechLabs, LLC (United States); Elijah Thimsen, Univ. of Minnesota (United States); Shannon C. Riha, Alex B. F. Martinson, Alexander V. Zinovev, Igor V. Veryovkin, Michael J. Pellin, Jeffrey W. Elam, Argonne National Lab. (United States)

Historically, the atomic layer deposition (ALD) community has focused intently on metal-oxides (MOs). It is known that multilayer MO films synthesized by ALD have morphology where discrete layers are separated by sharp boundaries within designated deposition regions – nanolaminate morphology. Solid-state diffusion at the deposition temperature is very low for these materials. The sharpness of interfaces in multilayer metal-sulfide (MS) thin films synthesized by ALD is virtually unexplored.

Comparison of MO nanolaminate MgO/ZnO and MS multilayer ZnS/SnS2/Cu2S, both synthesized by ALD, will be presented. Comparison is based on a newly proposed mixing number Mx, which is the diffusion distance of mobile atomic species during layer deposition divided by the layer thickness in which the mobile species is diffusing. Mx numbers were calculated from composition profiles measured by dual beam secondary ion mass spectrometry (SIMS) with ½ nm depth resolution. SIMS results confirmed that MO multilayer was in nanolaminate regime with Mx<<1, while MS multilayer was extensively premixed with Mx≈1 and >>1. This indicates that MS multilayer thin films are in an entirely different regime than MOs.

Since ultrathin multilayer ZnS/SnS2/Cu2S is of high interest due to its relevance for forming the photovoltaic alloy Cu2ZnSnS4 upon annealing, better understanding of solid-state transport in ALD could benefit for nanostructured photovoltaics/photocatalysis. Therefore, results of extended SIMS analysis will be reported. Most importantly, it was confirmed that mixing of the metal-sulfide binaries into Cu2ZnSnS4 obeys the predicted solid state reaction mechanism Cu2S+SnS2+ZnS 0Cu2SnS3+ZnS Cu2ZnSnS4 where the second step limits the overall reaction rate at low temperatures.

Single-polycrystalline core-shell silicon nanowires grown on copper

Kate J. Norris, Junce Zhang, David M. Fryauf, Univ. of California, Santa Cruz (United States) and NECTAR (United States); Elane Coleman, Gary S. Tompa, Structured Materials Industries, Inc. (United States); Nobuhiko P. Kobayashi, Univ. of California, Santa Cruz (United States) and NECTAR (United States)

The growth of silicon core-shell nanowires with a crystalline core and a polycrystalline shell on copper substrates pretreated with carbon via Plasma Enhanced Chemical Vapor Deposition (PECVD) was demonstrated. By altering the copper surface with carbon treatment and using gold colloids, highly dense silicon nanowire networks can be grown on copper substrates. Scanning electron microscopy (SEM), energy dispersive x-ray spectroscopy (EDX), x-ray diffraction (XRD), Raman spectroscopy, and transmission electron microscopy (TEM) were performed to characterize the nanowires. TEM showed that the core of the nanowires is single crystalline while the shell surrounding the single crystalline core is polycrystalline (single-polycrystalline core-shell nanowires). The nanowires have diameters ranging from 120 to 250nm including their crystalline cores which appeared to range from ~10-20nm. These crystalline cores appear to follow the length of the nanowires without expanding or narrowing. The diameter of the polycrystalline shell surrounding the core also remains consistent. Possible growth mechanisms that induce the spontaneous growth of single-polycrystalline core-shell silicon nanowires are discussed based on the structural analysis. There are several possible benefits obtained from this unique nanowire structure. For example, the single-polycrystalline core-shell nanowires with their large diameters allow for easier methods of electrical/thermal contact while maintaining the benefits of small diameter nanowires with their single-crystalline cores. The single-polycrystalline core-shell nanowires are assessed with the view toward a thermoelectric material with the concept that the small diameter single-crystal core could allow for efficient transport of charge carriers while the polycrystalline shell could effectively backscatter phonons.

8821-1, Session 1

A fiber luminescent solar concentrator with 5.7% optical conversion efficiency *(Invited Paper)*

Esmaeil-Hooman Banaei, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States) and Univ. of Central Florida (United States); Ayman F. Abouraddy, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

Conventional Luminescent Solar Concentrators (LSC's) are slab waveguides coated or doped with luminescence materials for absorption and guiding of light to the slab edges for conversion to electricity by attached PV cells. LSC's are a promising alternative for reducing the cost of solar power. Exploiting the advantages of optical fiber production, we present here a Fiber LSC (F-LSC) in which the waveguide is a polymer optical fiber. We propose a hybrid fiber structure for an efficient two-stage concentration of incident light into a small doped core and eventually to the fiber ends. Flexible sheets are assembled with fibers that can be bundled and attached to small-area PV cells. Fiber dimensions and directional guiding allow for geometrical gain improvement over that of existing LSC's. In addition, the undesired limit of LSC size is eliminated in one direction.

We present modeling and optimization of an F-LSC design using polarization ray tracing under realistic conditions with solar spectrum radiation and broad-band absorption and emission spectra with their inevitable self-absorption effect.

We also present the results of fabrication and optical characterization of such F-LSC using two off-the-shelf organic dyes and a commercially available polymer, COP. Fiber preforms, fabricated under optimized conditions for low light transport loss, are thermally drawn into sub-millimeter-size fibers. Characterization of several samples with various concentrations of the two dyes shows an optical conversion efficiency of 5.7% for a tandem combination of two fibers 2.5-cm long with the efficiency gradually decreasing to 3.1% with increase in fiber length to 10 cm.

8821-2, Session 1

Monte Carlo simulations of luminescent solar concentrators for building integrated photovoltaics

Shin Woei Leow, Carley Corrado, Melissa Osborn, Sue A. Carter, Univ. of California, Santa Cruz (United States)

Luminescent solar concentrators (LSCs) have the ability to receive light from a wide range of angles and concentrate the captured light on to small photo active areas. This enables LSCs to be integrated more extensively into buildings as windows and wall claddings on top of roof installations. LSCs with front facing PV cells collect both direct and concentrated light ensuring a gain factor greater than one. It also allows for flexibility in determining the placement and percentage coverage of PV cells when designing panels to balance reabsorption losses, power output and the level of concentration desired. A Monte-Carlo ray tracing program was developed to study the transport of photons and loss mechanisms in LSC panels and aid in design optimization. The program imports measured absorption/emission spectra and transmission coefficients as simulation parameters with interactions of photons in the panel determined by comparing calculated probabilities with random number generators. LSC panels with multiple dyes or layers can be simulated. Results of a thin single dye system optically coupled to a clear waveguide closely parallels measured data and reveals optimal panel dimensions and PV cell layouts for maximum power output.

8821-4, Session 1

Experimenal validation of ray-tracing/Monte-Carlo simulations for LSC-devices based on fluorophores with variable self-absorption

Zachar Krumer, Wilfried G. J. H. M. van Sark, Celso Mello Donegá, Ruud E. I. Schropp, Utrecht Univ. (Netherlands)

Luminescent solar concentrators (LSCs) are low cost photovoltaic devices, which reduce the amount of necessary semiconductor material per unit area of a photovoltaic solar energy converter by means of concentration. The device is comprised of a thin plastic plate in which luminescent species (fluorophores) have been incorporated. The fluorophores absorb the solar light and radia¬tively re-emit part of the energy. Total internal reflection traps most of the emitted light inside the plate and wave-guides it to a narrow side facet with a solar cell attached, where conversion into electricity occurs. The efficiency of such devices is as yet rather low, due to several loss mecha¬nisms, of which self-absorption is of high importance.

Combined ray-tracing and Monte-Carlo simulations is a widely used tool for efficiency estimations of LSC-devices prior to manufacturing. We have applied this method to a model experiment, in which we analysed the impact of self-absorption onto LSC-efficiency of fluorophores with different absorption/emission-spectral overlap, i.e., Stokes' shift.

We have also validated the model experiment and compared experimental with simulation results. We experimentally found that LSCs with type-II semiconductor nanocrystals as fluorophores are the least affected by self-absorption, while single compound semiconductor nanocrystals are affected the most. Simulations confirm this result. The suitability of the model for variable self-absorption effects has been assessed.

8821-5, Session 2

Holographic spectrum splitting in eight-junction, ultra-high efficiency photovoltaic module *(Invited Paper)*

Sunita Darbe, Matthew D. Escarra, Emily C. Warmann, Harry A. Atwater Jr., California Institute of Technology (United States)

To achieve photovoltaic solar energy conversion with greater than 50% module efficiency, the number of semiconductor junctions must be increased beyond the 3-5 used in conventional lattice-matched multi-junction photovoltaics. In this work, we demonstrate a photovoltaic module design that incorporates eight III-V semiconductor junctions arranged laterally as four dual-junction subcells operating electrically and optically in parallel. These eight bandgaps span the entire solar spectrum, and the corresponding alloys can be grown lattice-matched to GaAs and InP substrates. A compound holographic optical element splits the incoming solar spectrum into four spectral slices, each diffracted onto the appropriate tandem subcell. This compound element consists of a 4x3 array of volume holographic gratings, with grating parameters optimized using an algorithm based on generalized coupled wave analysis.

Concentration is shown to be essential to achieving 50% module efficiency with this geometry. Thus, a two-stage trough compound parabolic concentrator is incorporated into the design to achieve concentration of >100 suns. This concentration occurs after the spectrum is split to avoid negatively impacting the performance of the holographic optics. To accurately model the performance of this module, subcell performance is derated from detailed balance ideals by incorporating average external radiative efficiency of 0.3% and Jsc that is 90% of its ideal value. Additional realistic optical and electrical losses are included. A preliminary design achieves spectrum splitting with

75% optical efficiency, resulting in a two-terminal module efficiency of 35.1%. Considerable design space remains to be explored in this module geometry, with potential to reach 50% module efficiency.

8821-6, Session 2

Grating-over-lens CPV spectrum splitting systems with volume holographic optical elements

Juan M. Russo, Deming Zhang, The Univ. of Arizona (United States); Michael Gordon, College of Optical Sciences, The Univ. of Arizona (United States); Shelby D. Vorndran, Youchen Wu, Raymond K. Kostuk, The Univ. of Arizona (United States)

In previously described grating-over-lens spectrum splitting designs, a planar transmission grating is placed at the entrance of a plano-convex lens. A spectral range is diffracted at 15-30° from normal incidence and into the lens. The diffracted spectral range comes to a focus at an off-axis point and the undiffracted spectrum comes to a focus at the paraxial focal point. Since the diffracted wave is planar and off-axis, the off-axis focal points suffer from aberrations that increase the losses of the system. Field curvature, chromatic and spherical aberrations are compensated using defocusing and a curved focal plane (approximated with each photovoltaic receiver). Coma is corrected modifying the off-axis wavefront itself. In this paper, we analyze the use of non-planar transmission gratings recorded using a conjugate geometry (opposite propagation direction from operation) to modify the off-axis wavefront. Diverging sources are used as conjugate object and reference beams respectively. The spherical waves are incident at the lens and the grating is recorded at the entrance aperture of the solar concentrator. The on-axis source is adjusted to produce an on-axis planar wavefront on the hologram plane. The off-axis source is approximated to a diffraction limited spot producing a non-planar off-axis wavefront on the hologram plane. Illumination with a planar AM1.5 spectrum reproduces an off-axis diffraction-limited spot on the focal plane. This paper presents ray trace and coupled wave theory simulations used to quantify the reduction in losses achieved with aberration correction. Also, we present a design for a solar simulator based on this geometry.

8821-7, Session 2

Limitations of multiplexed volume holograms as broadband dispersive elements for solar concentrators

Gregory B. Ingersoll, Di Lin, James R. Leger, Univ. of Minnesota, Twin Cities (United States)

Using diverse bandgap photovoltaic cells can improve solar conversion efficiency, but these systems also require efficient dispersive optics to direct portions of the solar spectrum onto the appropriate optimized cells.

One advantageous technique for spectrum spitting employs transmission-mode volume holograms. These grating structures can be made highly efficient but are often also highly selective, interacting only with narrow wavelength bands and narrow ranges of incidence angles. To widen the bandwidth for a solar concentration application, planar volume gratings can be multiplexed in a single HOE. But this technique has its limits.

In this work we use an extended coupled-mode model to show how multiplexed gratings interact with one another leading to reduced efficiency in the diffraction orders of interest as well as increased stray light in certain conditions. This technique reveals effects that cannot be seen through superposition of single grating models, which suggests that multiplexed gratings must be treated simultaneously when designing such a system.

Further, these inter-grating interference effects are demonstrated experimentally in dichromated gelatin. Multiplexed gratings are constructed in the lab, and grating diffraction efficiencies are measured at multiple laser wavelengths suggesting the expected results when applying these techniques to a continuous spectrum. Measurements are compared with theory, and the mathematical model is extended to simultaneously treat spurious reflection gratings from the construction process as well as harmonic effects that can arise as a result of the limited dynamic range of the recording medium.

8821-8, Session 3

Single element point focus spectral splitting concentrator with CIGS multiple bandgap solar cells

Marco Stefancich, Ahmed Zayan, Matteo Chiesa, Masdar Institute of Science & Technology (United Arab Emirates); Stefano Rampino, Istituto dei Materiali per l'Elettronica ed il Magnetismo (Italy); Carlo Maragliano, Masdar Institute of Science & Technology (United Arab Emirates)

The combination of optical concentration, spatial spectral splitting and the use of multiple cells of suitable bandgap, allows to achieve extreme PV conversion efficiency [1] and high concentration modules have been designed employing separate elements for concentration and splitting [2].

We recently demonstrated a proof of concept approach where a single low cost refractive optical element is employed [3] for simultaneous splitting of sunlight and linear concentration at moderate levels.

We propose here point focus higher concentration version of spectral splitting/concentrating element coupled with multiple inexpensively developed Cu(InxGa1-x)Se2 solar cells designed for concentration [4]. The cells absorbers are developed in a single step by Pulsed Electron Deposition method [5] and different bandgaps are achieved by suitable In-Ga balancing. The concentrator is obtained by injection molding and can be mass produced at low cost.

This approach hints to the possibility of developing a low cost framework for high efficiency spectral splitting photovoltaics systems.

Theoretical framework, simulations and preliminary experimental results will be discussed.

8821-9, Session 3

Spectrum splitting photovoltaics: light trapping filtered concentrator for ultrahigh photovoltaic efficiency

Emily D. Kosten, John Lloyd, Emily C. Warmann, Harry A. Atwater Jr., California Institute of Technology (United States)

While monolithic multijunction solar cell approaches have been quite successful, current and lattice matching requirements limit the maximum possible achievable efficiencies. Spectrum splitting, where light is optically distributed among subcells with differing bandgaps,

avoids these constraints and offers a route to achieving higher efficiencies (>50%). We investigate a spectrum splitting approach where concentrated sunlight is trapped in a textured dielectric slab and then selectively coupled into underlying solar cells of different bandgaps through omnidirectional filters. We develop a multipass optical model to find regimes of high optical efficiency based on parameters such as slab refractive index, number of subcells, and angle restriction of light escape from the slab. Based on these results and filter design considerations, we describe a specific design featuring an SiO_2 textured slab coated with angle restricting incoupling elements based on compound parabolic concentrators and two underlying triple junction solar cells, one with bangaps from 1.32 to 2.1 eV and the other with bandgaps from 0.71 to 1.12eV . Using the multipass model in conjunction with modified detailed balance calculations, we find module efficiencies exceeding 50% are possible with an acceptance angle restricted to 20° or less and concentrations of a few hundred suns. Finally as proof of concept, we demonstrate a nearly omnidirectional filter design for use underneath the SiO_2 slab. Based on alternating layers of TiO_2 and SiO_2, we achieve angle averaged reflectivity greater than 90% within the reflection band and angle averaged transmission of approximately 90% within the transmission band.

8821-10, Session 3

Concentrating and spectrum splitting optical device in high efficiency CPV module with five bandgaps

Jerker Y. Taudien, Ludwig A. Kern IV, Vertex Solar (United States)

There is a need for a high efficiency low cost solar energy conversion system. Currently, most concentrating photovoltaic (CPV) systems concentrate the solar spectrum onto triple junction cells to strive for high conversion efficiencies and low cost. Other approaches to high efficiency use spectrum splitting. Triple junction systems are limited in efficiency and spectrum splitting systems are usually too costly for mass production. The objective is to design a spectrum splitting solar concentrator, using reverse ray tracing methods, to overcome the efficiency and cost limitations of current systems by using a single low cost optical device to concentrate and split the solar spectrum onto a large number of target photovoltaic (PV) cells. Dispersive properties of standard optical materials, such as glass or plastic, are utilized to achieve the desired spectral separation. Reverse ray tracing is used to simultaneously optimize the shape of the top and bottom interfaces of the solar concentrator to achieve the desired split spectrum at the target PV cells. Additional strategies to increase system efficiency and minimize optical losses, including draft surface shading and corner rounding losses, are explored. A CPV module, including the spectrum splitting solar concentrator and five PV cells of different bandgaps, is proposed. This spectrum splitting CPV system has a calculated aggregate cell conversion efficiency that exceeds 45%, has the potential to be mass produced, and meets the need for a high efficiency low cost solar energy conversion system.

8821-11, Session 3

Polyhedral specular reflector design for ultra high spectrum splitting solar module efficiencies (>50%)

Carissa N. Eisler, Emily D. Kosten, Emily C. Warmann, Harry A. Atwater Jr., California Institute of Technology (United States)

One pathway to achieving ultra high solar efficiencies (>50%) is employing a spectrum splitting optical element with more junctions (>6) and some concentration (100-500 suns). We propose a design to obtain these efficiencies, employing basic specular reflection to split and divide the light onto appropriate subcells. The polyhedral specular reflector incorporates a high index parallelepiped with seven subcells. The subcells are placed around the parallelepiped such that light entering at normal incidence encounters the subcells in order from highest to lowest bandgap, with the ray path reflecting at a 90° angle until the light is fully absorbed.

Using detailed balance calculations that account for realistic cell performances, we find that concentration is necessary for >50% module efficiency. However, concentration increases the range of input angles, causing the misallocation of photons. These optical losses can be mitigated by using a higher index parallelepiped, such as TiO_2 or GaP, as refraction reduces the angular spread of light. For example, for the same optical losses, more than twice the concentration can be accommodated for a parallelepiped made of GaP than of glass. We analyze these losses and optimize the design using modified compound parabolic concentrators. We find that moderate concentration designs (90-170x) achieve 50% module efficiency, with GaP achieving the maximum efficiency at 53%. However, some junctions may parasitically absorb light not intended for that junction, reducing overall efficiency. We quantify these losses and demonstrate initial designs for filters to prevent unwanted light from entering each junction.

8821-12, Session 4

Solar internal lighting system with an automated solar tracker for daylight harvesting

Upkar Kumar, Retheesh Raj, Kavitha K. Gopalan, Vadakedathu P. N. Nampoori, Animesh Aaryan, Cochin Univ. of Science & Technology (India)

This paper reports the design and realization of a solar internal lighting system equipped with a solar tracker for sunlight harvesting during daytime. An experimental prototype was designed and results have proven an excellent performance of the developed system. The system mainly consists of two parts: solar concentrator and a solar tracker. The solar concentrator has been designed by pasting small pieces of mirror on a parabolic dish which focuses the light coming from sun at its focus. Optical fibers have been used to guide the focused light inside the building after removing the infra-red component using a water column. The other end of the fiber is connected to a fiber texture which is used for lighting inside the building. A simple solar tracking system has been implemented here using a programmed stepper motor which follows the Sun, right from dawn, throughout the day, till evening, and starts all over again from dawn next day. This tracking mechanism helps to enhance light collecting efficiency of the parabolic solar light collector. A micro-controller sends control pulses to stepper motor according to the program. The controller is programmed using AVR (Advanced Virtual RISC) Dragon which is connected to PC through a standard USB port. The source code has been written in C language. IC ULN2003A has been used to drive the motor. There is practically no maintenance costs associated with the system. Thus it is expected that the present 'Solar lighting System' will to be an efficient system for interior lighting during the day.

8821-13, Session 4

An introduction to the Amonix 8700 Solar Power Generator *(Invited Paper)*

Adam P. Plesniak, Vahan Garboushian, Amonix Inc. (United States)

From 2009 through early 2012, Amonix installed nearly 40MW of the flagship 7700 Solar Power Generator product in many locations all across the southwestern USA. Since completion of these projects, Amonix has been adapting lessons learned from the 7700 scale-up and new CPV technologies into the company's 8700 Solar Power Generator, to be released in late 2013. The presentation will focus on the new features of the 8700 product, including drastically higher performance and lower cost. This includes discussion about methodologies used in the design process and how these were used to improve the product.

The presentation will also aim to discuss in summary the performance stability of the 7700 products currently in the field. Overall, the presentation will focus on what is being done at Amonix in the 8700 product to keep CPV competitive in the solar marketplace.

8821-14, Session 4

Concept and initial design of a stationary concentrator photovoltaic system based on a mirror array

Takumi Kamimura, Ryo Amano, Ichiro Fujieda, Ritsumeikan Univ. (Japan)

We propose a stationary module in which a mirror array is inserted between a lens and a solar cell. Each mirror is set up so that the light passing the principal point of the lens reaches a fixed point on an exit plane and that the length of its optical path is equal to the focal length of the lens. The light passing the other points in the lens reaches other mirrors. If the reflected light mostly reached the area near the fixed point, a slightly larger solar cell would harvest it. We have carried out ray tracing simulations to see how the optical power is distributed on an exit plane of such a module. The model consists of a hollow rectangular parallelepiped containing a mirror array, a plano-convex lens attached to the top plane of the parallelepiped, and a detector attached to one of the side planes. A light source generates parallel beams with various directions defined by the declination angle and the hour angle. Although the irradiance distribution at the exit plane depends on these angles, the basic concept of confining the optical power inside a certain area is demonstrated. Further studies on its design would improve its light utilization. For example, the rays with large incident angles suffer from total internal reflection at the bottom of the lens. Filling the hollow parallelepiped by a material with a matching refraction index solves this problem.

8821-15, Session 5

9-fold Fresnel-Köhler concentrator for increased irradiance uniformity on high concentrations

João Mendes-Lopes, Univ. Politécnica de Madrid (Spain); Pablo Benítez, Light Prescriptions Innovators, LLC (United States); Pablo Zamora, Juan C. Miñano, Univ. Politécnica de Madrid (Spain)

Non-uniform irradiance patterns created by Concentrated Photovoltaics (CPV) systems over Multi-Junction Cells (MJC) can originate significant power losses. Furthermore, when chromatic aberrations between irradiance distributions over the different MJC sub-cells are significant, power losses increase considerably, especially when considering 4, 5 and 6 junction cells.

Recent advances in optical designs for CPV, namely Fresnel-Köhler (FK) technology, proven that a spectral balanced high irradiance uniformity is achievable for systems of 850-1000x and large acceptance angle. However, when aiming for larger concentrations, irradiance uniformity decreases for the same optical design family.

Interest on Silicon-on-Glass (SoG) lens has been growing due to the combination of mass production simplicity (injection molding) and high resistance to external factors. SoG lens refractive index is affected by thermal changes, affecting considerably spectral balance of irradiance distributions.

A new CPV optical design, with large acceptance angle and prepared to overcome these effects, is presented.

The 9-fold Fresnel-Köhler (FK-9) 1000x concentrator, with acceptance curve of 1.19º, is based on a SoG nine sectors Fresnel lens combined with a Secondary Optical Element with nine refractive free-form surfaces.

The advanced design was developed such that the performance features (concentration-acceptance products - CAP- between 0.62-0.66, depending on design parameters, excellent irradiance uniformity and spectral distribution) are kept when concentration increases to 2000x and when SoG lens refractive index is affected by thermal effects, revealing excellent tolerance to manufacturing and external factors.

This paper will show the main design features, along with realistic performance simulations considering all spectral characteristics of the elements involved.

8821-16, Session 5

Development and characterization of an FK photovoltaic concentrator for maximum conversion efficiency

Maikel Hernández, Juan F. Vilaplana, Light Prescriptions Innovators Europe, S. L. (Spain); Pablo Benítez, Univ. Politécnica de Madrid (Spain); Rubén Mohedano Arroyo, Light Prescriptions Innovators Europe, S. L. (Spain); Pablo Zamora, Juan C. Miñano, Univ. Politécnica de Madrid (Spain)

Most cost-effective concentrated photovoltaics (CPV) systems are based on an optical train comprising two stages, the first being a Fresnel lens. Among them, the Fresnel-Köhler (FK) concentrator stands out owing to both performance and practical reasons. The FK features a set of advanced characteristics, desirable in CPV: high optical efficiency, large acceptance angle, insensitivity to manufacturing tolerances, very good irradiance uniformity on the cell surface and easy cell to SOE gluing. All these features are achieved without the need of any kind of additional complexity: this system is still a Fresnel based system whose primary concentrator stage can be manufactured in large inexpensive panels and, as other CPV systems, utilizes a secondary lens to attain the necessary enhanced characteristics to achieve cost-effectiveness: high CAP to minimize the investment of solar cells but assuring the performance at array level. Moreover, FK POE can be developed on both extended CPV materials: PMMA and Silicone-on-Glass (SoG).

Recent on-sun measurements carried out on an FK mono-module prototype have already shown outstanding results, achieving electrical efficiencies over 34% (no AR coating applied on SOE) for the SoG case. Since in this case a first prototype of this design has been used, optical elements are not perfectly optimized yet. This fact brings enough room to predictably go over efficiency values of 35% (additionally applying an AR coating on the SOE) during the next months.

8821-17, Session 5

Design of a etendue-cascading solar concentrator

Jhe-Syuan Lin, Chao-Wen Liang, National Central Univ. (Taiwan)

Solar concentrators are often used in conjunction with III-V multi-junction solar cells for the competitive cost and the better efficiency. A successful concentrator design can significantly reduce the per watt cost of generated solar energy. This research paper describes a novel concentrator design that combines the concepts, and thus the advantages, of both the refractive type and the reflective type concentrator.

This design adopts the novel Etendue-Cascading concept that allows the optical flux from all concentric segments of the entrance pupil to be collected and transferred to the solar cell. This novel concept enables the system to perform at its theoretical Etendue maximum limit. The increased Etendue of the system results in a solar concentrator design with higher flux concentration ratio while maintaining a minimal optical system thickness and zero back focal distance, and thereby reducing the per-watts cost.

The optical design resulted in an aspect ratio of 0.25, geometrical concentration ratio of 625 times while the optical delivery efficiency is as high as 78% and the acceptance angle of 1.6 degrees. The concentrator is also featured with zero back focal distance for easier alignment and relaxed manufactured tolerance.

8821-18, Session 5

Solar spectral variations and their influence on concentrator solar cell performance: a comparative study between tandem and spectrum splitting parallel junctions

Lirong Z. Broderick, Brian R. Albert, Brian S. Pearson, Lionel C. Kimerling, Jurgen Michel, Massachusetts Institute of Technology (United States)

Traditional multi-junction concentrator solar cells use a vertically stacked tandem configuration. In recent years, parallel junctions where laterally aligned solar cells with differing bandgaps are used along with spectrum splitting optical elements stimulated renewed interest due to their potential of higher efficiency, less spectral sensitivity and more flexibility in materials choices. However, no quantitative data are available regarding the difference of efficiency and spectral sensitivity between the two types of junctions. For the first time, our research addresses these issues through a comparative study.

Direct normal solar spectra in a representative sunny site, Tucson, Arizona at 15-minute intervals throughout a whole year are calculated using the SPCTRAL2 model. Real-time meteorological data including aerosol optical depth and precipitable water vapor provided by AERONET for the year 2000, ozone amount obtained using the van Heuklon model, and geographical parameters of Tucson (latitude, longitude and elevation) are used as input for the spectral calculations. The corresponding efficiencies of tandem and parallel junctions under 500X concentration are computed for each spectrum. Both junction structures comprise the same materials, InGaP, GaAs and Ge, and are each optimized to the AM1.5D standard spectrum, under which the parallel junction achieves an efficiency 1.9% absolute (and 4.6% relative) higher than the tandem junction. The two junctions are compared for their hourly, daily, monthly, and yearly average efficiencies. It is found that the yearly average efficiency of the parallel junction is 4.2% absolute higher than for the tandem cell, corresponding to an annual energy production difference of 71.6 MWh/m2.

8822-1, Session 1

Progress in advanced solar to hydrogen production technologies *(Invited Paper)*

Eric L. Miller, Sara Dillich, Erika Sutherland, Sarah Studer, Katie Randolph, David Peterson, U.S. Dept. of Energy (United States)

The US Department of Energy's (DOE) Fuel Cell Technologies Office (FCT) has made significant progress in fuel cell technology advancement and cost reduction, highlighted by reducing the cost of automotive fuel cells by more than 80% since 2002. The next major challenge is the widespread production of affordable renewable hydrogen. FCT programs aim to address this challenge with a balanced research and development (R&D) portfolio of both near- and longer-term hydrogen production technologies. The portfolio design is informed by ongoing R&D progress, through technoeconomic analysis, and with expert recommendations (such as those from the 2012 Hydrogen Production Expert Panel, a subcommittee of the Hydrogen and Fuel Cell Technical Advisory Committee). Central to the long term vision for renewable hydrogen are the solar-to-hydrogen conversion processes, including the photoelectrochemical, biological and thermochemical routes. To be successful, these pathways require continued advances in novel materials, nano-structures and interfaces (organic and inorganic). Cross-cutting research collaborations across DOE programs and other federal agencies are leading to important progress in the materials development for the solar-hydrogen production technologies, which is discussed in this presentation.

8822-2, Session 1

Modeling of complex phenomena in materials science: challenges and successes *(Invited Paper)*

Biplab Sanyal, Uppsala Univ. (Sweden)

In this talk I will discuss the challenges and successes in theoretical materials science with a focus on energy related research. The limitations of standard approximations in single-particle based materials specific theories will be mentioned along with remedies using sophisticated many body based methods. Issues like quantum confinement, band gaps, electron correlation in oxides, complex magnetism etc. will be discussed. In this regard, I will mention relation to several experimental techniques with a focus on synchrotron based measurements.

8822-3, Session 1

Optimisation of photo-active oxides and composites through solution based processing *(Invited Paper)*

Gunnar Westin, Uppsala Univ. (Sweden); Kjell Jansson, Stockholm Univ. (Sweden); Annika Pohl, Koroush Lashgari, Michael Leideborg, Uppsala Univ. (Sweden)

For practical use of catalysts for solar fuels, solar cells and photo-assisted cleaning of water and air, robust, low cost routes to advanced complex materials are a requisite. These multi-functional devices should both be effective in photon generation of holes and electrons, transport and catalysis of surface reactions, where different functions most probably need to be optimised in different parts of a nano-structure. Quantum confinement in typically less than 3 nm sized oxide systems may also be an efficient means for improved properties, which puts high demands on the precision of the processing routes. For such demands solution based routes are the best suited, but there is a need for further development of well understood, flexible routes to high quality, complex nano-structures. Here we discuss solution based processing routes of different kinds of doped and non-doped oxide and metal nano-particles, thin- and ultra thin films. The oxide systems involve doped and non-doped Fe_2O_3, TiO_2, ZnO, spinel and perovskite nano-particles, films and ultra-thin films, as well as metal nano-particles and ultra-thin films. The processes and materials were studied by a wide array of techniques including; SEM, TEM, XRD, TGA, DSC/DTA, IR-, Raman and UV-Vis-NIR spectroscopy, and connected with band-structure and properties.

8822-4, Session 2

First-principles studies of TiO_2 for photocatalysis *(Invited Paper)*

Chris G. Van de Walle, Poul Moses, Joel B. Varley, Anderson Janotti, Univ. of California, Santa Barbara (United States); André Schleife, Lawrence Livermore National Lab. (United States)

TiO_2 is a material of increasing interest in electronics, optoelectronics, and chemistry, with applications in high-k dielectrics, solar cells, and (photo)catalysis. Rutile TiO_2 has a wide band gap of 3.1 eV and exhibits a tendency for unintentional n-type conductivity. Understanding and controlling the conductivity and absorption characteristics of TiO_2 is a key step toward the wider application of this material. Here we use advanced first-principles calculations to address the structural and electronic properties of bulk and surface, as well as point defects and impurities in TiO_2. The use of a hybrid functional in density functional theory allows us to overcome the "band-gap problem". Optical spectra are calculated using many-body perturbation theory by solving the Bethe-Salpeter equation (BSE). We discuss the role of nitrogen and sulfur in changing the absorption properties.

Collaborations with F. Bechstedt, C. Franchini, G. Kresse, and P. Rinke are gratefully acknowledged.

8822-5, Session 2

Fundamental aspects of disorder-engineered titanium dioxide *(Invited Paper)*

Samuel S. Mao, Lawrence Berkeley National Lab. (United States)

This presentation will provide an overview of recent progress in the development of oxide-based photocatalytic and photoelectrochemical approaches for solar-driven production of hydrogen from water. The emphasis will be on fundamental aspects of disorder-engineered titanium dioxide nanoparticles, starting with an introduction of the basic electronic band structure resulted from disorder incorporation, followed by recent synchrotron radiation-based experiments aimed to provide an insight into the unique material that has shown significant activity of solar-driven hydrogen production.

8822-6, Session 2

Surface disordered metal oxide nanostructures for photoelectrochemical water splitting

Aadesh P. Singh, Indian Institute of Technology Delhi (India); Sanjay Mathur, Univ. zu Köln (Germany); B. R. Mehta, Indian Institute of Technology Delhi (India)

The use of metal oxide semiconductor as a solar energy harvesting element in photoelectrochemical cell for water splitting is a topic of growing interest for solar energy conversion to chemical fuel. Surface disordering in metal oxides at nano-level is a promising tool for altering optical absorption and carrier transport in metal oxide semiconductors which can be used an efficient photoelectrode in PEC cell for solar energy harvesting. Gas phase techniques offers a viable solution for overcoming thermodynamic impediments involved in thin film growth and disorder-engineering through in-suit molecule precursor-based plasma coatings of metal oxides and anisotropic hydrogen plasma treatment.

This talk will present how PE-CVD processed nanostructured films of different metal oxides open up new vistas of material properties, which can be transformed into advanced material technologies. Further, the effect of surface disordering of metal oxide nanostructures created by reducing hydrogen plasma treatment on optical, electrical and photoelectrochemical will be discussed.

8822-7, Session 3

Water structure and redox level alignment at the water/semiconductor interface from first principles *(Invited Paper)*

Marivi Fernandez-Serra, Philip B. Allen, Jian Liu, Luana Pedroza, Stony Brook Univ. (United States)

To achieve high photocatalytic oxidation activity in semiconductor surfaces two physical requirements need to be satisfied. The first, which is necessary, but not sufficient, is that candidates need to absorb light in the visible. The second is associated to the suitability of the conduction and valence band edges of the semiconductor for the overall water splitting reaction.

In this presentation I will show results from first principles molecular dynamics simulations of water at the interface of GaN and perovskite oxides semiconductors and will discuss how to accurately compute the alignment of the water electronic levels with respect of those of the semiconductor bulk. In particular, I will discuss how the first principles results are dependent both on the theory approximations (exchange and correlation functionals, including hybrid functionals) and on the adequate sampling of the structure of the liquid at the interface. When water dissociation occurs at the interface, new surface states can influence the path for the photo-hole transfer to water. I will also discuss the role of surface polarity and its link to the structure of the interfacial water. Our results will help to understand both the efficiency of certain surfaces on catalyzing the oxidation reaction and the relevance of surface acidity for prospect semiconductor photo-catalysts.

8822-8, Session 3

On quantum confinement effects in large bandgap semiconductors *(Invited Paper)*

Lionel Vayssieres, Xi'an Jiaotong Univ. (China)

The overview and the latest advances in quantum confinement effects and interfacial electronic structure of visible light-active all-oxide heteronanostructures for solar hydrogen generation by water splitting without sacrificial agent will be presented. The study includes the synthesis of highly oriented nanorod-based arrays at low temperature from aqueous precursors without any surfactant on various substrates, the bandgap and bandedge engineering of photoactive oxide semiconductors, their size dependent surface chemistry, conduction band orbital character and electrical properties as well as the in-depth understanding and engineering of the interfacial electronic structure by synchrotron-based studies of all-oxide heteronanostructures including orbital symmetry and crystal field splitting optimization for better efficiencies.

8822-9, Session 3

Towards a perfect system for solar hydrogen production: an example of synergy on the atomic scale

Ramy Nashed, Georgia Institute of Technology (United States) and The American Univ. in Cairo (Egypt); Jang Seung-Soon, Georgia Institute of Technology (United States); Yehea Ismail, Nageh K. Allam, The American Univ. in Cairo (Egypt)

The effect of metal doping on electronic band structure and charge carriers effective mass of Ta2O5 were studied using hybrid functionals in density functional theory. PBE0 hybrid functional proved to be very efficient in predicting the band structure with less than 5% error compared to experimental data. The bandgap decreases monotonically as the percentage of the dopant increases. Furthermore, the indirect bandgap behavior of Ta2O5 was found to initially increase on doping before it decreases again to its original value of pristine Ta2O5. We found that high percentage doping or even mixing with another metal is required in order to modify the band structure of Ta2O5. The effect of doping on the crystal structure was also studied. XRD measurements show that the crystal lattice tends to expand upon doping with metals with larger atomic radius than Ta and this effect is more pronounced as the dopant concentration increases.

8822-10, Session 3

Pulsed plasma deposition methods for photoactive ?-Fe2O3 hematite thin films

Stepan Kment, Zdenek Hubicka, Institute of Physics of the ASCR, v.v.i. (Czech Republic); Josef Krysa, Institute of Chemical Technology (Czech Republic); Jiri Olejnicek, Martin Cada, Michaela Brunclíková, Institute of Physics of the ASCR, v.v.i. (Czech Republic); Rodney J. Soukup, Natale J. Ianno, Univ. of Nebraska-Lincoln (United States)

Highly photoactive hematite (?-Fe203) thin films have been deposited by magnetron sputtering, high power impulse magnetron sputtering (HiPIMS) and hollow cathode plasma-jets. All these method are capable of producing crystalline films during the deposition process. Moreover, the crystalline plane orientation can be influenced. The films were characterized using a broad range of methods (XRD, Raman spectroscopy, XPS, AFM, SEM, etc.). The solar photocurrent measurements were done to assess the photoelectrochemical performances of the electrodes. The dependency of the pulsing frequency, current density and further deposition plasma parameters on the on the properties and photoelectrochemical activity of the films were discussed.

8822-11, Session 3

Cold gas spraying of semiconductor coatings for the photooxidation of water

Thomas Emmler, Helmholtz-Zentrum Geesthacht (Germany); Henning Gutzmann, Helmut-Schmidt Univ. (Germany); Mauricio Schieda, Helmholtz-Zentrum Geesthacht (Germany); Frank Gärtner, Iris Herrmann-Geppert, Helmut-Schmidt Univ. (Germany); Thomas Klassen, Helmut-Schmidt Univ. (Germany) and Helmholtz-Zentrum Geesthacht (Germany)

The switch of the energy production towards regenerative energies is currently of large general interest. Especially the production of hydrogen via photo induced water splitting is promising since it allows the storage of solar energy.

This contribution shows the potential of cold-gas-spraying for the production of photo-chemical electrodes employing photoelectrocatalysts for the water oxidation reaction (OER). Conventional methods of coating usually employ sol-gel methods and calcination to obtain a good binding of the coating to the substrate. In the cold-gas-spraying process particles are accelerated to high velocities in a laval nozzle. By the impact on the substrate the particles are deformed and build up an efficient interface to the back contact (analyzed e.g. by cross-section SEM). Cold-gas-spraying is a method for the direct coating of surfaces and does not make use of additives that have to be removed afterwards e.g. by a calcination step but allows the direct formation of a working electrode ensemble.

In first tests the "classical" photocatalyst Titanium dioxide was probed whose cold-gas sprayed films revealed similar activities compared to films derived from wet-chemical processes. This approach was extended to the photoelectrocatalyst hematite for the OER. Employing analytical methods like SEM, Raman, XRD and XPS in correlation with photoelectrochemical measurements the operation parameters of the cold gas spray process are discussed in terms of their influence on the photocatalytic properties of the semiconductor. Moving further to new materials based on TiO2 and hematite the problems of the coating stability are discussed.

8822-12, Session 4

Ceria chemistry at the nanoscale *(Invited Paper)*

Kersti Hermansson, Jolla Kullgren, Peter Broqvist, Uppsala Univ. (Sweden)

Ceria (CeO2) is used in solid oxide fuel cells and for the purification of exhaust gases in vehicle emissions control. Behind these technically important applications of ceria lies one overriding feature, namely ceria's exceptional reduction-oxidation properties enabled by the duality of the cerium, which toggles easily between Ce4+ and Ce3+ thanks to its 4f electron. Traditionally, much of the technical functionality of ceria has been ascribed to oxygen vacancies. However oxygen vacancies are not the only players [1]. We have performed extensive theoretical simulations of various flavors (quantum-mechanical calculations, force-field calculations, MD simulations, structure optimization with genetic algorithms, . . .) to explore the character and chemistry of ceria. In particular, experiments [2] have shown that small nanoparticles of ceria, with an average diameter of approximately 4 nm, possess a dramatically increased oxygen storage capacity (OSC) compared to larger particles. We find that - for such small particles - it is not explicit oxygen vacancies that govern the OSC, but instead it is governed by superoxo ions (O2-) that decorate the nanoparticle.

8822-13, Session 4

Development of metal tungstate alloys for photoelectrochemical water splitting

Dixit Prasher, Marina Chong, Y. Chang, Hawaii Natural Energy Institute (United States); Pranab Sarker, Muhammad N. Huda, The Univ. of Texas at Arlington (United States); Nicolas M. Gaillard, Hawaii Natural Energy Institute (United States)

The last decade has witnessed about much efforts devoted to identify a suitable semiconductor to be integrated in an efficient, economical and stable photo-electro-chemical (PEC) system. Among the various materials, binary transition metal oxides are still considered to be a promising as most of them offer good ionic as well as electronic conductivity and are inexpensive to produce. But unfortunately, no binary oxide has yet fulfilled all the PEC criteria like optical function required to obtain maximum light absorption and photo-conversion efficiency simultaneously. To overcome the above situation, we demonstrate how density functional theory (DFT) can be of great boost in the category of new oxide-based PEC materials. As suggested by DFT, copper was first evaluated to form ternary CuWO4 mineral and also literature highlighted that addition of Copper to the host tungsten trioxide improves the visible light absorption. Several techniques were used to form this new PEC material (PVD, spray pyrolysis, solid state reaction), all leading to 2.2 eV band-gap n-type CuWO4 systems capable of generating photocurrent density of 0.5 mA.cm-2 at saturation (1 VSCE, pH10, AM1.5G). Furthermore, DFT calculations revealed that the addition of bismuth to form CuBiW2O8 mineral could suppress the unfilled mid-gap states present in CuWO4 resulting in less charge trapping and also would improve the electron mobility with more dispersed conduction band. To validate this hypothesis, CuWO4 and CuBiW2O8 pellets were prepared with mortar mix nanopowders of CuO, WO3 and Bi2O3. After annealing the pellets in air at 8500C for 6 hours, resistance measurement was carried out at various temperatures using impedance spectroscopy analysis. Electrical measurements performed on both CuWO4 and CuBiW2O8 ceramic pellets confirmed an increase in electrical conductivity by a factor of 100 after addition of bismuth (from 5.7?10-8 S.cm-1 to 3.8?10-6 S.cm-1). Research is currently focused on CuBiW2O8 thin films synthesis to evaluate the PEC performances of this new material class.

8822-14, Session 4

Photoelectrochemical performance of doped BiVO4 thin-films deposited by spray pyrolysis

Stephen K. Holland, David J. Lawrence, Thomas C. DeVore, James Madison Univ. (United States)

The solar water splitting performance of thin-film BiVO4 photoanodes deposited by low-cost spray pyrolysis deposition exhibits a significant dependence on the chemical precursor solution formulation, deposition substrate material, and post-deposition treatment methods. BiVO4 thin films were deposited on indium tin oxide (ITO), fluorine doped tin oxide (FTO), and tungsten oxide (WO3) by spray pyrolysis of aqueous solutions of Bi(NO3)3 and VOSO4. N-type films were produced by including various ratios of silicotungstic acid or ammonium metatungstate in the precursor solutions. The resulting BiVO4 films exhibited a porous microstructure. X-ray diffraction measurements confirmed that monoclinic BiVO4 was formed following 500ºC annealing in air. The photoelectrochemical (PEC) water splitting performance of the photoanode samples was evaluated in a three-electrode cell under AM1.5 illumination of 0.1 W/cm2 from a solar simulator. Films that received additional annealing in 3% H2 produced the largest measured photocurrent densities, exceeding 2 mA/cm2 with an applied bias of 1.5 V. Results indicate that the substitution of tungsten for vanadium rather than bismuth in the precursor solutions produces films with better PEC performance. Results indicated that tungsten doping resulted in a photocurrent reduction relative to the undoped samples. Results also indicated a strong correlation between the PEC performance of the photoanodes and the substrate materials on which the BiVO4 was deposited. The effects of tungsten and molybdenum doping of the BiVO4 films as well as heterojunction and material combination effects are the subject of ongoing investigations.

8822-15, Session 4

Control over crystal growth and morphology of nanostructured BiVO4 films for water photo-splitting

Abdelkrim Chemseddine, Roel Van de Krol, Lichao Jia, Tayfun Mete, Ursula Michalczik, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany)

Bismuth acetate and vanadium oxo isopropoxide were used as precursors. Their reactivity was adjusted by adding chelates and therefore controlling the nucleation and growth processes of BiVO4. The films were grown on a seed film in a chemical bath by controlling the temperature. Compared to films made by spin-coating or spray pyrolysis, XRD shows a preferred orientation of BiVO4 crystallites with the monoclinic crystal structure. Scanning electron microscopy shows well defined crystals with sharp edges and smooth surfaces. Highly transparent and dense films or highly nanoporous films can be obtained by adjusting the composition of the precursors solution.

Multilayers films can be prepared by spin-coating. In this contribution, the texture of the final film, the porosity, the grain boundaries and the orientation of the crystallites depend strongly the intermediate heat-treatment and on the final heat-treatment of the final multilayers films. The photoactivity of the films is investigated using surface photovoltage, followed by photoelectrochemical measurements.

8822-16, Session 5

Challenges and opportunities in the atomistic modelling of interfaces for energy harvesting *(Invited Paper)*

Feliciano Giustino, Univ. of Oxford (United Kingdom)

Understanding and designing functional interfaces has become a priority in many areas of science and technology, ranging from photovoltaics and photocatalysis to electronics and biosensing. A fundamental property of functional interfaces is the alignment of the electron energy levels between the two materials. Such alignment underpins several important phenomena, eg charge-transfer doping, carrier injection, and exciton dynamics. In the context of solar energy technology the level alignment determines the ability of the interface to transfer energy from a donor to an acceptor by exchanging photoexcited charges. While the physics of the energy-level alignment at conventional semiconductor heterojunctions is currently well established, little is known about functional interfaces involving metal oxides and soft materials such as polymers and light-harvesting molecules. Here I will review our recent activity [1-5] in the computational modelling of TiO2 and ZnO interfaces of current interest for nanostructured solar cells, and of experimental probes such as X-ray photoemission spectroscopy and ultraviolet photoemission spectroscopy. In this area the first challenge that we have to face is to determine the structure of the interface at the atomic scale. Here standard optimization techniques are bound to fail due to the large number of possible interface morphologies. I will argue that a possible way forward is to build interface models by reverse-engineering experimental data using first-principles computational spectroscopy. This notion will be illustrated by discussing core-level photoemission at interfaces between TiO2 and metal-organic chromophores. The second challenge is the development of robust computational methods for studying the electronic structure of functional interfaces. In this case standard density-functional techniques are rarely in quantitative agreement with photoemission data and more sophisticated approaches become necessary. This will be illustrated by discussing semiconductor-polymer [4] and metal-oxide/molecule interfaces [5]. Here I will briefly review our activity in the area of many-body perturbation theory techniques (GW method), and in particular the use of quasiparticle methods in the case of transition metal oxides with localized d electrons [3].

8822-17, Session 5

Toward in-situ time-domain x-ray studies of interfacial photochemistry *(Invited Paper)*

Oliver Gessner, Lawrence Berkeley National Lab. (United States)

Interfacial photochemistry is governed by the flow of charge, mass, and energy among molecules and between molecules and condensed phase substrates. By definition, the quest for a deeper understanding of interfacial photochemical processes is directly related to the capability to monitor non-equilibrium dynamics of complex systems in electronically and/or vibrationally excited states. Time-domain x-ray spectroscopy techniques offer new opportunities to unravel the fundamental electronic and nuclear dynamics that underlie chemical and electronic function in processes such as photoelectrochemical water splitting or photovoltaic power generation. The simultaneous element specificity and chemical sensitivity of x-ray transitions in combination with the time-structure of accelerator-based x-ray light sources provides real-time access to transient oxidation states and local bonding motives with atomic pinpoint accuracy. Recent femtosecond time-resolved x-ray photoelectron spectroscopy (TRXPS) measurements at the Linac Coherent Light Source (LCLS) and the Advanced Light Source (ALS) provide a molecular scale perspective of the visible light induced transient oxidation states of N3 dye molecules adsorbed to nanocrystalline ZnO, one of the key components of dye-sensitized solar cells. The underlying physics are explored in a concerted effort of TRXPS experiments and ab-initio calculations of the interfacial electronic structure. Building on these proof-of-principle studies, current efforts focus on the extension of time-domain x-ray techniques toward in-operando studies of photochemical processes. A pathway will be outlined to study the dynamics of interfacial states at a hematite-electrolyte interface in an operational photoelectrochemical cell by time-resolved x-ray absorption spectroscopy (TRXAS).

8822-18, Session 5

Semiconductor quantum dot sensitisation: application to solar energy conversion *(Invited Paper)*

Yasuhiro Tachibana, RMIT Univ. (Australia)

Semiconductor quantum dot (QD) is one of the most attractive nanomaterials to be utilized for solar energy conversion devices. Similar to dye sensitised solar cells, sensitization of metal oxide nanostructures by QDs can be realized. The sensitised nanostructure maximises the light harvesting efficiency and charge separation process, thereby being suitable for the device design. This configuration has been intensively studied to be applied for QD sensitised solar cells, and possibly applicable to solar water splitting processes.

The function of QD sensitised device is controlled by kinetic processes of the charge separation and charge recombination. For example, the device performance can be improved by accelerating the charge separation process and retarding the recombination process. However, the control of these reaction kinetics has rarely been studied, and the mechanisms of these reactions have not been well understood. In this presentation, we will demonstrate relationship of the QD nanostructures with the interfacial electron transfer reactions by employing time-resolved laser spectroscopies.

Several types of QDs with a narrow size distribution are synthesized to control the potential energy levels of the conduction and valence bands. Here we employ TiO2 nanocrystalline films, which are commonly used for the sensitised solar cells. The structure at the QD/TiO2 interface is modified to control electronic coupling between the QD and the TiO2. These QD sensitised TiO2 films are employed for transient laser spectroscopies.

This work was financially supported by JST PRESTO program, Japan. The Office for University-Industry Collaboration, Osaka University is also acknowledged for the financial support.

8822-19, Session 5

Kinetic studies of water oxidation on ?-Fe2O3 photoanodes

Florian Le Formal, Stephanie R. Pendlebury, James R. Durrant, Imperial College London (United Kingdom)

A combination of transient absorption spectroscopy and photo-electrochemical methods has been performed on iron oxide photoanodes to investigate the limitations of this material for water splitting.

Hematite, or ?-Fe2O3, is widely recognized as a promising candidate material to produce hydrogen from the Sun because of its low cost and high chemical stability. However the fall off in light absorption at long wavelengths and the poor charge carrier conductivity observed in iron oxide have been major drawbacks to implement this material in a water photolysis device. Recent advances in film preparation involving addition of dopants, increasing the electron conductivity, and nanostructuring strategies have substantially increased the performance of hematite electrodes. This enhancement has been mainly related to the reduction of the distance between where holes are photogenerated and where they react.

The second main limitation of hematite is the large overpotential required to drive the oxygen evolution reaction (O.E.R.) on its surface. This has been assigned to the slow reaction kinetics resulting in positive charge accumulation at the semiconductor electrolyte interface. Additionally to reduce the space charge layer, the accumulation can increase the competition between the reaction of holes and other detrimental processes such as charge trapping and charge recombination. Photo-electrochemical and optical spectroscopies have been performed to characterize the different processes occurring for photogenerated charges on the hematite surface. The different techniques used in addition to the different time scales scrutinized, help to distinguish the several reactions involved and to elucidate the origin of the low solar-to-hydrogen energy conversion efficiency.

8822-20, Session 6

In search of optimal photoelectrode: microscopic property of liquid-solid interfaces studied from first principle *(Invited Paper)*

Tadashi Ogitsu, Lawrence Livermore National Lab. (United States)

The surface morphology of III-V semiconductors such as GaP, InP, and GaInP2 were studied with ab-initio DFT total energy calculations. Several surface structural motifs, with and without oxygen or hydroxyl, were identified as likely to be present at the real electrode surface based on energetics. Contrasting chemical properties of these motifs for a water molecule adsorption were observed: M-O-M (M=Ga or In) motif initiates dissociative adsorption of water, while M-O-P (M=Ga or In) does not.

The water-semiconductor (GaP or InP) interfaces were studied using the ab-initio molecular dynamics simulations (MD). We find that the consistent behavior on the chemical activities of surface motifs in our interface MD simulations: M-O-M is reactive, while M-O-P is not. Detailed analysis on the properties of interfacial water was performed on the hydrogen bonding network topology, on the density profiles, on the rotational auto-correlation time, on the hydrogen bond dissociation-association frequency. The detail, particularly on the comparison between GaP and InP, will be discussed in the presentation.

Bridging between the atomistic simulation results and the reality is a major challenge in PEC field. The recent advancement on X-ray based spectroscopy technique made it possible to obtain atomistic insight on the chemical environment of the elements of our interest under the device operation condition. We have investigated on the computational X-ray absorption/emission spectrum for systems of our interest using the method developed by Prendergast of The Molecular Foundry, LBNL. The simulation procedure, results and interpretations will be discussed at the presentation.

8822-21, Session 6

Water-induced modifications of GaP(100) and InP(100) surfaces studied by photoelectron spectroscopy and reflection anisotropy spectroscopy

Matthias M. May, Oliver Supplie, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany) and Humboldt-Univ. zu Berlin (Germany); Christian Höhn, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany); Wolf-Dietrich Zabka, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany) and Humboldt-Univ. zu Berlin (Germany); Hans-Joachim Lewerenz, California Institute of Technology (United States) and Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany); Roel Van de Krol, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany); Thomas Hannappel, Technische Univ. Ilmenau (Germany) and Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany)

The high photoconversion efficiency of III-V semiconductors makes them promising absorber materials for solar water splitting, especially in multi-junction approaches such as GaP(N)/Si [1]. A microscopic understanding of the semiconductor-electrolyte interface is crucial for a knowledge-based device design [2].

We explore the electronic and morphologic modifications of GaP(100) and InP(100) surfaces induced by the exposure to water in situ with reflection anisotropy spectroscopy (RAS). To this end, well-defined III- and V-rich surfaces were prepared by metal-organic vapour phase epitaxy (MOVPE) using in situ RAS to control the growth [1], and transferred contamination-free to UHV for further analysis. Water was adsorbed in a dedicated UHV chamber and its impact on the surface reconstruction was monitored in situ with RAS.

In-system LEED and photoelectron spectroscopy analysis before and after water exposure show that especially P-rich surfaces, which are typical for MOVPE preparation, are more stable than e.g. UHV-cleaved surfaces [3]. Subsequent annealing in N2 and H2 VPE ambient reveals that InP tends to form an ordered oxide. The P-rich surface reconstruction of GaP, on the other hand, can be largely restored upon annealing in H2. Our findings could lead to a better understanding of initial surface modification/oxidation, contributing vitally to in situ surface functionalisation strategies [4].

8822-22, Session 6

Developing high quality BiVO4 thin film for photoelectrochemical study *(Invited Paper)*

Le Chen, Lawrence Berkeley National Lab. (United States); Esther Alarcon-Llado, Ecole Polytechnique Fédérale de Lausanne (Switzerland); Ian Sharp, Mark Hettick, Yongjing Lin, Joel W. Ager III, Lawrence Berkeley National Lab. (United States)

BiVO4 (BVO) has attracted more and more attention as a potential photoanode candidate for photoelectrochemical (PEC) water splitting. However, according to the literature, most of BVO was synthesized in bulk by solution based methods. There lacks a high quality thin film synthesis method for BVO, which leads to a lack of fundamental study of electrochemical, electronic and optical properties of BVO.

In JCAP, we have successfully developed high quality BVO thin films by vapor deposition methods as sputtering and chemical vapor deposition

(CVD). For both of the synthesis methods, the control of stoichiometry is most critical and challenging since Bi and V has very different thermal conductivities. We also found out the different stoichiometry can give rise to different electronic conductivity and PEC performance. The structure and stoichiometry of the thin films were characterized by XRD, Raman, SEM and XPS. The PEC performance was evaluated by IV curve (with or without light), impedance as well as IPCE. Furthermore, we were able to carry out some fundamental studies of electronic and optical properties including diffusion length, surface states and carrier dynamics on the deposited thin films by using Surface Photovoltage (SPV) and Transient Absorption Spectroscopy (TA). The attempt to improve BVO PEC properties such as adding hole blocking layer, introducing W or Mo doping as well as coupling with OER catalysts were also going to be presented in the talk.

8822-23, Session 7

Exploring electrochemistry from first-principles with simulated core-level spectra *(Invited Paper)*

David Prendergast, Lawrence Berkeley National Lab. (United States)

In order to develop reliable insight into the working principles of electrochemical systems, one needs chemical model which can be validated against in situ characterization. Often, x-ray spectroscopy is applied, due to its elemental specificity and sensitivity to local electronic structure around the excited atom. However, such techniques probe electronic structure and not atomic structure, and rely on interpretation to make connections to chemical models. We have developed a first-principles approach to simulate x-ray spectroscopy using constrained density functional theory that is applicable to condensed phases. We provide several examples of the application of this method to problems in electrochemistry and photoelectrochemistry, illustrating the invaluable insight such methods provide for unraveling the meaning in spectroscopy and elucidating the mechanism of materials under bias and illumination.

8822-24, Session 7

The search for the optimal PEC material, soft x-ray spectroscopy, and the band gap *(Invited Paper)*

Clemens Heske, Univ. of Nevada, Las Vegas (United States) and Karlsruhe Institute of Technology (Germany)

The search for the optimal material for photoelectrochemical water splitting (PEC) can likely be accelerated by adopting an insight-based approach. For this, sophisticated characterization is needed, such that subtle modifications in the PEC material, which can lead to significantly different PEC performance, can be identified and understood.

This presentation will demonstrate that soft x-ray spectroscopies, in particular direct and inverse photoemission and soft x-ray emission, are well suited to derive a comprehensive view of the electronic structure (including the band gap) of candidate materials. However, as with all measurements, assumptions need to be made and pitfalls need to be avoided. Using GaInP2 and WO3 as model systems, experiments elucidating their electronic properties will be presented and discussed.

8822-25, Session 7

Soft x-ray spectroscopic study of mesoscale renewable energy materials *(Invited Paper)*

Jinghua Guo, Lawrence Berkeley National Lab. (United States)

Solar energy can be converted to electricity and chemical fuels for energy use and storage. However, the cost and conversion efficiency have been the biggest challenge for potential use of solar energy. There are the emerging technologies of using semiconductors for light harvesting assemblies; and charge transfer processes to solar cells. Controlling the crystallographic structure and the arrangement of atoms along the surface of novel materials will determine most of the physical and chemical properties.

Electronic structure ultimately determines the properties of matter. Soft x-rays address what the electrons are doing as they migrated between the atoms. Soft x-ray absorption spectroscopy (XAS) and emission spectroscopy (XES) have some unique features that are important to consider in regards to the element and atomic site selectivity and chemical state and symmetry sensitivity. The high-resolution selectively excitation has opened a new field of study by disclosing many new possibilities of soft x-ray resonant inelastic scattering (RIXS). In this presentation, some in-situ soft X-ray spectroscopy instrumentation development and recent studies of various solar energy conversion are presented. The results reveal the electronic structure of the 3d metal compounds in pure form and their variations upon doping. Also, in-situ characterization of photocatalysts demonstrated the way for real-time studies of chemical reactions.

8822-26, Session 8

Electronic transport and magnetic properties of graphene nanoribbons *(Invited Paper)*

Katsunori Wakabayashi, National Institute for Materials Science (Japan)

The electronic states of graphene near the Fermi energy are well described by massless Dirac Fermion [1]. The presence of edges, however, makes strong implications for the spectrum of the electrons [2][3]. In graphene nanoribbons with zigzag edges, localized states appear at the edge with energies close to the Fermi level. In contrast, edge states are absent for ribbons with armchair edges. Recently several reports appear on the synthesis of graphene nanoribbons using lithography techniques[4], chemical techniques[5].

In my talk, we focus on edge and nanoscale effect on the electronic properties of graphene nanoribbons. The electronic states of graphene nanoribbons strongly depend on the edge orientation. (A) In zigzag nanoribbons, for nonmagnetic long-ranged disorder, a single perfectly conducting channel emerges associated with a chiral mode due to the edge state, i.e., the absence of the localization in this class[6][7][8]. (B) We show the electronic transport properties of graphene nanojunctions crucially depend on the peripheral lattice structures[9]. The condition for electron confinement is discussed. We also show that the magnetic response of conductance peaks in the graphene nanojunctions depends on the configuration of nanojunctions. (C) Finally, we will discuss the effect of edge chemical modification on magnetic properties of nanographene systems[10]. Also, we discuss the hole doping effect on the spin-polarized states appearing along the graphene zigzag edges[11].

8822-27, Session 8

Reversible hydrogen evolution and oxidation mediated by molecular ion

Kestutis Juodkazis, Institute of Chemistry (Lithuania); Jurga Juodkazyte, Ctr. for Physical Sciences and Technology (Lithuania) and Institute of Chemistry (Lithuania); Benjaminas Sebeka, Institute of Chemistry (Lithuania); Saulius Juodkazis, Swinburne Univ. of Technology (Australia)

Detailed steps of hydrogen generation/oxidation on the surface of polycrystalline platinum electrode are revealed based on analysis of mass and charge changes, thermodynamic, steric, and surface coverage arguments. Newly proposed intermediate - the molecular hydrogen ion - is shown to be essential mediator of the hydrogen evolution and oxidation reactions. The reversible character of the multi-step process is demonstrated. The entire electrochemical water reduction - hydrogen oxidation cycle has been explained on the molecular level and matches quantitatively with the most recent experimental and numerical results. These findings based on thermodynamic balance provides further insights in understanding and interpretation of hydrogen-related surface processes on Pt electrode and are expected to affect practical solutions relevant to water splitting, hydrogen generation, storage and development of fuel cells.

The presented analysis revisits the mechanism of reversible hydrogen evolution and oxidation reactions on Pt electrode and explains a thermodynamic contradiction related to participation of adsorbed hydrogen as intermediate in these processes, which has been unresolved for more than half a century. Novel mechanism makes it possible to account quantitatively for: (i) depolarization of hydrogen ion discharge from the theoretical standard potential value of –2.1 V to 0 V (vs. standard hydrogen electrode) and (ii) for mass changes on the electrode consistent with OH- ion release from the surface. By invoking molecular hydrogen ion as an intermediate in hydrogen evolution/oxidation on platinum, the quantitative agreement between the model and experimental data has been achieved and it is well supported by thermodynamic arguments.

8822-28, Session 8

Nanocrystal based hydrogen production with size-controlled cluster catalysts

Jochen Feldmann, Ludwig-Maximilians-Univ. München (Germany)

We report on hydrogen production with size-selected sub-nanometer cluster catalysts deposited on thin films of colloidal semiconductor nanocrystals. Pt clusters have been deposited under ultrahigh vacuum (UHV) conditions on CdS nanorods. For these UHV cluster decorated CdS nanorods we find higher hydrogen production rates than for CdS nanorods which have been cluster decorated via photodeposition.

The number of clusters per rod as well as the size of the Pt clusters have been varied [1]. Pt_{46} clusters show the best quantum efficiency as compared to smaller and bigger clusters. Quantum size effects are discussed to explain this non-monotonic behavior. We find in addition that below 40 Pt clusters per rod the quantum efficiency drastically drops, whereas the quantum efficiency saturates for higher cluster numbers.

8822-29, Session 8

Nanowires from multi-crystalline Si for hydrogen generation

Stefan L. Schweizer, Martin-Luther Univ. Halle-Wittenberg (Germany); Xiaopeng Li, Martin-Luther Univ. Halle-Wittenberg (Germany) and Max-Planck-Instute of Microstructure Physics (Germany); Alexander N. Sprafke, Martin-Luther Univ. Halle-Wittenberg (Germany); Jung Ho Lee, Hanyang Univ. (Korea, Republic of); Ralf B. Wehrspohn, Martin-Luther Univ. Halle-Wittenberg (Germany) and Fraunhofer-Institut für Werkstoffmechanik (Germany)

Silicon nanowire arrays seems to be a promising architecture for solar energy conversion systems. By metal assisted chemical etching large areas of high quality nanowires can be produced on multi-crystalline silicon substrates. These areas show a low reflectance comparable to black silicon.

Here we studied multi-crystalline silicon nanowires for photoelectrochemical hydrogen generation. Nanowire array architecture provides good optical absorption along its axial direction, while facilitating collection of carriers radially. Because of the small diameter the limited minority diffusion length is no handicap.

A prototype cell showed enhanced open circuit voltage. However with increasing nanowire length lots of surface states were introduced leading to severe surface recombination. As a result the photocurrent is greatly reduced. Therefore the nanowire length should be well controlled.

The nanowire can greatly reduce the on-set potential for water splitting. The reason is that Si-H bond would attract electrons from inside of nanowire, leading to the enhanced p-type doping in nanowire.

8823-1, Session 1

Cu(In,Ga)Se2 semiconductor formation via the laser annealing of electrodeposited precursors

Helen J. Meadows, Univ. du Luxembourg (Luxembourg); Ashish Bhatia, The Univ. of Utah (United States); Christiane Stephan, Susan Schorr, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany); Michael A. Scarpulla, The Univ. of Utah (United States); Phillip J. Dale, Univ. du Luxembourg (Luxembourg)

Cu(In,Ga)Se2 is used as an absorber layer material for thin film photovoltaic devices with record power conversion efficiencies of >20%. In order to make such devices more economical, production costs need to be minimized. Electrodeposition of the absorber layer offers a low cost and resource efficient production route. However, the precursor film produced by this technique is a nanocrystalline, inhomogeneous material that requires thermal treatment to obtain good semiconductor properties. By combining electrodeposition with laser annealing we aim to investigate a possible high speed and economic production route.

Previously, we demonstrated that continuous wave laser annealing using a 1064 nm Nd:YAG laser at fluxes between 720 – 1080 Wcm-2 for one second improved crystallinity and optoelectronic properties of the electrodeposited material.

Here, we carry out a detailed structural characterisation of electrodeposited CuInSe2 and Cu(In,Ga)Se2 precursors annealed with this laser at fluxes of 50 and 945 Wcm-2. However, all films show the presence of secondary phases which will reduce device efficiency. In order to both improve the material and refine the annealing process, these phases must be identified. XPS and Raman analysis suggest the presence of a Cu-poor region at the surface. Additionally, grazing incidence XRD measurements evidence In-rich secondary phase(s) through the full depth of the absorber layer, for example CuIn3Se5 or In2Se3 which may stem from decomposition of CuInSe2. The presence of these phase(s) irrespective of precursor type and annealing conditions as well as past literature also suggests that this stems from the Cu-poor precursor composition.

8823-2, Session 1

CIGS thin film solar cell prepared by reactive co-sputtering

Jeha Kim, Cheongju Univ. (Korea, Republic of)

The reactive co-sputtering was developed as a new way of preparing high quality CuInGaSe2(CIGS) films from two sets of targets; Cu0.6Ga0.4 and Cu0.4In0.6 alloy and Cu and (In0.7Ga0.3)2Se3 compound targets. During sputtering, Cu, In, Ga metallic elements as well as the compound materials were reacted to form CIGS simultaneously in highly reactive elemental Se atmosphere generated by a thermal cracker. CIGS layer had been grown on Mo/soda-lime glass(SLG) at 500?C. For both sets of targets, we controlled the composition of CIGS thin film by changing the RF power for target components. All the films showed a preferential (112) orientation as observed from X-ray diffraction analysis. The composition ratios of CIGS were easily set to 0.71-0.95, 0.10-0.30 for Cu/[III] and Ga/[III], respectively. The grain size and the surface roughness of a CIGS film increased as the Cu/[III] ratios increased. The solar cells were fabricated using a standard base line process in the device structure of grid/ITO/i-ZnO/CdS/CIGS/Mo/ SLG. The best performance was obtained the performance of Voc = 0.45 V, Jsc =35.6, FF=.535, efficiency = 8.6% with a 0.9 ?m-CIGS solar cell from alloy targets while Voc = 0.54 V, Jsc =30.8, FF=.509, efficiency = 8.5% with a 0.8 ?m-CIGS solar cell from Cu and (In0.7Ga0.3)2Se3. In this paper, we report the growth and characterization of reactively co-sputtered CIGS thin films and the fabrication of solar cells.

8823-3, Session 1

How does the selenium activity influence CuInSe2 devices grown under Cu-excess?

Valérie Deprédurand, Tobias Bertram, Jennifer Luckas, Susanne Siebentritt, Univ. du Luxembourg (Luxembourg)

In spite of their better electronic properties, Cu-rich based CuInSe2 solar cells, limited by a high native doping which leads to tunneling enhanced recombination and shorter space charge region, performed worse than the Cu-poor ones. In order to decrease this doping, we investigate the effect of the selenium environment during the absorber growth, as it is known that changes in the selenium content of the material have dramatic consequences for the electronic structure. The selenium activity in the films was varied by either changing the selenium fluxes or by supplying different selenium species via our cracking system.

We demonstrate that the chemical activity of the selenium during the growth strongly influences both the film macrostructure and the solar cell performance. Firstly, X-Ray Diffraction measurements reveal that the texture of the absorbers is clearly affected by the selenium activity. Furthermore, all the solar cells characteristics improved, the efficiencies increasing from 4,3% to 8,6% with decreasing selenium activity. Intriguingly, this behavior is exactly the opposite of the Cu-poor ones.

We suspect that under low selenium activity, selenium vacancies are created which impact the doping of the Cu-rich material. A complete characterization of the defects levels via photoluminescence measurements on the films, admittance and capacitance-voltage measurements on the solar cells will be provided. We conclude that selenium deficiency enables reduction of the native doping of this material, which opens the way to benefit fully from the superior properties of this absorber for solar cell applications.

8823-4, Session 2

Spectrally and directionally selective intermediate reflectors for thin-film silicon tandem solar cells

Andre Hoffmann, Ulrich W. Paetzhold, Forschungszentrum Jülich GmbH (Germany); Andreas Lambertz, Forschungszentrum Jülich GmbH (Germany) and Jülich (Germany); Oliver Höhn, Fraunhofer-Institut für Solare Energiesysteme (Germany); Carolin Ulbrich, Karsten Bittkau, Uwe Rau, Forschungszentrum Jülich GmbH (Germany)

In thin-film silicon tandem solar cells, a hydrogenated amorphous silicon (a-Si:H) top cell and a hydrogenated microcrystalline silicon (µc-Si:H) bottom cell are connected in series. The two absorber layers are sensitive to high and low energy photons, respectively. The a-Si:H top cell is strongly affected by light-induced degradation, and a thin top cell is favorable. A spectrally and directionally selective intermediate reflector layer (IRL) eludes the opposing requirements to have a thin cell but a long optical path. The IRL between top and bottom cell is designed to reflect the light which can still be absorbed by the top cell, as well as having a sufficiently high electrical conductivity. Hydrogenated microcrystalline silicon oxide (µc-SiOx:H) is known to be a promising IRL material. By varying the oxygen content, refractive indices between 1.7 and 3 can be achieved. If properly designed, such an IRL reflects light back into the top cell. Yet, a poor spectral selectivity implies optical losses in the bottom cell caused by reflection side-lobes of the IRL in the long-wavelength range. We introduce a µc-SiOx:H-layer stack with alternating refractive indices. This spectrally and directionally selective IRL provides increased reflection in the desired spectral range while suppressing reflection in the long-wavelength range. As shown in wave-optical simulations for a flat layer stack, the reflection side-lobes are reduced leading to a 10% gain of short-circuit current density in the top cell accompanied by a severe reduction of losses of the bottom cell current of 22% compared

to the single layer IRL. First measurements, integrating the µc-SiOx:H layer stacks into thin-film silicon tandem solar cells, are presented and compared to the simulation.

8823-5, Session 2

Optical and electrical modeling of amorphous-silicon tandem solar cell with nonhomogeneous intrinsic layers

Muhammad Faryad, Liu Liu, Theresa S. Mayer, Akhlesh Lakhtakia, The Pennsylvania State Univ. (United States)

A tandem solar cell made of amorphous-silicon alloys backed by a periodically corrugated metallic back-reflector was theoretically investigated. The absorptance for linearly polarized incident plane waves was computed using rigorous coupled-wave approach and the absorptance was used in Synopsys Sentaurus to compute the electrical properties of the solar cell. The intrinsic layers were taken to be nonhomogeneous in order to increase the probability of exciting multiple surface-plasmon-polariton (SPP) waves guided by the metal/semiconductor interface. The excitation of multiple SPP waves was identified by comparing the absorptance spectrums with the solution of the underlying canonical boundary-value problem. An AM1.5 solar irradiance spectrum was considered for computations.

8823-6, Session 2

A novel light trapping concept for liquid phase crystallized poly-Si thin-film solar cells on periodically nanoimprinted glass substrates

Veit Preidel, Daniel Amkreutz, Tobias Sontheimer, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany); Franziska Back, Eveline Rudigier-Voigt, SCHOTT AG (Germany); Bernd Rech, Christiane Becker, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany)

Recent progress in the field of liquid phase crystallization (LPC) of silicon thin films on glass by e-beam yields high quality poly-Si, enabling a-Si:H/poly-Si heterojunction thin-film solar cells with record open circuit voltages up to 580 mV [1]. However, only moderate photocurrents (Jsc ≤20 mA/cm^2) have been achieved so far. Advanced light trapping concepts are therefore needed to fully exploit the efficiency potential provided by the high Voc level. By combining nanoimprint lithography with LPC, we developed a light trapping concept based on two-dimensional periodic scatterers, which is compatible with high temperature e-beam crystallization and industrial processing with respect to large area application and throughput: We imprint a square lattice pattern on Schott AF glass substrates using nanoimprint lithography and a high temperature-stable solgel resist. A boron doped 2-10 µm thick Si absorber is deposited in the nanocrystalline phase by high rate e-beam evaporation at a rate of 0.5 µm/min on the imprinted grating and subsequently liquid phase crystallized using a line-focused electron-beam source. Structural characterization of the textured absorber yields a high crystal quality (FWHM Raman TO phonon =3.4 cm^-1) and large grains (100-1000 µm) extending from the flat silicon-air interface down to the grating. We show that the surface grating leads to strong light trapping enhancing the absorption by more than a factor 3 in the near infrared, while the high electrical material qualitity known from planar layers is maintained. A detailed analysis of the influence of the surface grating on the respective solar cell parameters will be presented.

8823-7, Session 3

Study of the effect of the charge transport layer in the electrical characteristics of the organic photovoltaics

Ronak Rahimi, West Virginia Univ. (United States); V Narang, Vamsi Krishna Kumbham, D. Korakakis, West Virginia Univ (United States); Alex Roberts, West Virginia Univ, United States (United States)

Significant progress in fabrication and optimization of organic photovoltaics (OPVs) has been made during the last decade. The main reason for popularity of OPVs is due to their low production cost, large area devices and compatibility with flexible substrates. Various approaches including optimizing morphology of the active layers, introducing new materials as the donor and acceptor, new device structures such as tandem structure have been adapted to improve the efficiency of the organic photovoltaics. However, electrical characteristics of the OPVs do not only depend on the active layer materials or device structure. They can also be defined by the interface properties between active layers and the charge transport layers or the metal contacts. Within this paper, the effect of the thickness variation of the charge transport layer in the electrical properties of the bilayer heterojunction OPVs has been studied. Several devices with CuPc/PTCDI-C8 as the donor/acceptor layers have been fabricated with different thicknesses of electron transport layer. MoO3 and Alq3 have been used respectively as the hole transport layer (HTL) and the electron transport layer (ETL). It has been shown that the S-shape effect in the current–voltage curve is attributed to the accumulation of the charge carriers at the interface between the active layer and the charge transport layer.

8823-8, Session 3

QCM-D characterization of dye adsorption in TiO2

Hannah K. Wayment-Steele, Lewis E. Johnson, Pomona College (United States); Matthew C. Dixon, Biolin Scientific, Inc. (United States); Malkiat S. Johal, Pomona College (United States)

Understanding dye adsorption and desorption to TiO2 is crucial for designing dye-sensitized solar cells (DSSCs) with enhanced efficiency. Maximizing dye adsorption to the TiO2 semiconductor increases efficiency by increasing the probability of charge transfer to the electrode. Understanding the kinetics of dye adsorption is useful for determining the optimal adsorption time and dye concentration that results in the highest dye loading. The dye monolayer also improves efficiency by acting as a blocking layer to prevent electron recombination from the semiconductor to the liquid electrolyte. One methodology that is used in studying recombination rate is a homogeneous partial coverage dye layer. There has been debate over the effectiveness of certain procedures of combined adsorption and desorption for creating a homogeneous partial coverage layer. A better understanding of the kinetics of desorption has applications in creating optimal partial coverage layers for research. QCM-D provides adsorption measurements in real time and therefore allows one to determine the kinetics of the process. Others have recently demonstrated the applications of QCM-D to show in-situ dye adsorption on flat TiO2 surfaces (Harms et al. 2012). In this work, we characterize the adsorption and desorption of a ruthenium-based dye using a TiO2-coated sensor to simulate the TiO2 substrate of a DSSC. We further propose a model to relate dye adsorption in mesoporous TiO2 and QCM frequency shift for further study.

8823-9, Session 3

Effects of surfactants on agarose-based magnetic polymer electrolyte for dye-sensitized solar cells

Ying Yang, Univ. of Wyoming (United States); Xueyi Guo, Pengfei Yi, Jiarui Cui, Si Xiao, Central South Univ. (China); Wenyong Wang, Univ. of Wyoming (United States)

A new type of magnetic polymer electrolytes is designed for solid-state dye-sensitized solar cell (DSSC) applications with agarose as the polymer matrix and Fe3O4 nanoparticles as the magnetic filler. The magnetic properties of the Fe3O4 nanoparticles is anticipated to prompt the formation of aligned polymer chains in the electrolytes after the application of an external magnetic field, which can improve their ionic conductivity and interfacial contact with the TiO2 porous film. However, due to the small grain size and high surface energy of the Fe3O4 nanoparticles, they are easy to aggregate, which limits the homodispersity of the nanoparticles and hinders the ionic transport in the electrolytes. In this work we utilized four different surfactants, i.e., sodium dodecyl sulfate, polyvinylpyrrolidone, polyethylene glycol (PEG200), and polysorbate 80 (TW-80), to modify the surface properties of the Fe3O4 nanoparticles in order to improve their distribution in the electrolytes and enhance the DSSC performance. TW-80 and PEG200-modified Fe3O4 nanoparticles were found to exhibit improved dispersion properties according to surface morphology characterizations of the electrolytes containing these nanoparticles. Electrochemical impedance spectroscopy measurements revealed improved ionic conductivity in the electrolytes and electron lifetime in the solid-state DSSCs, with TW-80 modified electrolyte achieving the highest ionic conductivity of 2.98 ? 10?3 S/cm. In addition, the DSSCs' performance was also enhanced due to the surfactant modification of the Fe3O4 nanoparticles, and the energy conversion efficiency was increased from 0.8% for the original cell to 1.83% for the cell that had the electrolyte with TW-80 modified Fe3O4 nanoparticles.

8823-10, Session 4

Enhanced light absorption in thin-film solar cells with light propagation direction conversion

Ikuo Suemune, Hokkaido Univ. (Japan)

Enhancement of optical absorption in thin-film solar cells (TF-SCs) has been the long-lasting issue to achieve high efficiencies. Key issues for the photon management in TF-SCs are divided into two categories. One is antireflection of light incident on TF-SCs, and the other is trapping of incident light in TF-SCs. Trapping of incident light has been actively studied employing diffraction gratings. Grating couplers (GC) have been actively studied as a method to trap incident light. GCs convert incident light into guided modes propagating along TF-SCs to extend optical path for higher optical absorption. However the wavelength band for the efficient conversion remained relatively narrow and the overall improvement of TF-SC efficiencies has been limited. This paper demonstrates that the grating height design as well as the phase matching condition is important for the enhancement of optical absorption in TF-SCs. Especially we show that the grating height that gives periodic lateral π-phase shift to the normal incident light gives the key factor to enhance the optical absorption. We demonstrate it with the calculation of short-circuit currents as a figure of merit for optimization. The influence of the light absorption coefficients and grating coupling strengths on the light absorption bandwidth is also discussed.

8823-11, Session 4

Natural evolution inspired design of light trapping structure for thin film organic solar cells

Chen Wang, Shuangcheng Yu, Wei Chen, Cheng Sun, Northwestern Univ. (United States)

Light trapping has been developed to effectively enhance the efficiency of the thin film solar cell by extending the path-length for light interacting with the active materials. Searching for optimal light trapping design requires a delicate balance among all the competing physical processes, including light refraction, reflection, and absorption. The existing design methods mainly depend on engineers' intuition to predefine the topology of the light-trapping structure, because the underlying nonlinear process often hinders the formulation of inverse design problem. However, these methods are not capable of handling the topological variation in reaching the optimal design. In this work, a systematic approach based on Genetic Algorithm is introduced to design the scattering pattern for effective light trapping. Inspired by natural evolution, this method can gradually improve the performance of light trapping structure through iterative procedures, producing the most favorable structure with minimized reflection and substantial enhancement in light absorption. A realistic organic thin film solar cell consists of a 200nm ITO front transparent electrode, a 30nm P3HT:PCBM active layer and a metallic back electrode. The scattering layer consisting of nano-scale patterned front layer is optimized to maximize absorption by strongly coupling incident sun light into the localized photonic modes supported by the multilayer system. Rigorous coupled wave analysis (RCWA) is implemented to evaluate the absorbance. Nearly 50% average absorbance over the solar spectrum is obtained for the optimized scattering pattern, with short circuit current density five times larger than the control case using planar ITO layer.

8823-12, Session 4

Submicron texturing for broadband light management in thin-film PV

Henrik Melkonyan, Sueda Saylan, Masdar Institute of Science and Technology (United Arab Emirates); Andreas Heidelberg, Harald Bloess, Masdar PV GmbH (Germany); Marco Stefancich, Jaime Viegas, Marcus Dahlem, Masdar Institute of Science and Technology (United Arab Emirates)

Developing appropriate light management schemes is one of the challenges in high-efficiency thin-film solar cells research, including minimizing reflection between layers and maximizing the optical path length in the absorbing layers. Traditional approaches are based on anti-reflection coatings (ARCs) and surface texturing. The latter is preferred due to its operation over a wider spectrum and its light scattering capability.

In this work we explore different submicron-scale periodic surface texturing morphologies through finite-difference time-domain (FDTD) computations. The broadband reflection response is studied at air/silica and silica/TO (Tin Oxide) interfaces, within a spectral range of 300-2500 nm. A Drude-Lorentz model is used to account for material dispersion and absorption within the wavelengths of interest. In order to optimize the light trapping performance, two-dimensional transmission and reflection simulations of the surface textures are compared with those of flat interfaces. Numerical results demonstrate a reduction in reflection for the air/silica interface to values below 1%, compared to up to 4% for the non-textured interface. For the silica/TO interface, reflection decreases to less than half when compared to the non-textured interface. Further structures that replicate perfect multiple-layer anti-reflection coatings are also studied. These structures are tuned to cancel specific wavelengths and can create an arbitrary effective index, overcoming the constraint of available discrete refractive indices. The best texturing results obtained for the air/silica and silica/TO interfaces are combined in one stacked structure, achieving reflection values about one order of magnitude below, when compared to a non-textured air/silica/TO stack.

8823-13, Session 5

Reactive sputtering of amorphous In-Zn-O TCO from metallic targets

Thomas Gennett, John D. Perkins, Meredith Nix, Arrelaine A. Dameron, David S. Ginley, National Renewable Energy Lab. (United States)

Amorphous In-Zn-O (a-IZO) transparent conducting oxides with conductivity ? ≈ 3000 S/cm can be sputter deposited at ambient temperature, are damp heat resistant and have been demonstrated to work well at transparent contacts for CIGS PV and Epi-Si PV. However, the high cost of ceramic In-Zn-O sputter targets has limited the widespread use of a-IZO TCOs in PV. Here, we demonstrate a new process that results in conductive and transparent a-InZnO thin films deposited via reactive sputtering from a metallic In-Zn alloy target. The highest conductivity obtained to date, ? ≈ 2100 S/cm, is an order of magnitude higher than the previous best literature result for reactively sputtered a-InZnO.

A series of 70 nm thick a-In-Zn-O thin films were grown on 2”x2” Eagle 2000 glass substrates by sputtering from a 3” diameter 87:13 In:Zn wt. % metal alloy target. We have found through a series of RF, DC and RF superimposed DC deposition techniques that DC sputtering produced the best results. Through careful control of target power density and incorporation of a high throughput cathode cooling circulator, we were able to avoid any melting of the high indium content target. The total deposition pressure was 2.5 mTorr from a 20 sccm total gas flow with approximately a 4:1 Argon-O2 flow ratio. First, in order to obtain the reproducible results necessary to enable reproducible experimental control the conductivity and transparency, it was necessary to obtain a stable surface composition on the metallic-target by pre-sputtering before deposition. Through control of process gas composition, the thin film transparency and conductivity could be varied from dark grey and metallic (<80% transmissive) (too little oxygen); to clear (>90% transmissive) and conducting (~16 – 18 % O2 in Ar); to clear/yellow (>90% transmissive) and low conductivity (too much oxygen). The best samples had ? ≥ 2000 S/cm with 90 % transparency. The X-ray diffraction measurements show the films to be amorphous. We will discuss how that it is essential to realize how and why that in order to optimize the conductivity of a-InZnO thin films careful Indium-content-specific control of the oxygen content within the sputter gas mix is required.

8823-15, Session 5

Electrical properties of point defects in CdS from first principles

Joel B. Varley, Vincenzo Lordi, Lawrence Livermore National Lab. (United States)

One of the most significant sources of efficiency loss in manufactured thin-film solar cells is absorption by the buffer layer without contributing useful photocurrent. The most common buffer layer material is cadmium sulfide (CdS), which exhibits very good electrical properties, but whose band gap (2.4 eV) is too small to be transparent to the entire solar spectrum. The use of a wider band gap material with good electrical properties is desired, but the precise material characteristics dictating the electrical properties are not fully understood. Here we present a first principles study of the thermodynamic and electrical characteristics of intrinsic (vacancy, interstitial, antisite) and common extrinsic (O, OH, Na, C, N) point defects in CdS, to serve as a reference. We use density functional theory to calculate the structures, formation energies, and energy levels the defects, from which we analyze the electrical nature, carrier compensation, and carrier recombination properties of the defects, in the context of buffer layer electrical properties in a thin-film solar cell. Correlation of defect properties with growth conditions is made in terms of film stoichiometry and presence of impurities. Prepared by LLNL under Contract DE-AC52-07NA27344; supported by the DOE EERE SunShot/BRIDGE program.

8823-17, Session 6

Characterization of printed CZTSSe films for photovoltaic applications

Wei Wu, Yanyan Cao, Jonathan V. Caspar, Qijie Guo, Lynda K. Johnson, Irina Malajovich, H. David Rosenfeld, Kaushik Roy Choudhury, Lee Silverman, DuPont (United States)

Cu2ZnSn(S,Se)4 (CZTSSe) is a promising alternative absorber material for thin-film photovoltaic applications because of its earth-abundant and non-toxic constituents, tunable band gap, and high optical absorption coefficient. Recently, we have reported a high efficiency (8.5% conversion efficiency) PV (photovoltaic) device employing CZTSSe thin film prepared by solution based chemical method (Cao et al, J. Am. Chem. Soc., 2012, 134 (38), 15644), which offers the exciting prospect of low-cost scalable processing routes to solar cells. In this talk, we will present more detail on the electrical characterization of these printed CZTSSe films. We will combine the experimental optoelectronic properties of the CZTSSe films and their corresponding PV devices to develop numerical models for the CZTSSe devices. We will compare the model results with real devices and discuss possible efficiency loss mechanisms and potential paths for device improvement.

8823-18, Session 6

Fabrication of Cu2ZnSnSe4 solar cells by liquid-phase pulsed laser ablation (LP-PLA) and electrophoretic deposition (EPD)

Wei Guo, Bing Liu, IMRA America, Inc. (United States); Mingjie Xu, Xiaoqing Pan, Univ. of Michigan (United States)

Previously, we have successfully developed a non-vacuum and environmental-friendly technique for fabrication of Cu(In,Ga)Se2 thin film solar cells using liquid-phase pulsed laser ablation (LP-PLA) and electrophoretic deposition (EPD). In this report, we extend this approach for fabrication of Cu2ZnSnSe4 (CZTSe) absorber layers, and achieve 4.77% power conversion efficiency for lab-scale CZTSe solar cells.

First, colloidal metallic nanoparticles of Cu-Zn-Sn (CZT) alloys are produced by pulsed laser ablation of a bulk alloy target in common organic solvents. Without addition of stabilizing ligands, the nanoparticles are found to be electrostatically stabilized against agglomeration. Without transferring to another solvent and without using additional binders, precursor CZT films are rapidly deposited on Molybdenum sheet substrates using two-electrode electrophoretic deposition in the as-made colloids. Highly pure and compact CZT thin films are obtained after optimization of the deposition parameters. Finally, the precursor CZT films are selenized in Se vapor to form well-crystallized CZTSe absorber layers, and solar cells are finished with standard procedures. Energy conversion efficiency up to 4.77% is measured for such cells fabricated on Molybdenum sheet substrates with VOC=0.32 V, JSC=34.7 mA/cm2, and fill factor=43.5%. XRD, SEM-EDS, and Raman spectroscopy are provided to characterize film structure, composition, and impurities. High resolution transmission electron microscopy (HRTEM) is also performed to study the colloidal nanoparticles’ microstructure and extended defects (e.g. grain boundaries) in the CZTSe absorber layers.

Particular advantages of the LP-PLA/EPD approach include high deposition rate (?m/min), nearly zero chemical waste, and compliance with streamline-based coating on flexible substrates or complex surfaces.

8823-19, Session 6

Synthesis of colloidal Cu2ZnSnS4 nanocrystals with different compositions and sizes for solar cell applications

Satoshi Suehiro, Keisuke Horita, Masayoshi Yuasa, Kyushu Univ. (Japan); Tooru Tanaka, Saga Univ. (Japan); Katsuhiko Fujita, Tetsuya Kida, Kengo Shimanoe, Kyushu Univ. (Japan)

There have been intensive efforts to use semiconductor nanocrystals(NCs) for solar cells with low cost and high efficiency. It has been reported that solar cells using photo absorber layers based on nanocrystals such as PbSe, CdTe, Cu(In1-x,Gax)Se, etc. shows efficiencies ranging of 1-5%. However, these materials are not preferable for practical application due to the cost and scarcity problems of Cd, In, Ga. Thus, one major challenge for thin film solar cells based on NCs is develop materials composed of earth abundant and nontoxic elements.

Cu2ZnSnS4 (CZTS) is composed of earth abundant, nontoxic elements, and has feature suitable for solar cells, including a direct band gap of ~1.5 eV ,and large absorption coefficient of ~1?104 cm-1. There have been efforts to synthesis CZTS nanocrystals and to use it for solar cells, but the device performance remains relatively low. In addition, the device fabrication process and device performance have not yet been well studied. In this study, we attempted to develop a feasible way for making CZTS thin film for solar cell applications. We also studied the effects of composition and sizes of CZTS nanocrystals on the performance solarcell made with a CZTS nanocrystal ink.

CZTS NCs were synthesized by heating metal acetylacetonates and elemental sulfur in Oleylamine at 220 C .their compositions was controlled by changing starting precursor compositions. Heterojunction having a structure ITO/ZnO/CdS/CZTS NCs/ Au were fabricated by wet processes. They showed photovoltaic effects, largely depending on the composition of CZTS nanocrystals.

8823-20, Session 6

A two-step synthesis of earth-abundant solar cell material, CZTS by co-sputtering and sulfurization

Nadarajah Muhunthan, Om Pal Singh, Nita Dilawar, Rashmi Rashmi, Keadr Nath Sood, Vidya Nand Singh, National Physical Lab. (India)

For the fabrication of low cost and sustainable thin film solar cells, it is essential that it should be made from earth abundant materials. Copper zinc tin sulfide (CZTS) is such a material. In the present study, CZTS thin films have been synthesized using co-sputtering and sulfurization. The co-sputtering was carried out by sputtering three metallic targets (Cu, Zn and Sn) simultaneously. Cu was sputtered using DC power; Zn and Sn were sputtered using RF power. The grown films were 800 nm -1000 nm thick. The deposition rate was 7- 10 nm/min. The sulfurization was carried out in a horizontal tube furnace using H2S diluted with argon (H2S-15% and Ar-85%) with a flow rate of 12.5 sccm. The furnace temperature was increased to 400oC in 10 min. Then, the temperature was increased from 400oC to 550oC in another 10 min and was kept at 550oC for 25 min. Finally, furnace was cooled down to room temperature. The films were characterized for its structural, optical and electrical properties. Grazing incidence XRD analysis showed that sulfurized films were having phase pure CZTS (kesterite structure) with orientation along (112) plane. Raman peak at 336 cm-1 confirmed the kesterite structure of CZTS films. The energy dispersive x-ray spectroscopic (EDS) analysis showed that the film consisted of Cu, Zn, Sn and S only; no other elements were detected in EDS analysis. SEM analysis showed a homogeneous, compact surface morphology and large columnar grains throughout the surface of the film. The CZTS films were having optical absorption coefficient higher than 104 cm-1 and an optical band gap of 1.50 eV was estimated using the Tauc's plot. The resistivity and activation energy of the CZTS film are 6.4 ?cm and 16 meV, respectively. The optical and electrical properties show that films are suitable for thin film solar cell applications.

8823-21, Session 6

Fabrication and analysis of high-efficiency CdTe thin-film solar cells *(Invited Paper)*

Yanfa Yan, Naba Paudel, The Univ. of Toledo (United States); Jonathan D. Poplawsky, Chen Li, Stephen J. Pennycook, Oak Ridge National Lab. (United States); John Moseley, Helio R. Moutinho, Mowafak M. Al-Jassim, National Renewable Energy Lab. (United States)

We report on our recent progress on the fabrication and analysis of high-efficiency CdS/CdTe thin-film solar cells. High-efficiency CdTe thin-film solar cells were fabricated on commercial SnO2:F-coated soda-lime glass substrates. The CdTe absorbers were deposited by close-spaced sublimation. The best small-area cell has shown an efficiency of 15.5% with an open-circuit voltage of 844 mV, a short-circuit current of 24.0 mA/cm2 and a fill-factor of 76.6% measured under an AM1.5 illumination. The cells were systematically characterized by current-voltage (J-V) and quantum efficiency (QE) measurement and electron-based techniques such as electron-beam induced current (EBIC), cathodoluminescence (CL), electron back scattered diffraction (EBSD), electron energy loss spectroscopy (EELS), and imaging. The characterization and analysis provided critical understanding on how the high-efficiency cells are achieved. We find that high-efficiency solar cells exhibit the following characteristics: (1) Grain boundaries are well passivated by Cl during the CdCl2 heat treatment, (2) CdTe/CdS junctions are optimized by incorporating O in CdS, (3) The back contacts must have resistance. In this presentation, we will review the device processes applied to realize these characteristics and characterization results obtained from high-efficiency CdTe thin-film solar cells.

8823-22, Session 6

Solution-processed CdTe/ZnO nanocrystal solar cells

Scott E. Watkins, Commonwealth Scientific and Industrial Research Organisation (Australia); Brandon I. MacDonald, Commonwealth Scientific and Industrial Research Organisation (Australia) and The Univ. of Melbourne (Australia); Jacek J. Jasieniak, Commonwealth Scientific and Industrial Research Organisation (Australia)

This paper describes the fabrication of thin film solar cells based on nanocrystal inks of CdTe. We demonstrate that totally solution processable solar cells can be fabricated in air at temperatures as low as 300 °C. Focusing on a CdTe/ZnO thin-film system, we report solar cells that achieve power conversion efficiencies of upto 10% with greater than 90% internal quantum efficiency. In our approach, nanocrystals are deposited from solution in a layer-by-layer process. Chemical and thermal treatments between layers induce large scale grain formation, turning the 4 nm CdTe particles into pinhole-free films with an optimized average crystallite size of ?70 nm. Through capacitance-voltage measurements we demonstrate that the CdTe layer is fully depleted which enables the charge carrier collection to be maximized. We will also discuss in detail the processing conditions that can be used to optimise these devices. We show that the extent of grain growth achieved during the CdTe sintering process is strongly dependent on the nanocrystal surface chemistry, with removal of the organic capping ligands prior to annealing leading to greatly enhanced growth. The overall performance of these solar cells is shown to be strongly dependent on both annealing temperature and time, with optimal results requiring a balance between crystal growth and degradation.

8823-23, Session 6

4-terminal tandem photovoltaics with organic top cells on CIGS bottom cells

Zach M. Beiley, Mark G. Christoforo, Andrea R. Bowring, Stanford Univ. (United States); Paul Gratia, Ecole Polytechnique Fédérale de Lausanne (Switzerland); Michael D. McGehee, Stanford Univ. (United States)

It is estimated that for photovoltaics to reach grid parity around the planet, they must be made with costs under $0.50 /Wp, and in order to keep installation costs down, must also achieve power conversion efficiencies above 20%. Recently we proposed a novel solar cell architecture, a hybrid tandem photovoltaic (HTPV), in which the top cell is an emerging photovoltaic technology that can be deposited at low temperatures and with rapid throughput, such as an organic or dye-sensitized cell, and the bottom cell is one of a variety of traditional inorganic photovoltaics, such as silicon or CIGS. Our efforts in modeling have already demonstrated that it should be possible to add an organic photovoltaic on top of moderately efficient silicon and CIGS bottom cells to improve their efficiencies to over 20%. In this work, we demonstrate a prototype HTPV device, which consists of an organic photovoltaic that is mechanically stacked on a CIGS bottom cell. In this architecture, the top and the bottom cells each have their own electrodes, which removes the current matching constraint of traditional tandem cells and allows for the independent optimization of the subcells. To make high performing organic top cells with two transparent electrodes, we use meshes of silver nanowires embedded in a less conductive material to fill the gaps in the mesh. We present our strategy for fabricating these electrodes and discuss the developments in organic photovoltaic technology that will be necessary to push HTPV efficiencies above 20%.

8823-25, Session PMon

Comparison of CIGS thin films prepared by sequential HiPIMS or DC magnetron sputtering and selenization process

Jirí Olejnícek, Zdenek Hubicka, Petra K?írová, ?tepán Kment, Michaela Brunclíková, Michal Kohout, Martin Cada, Institute of Physics of the ASCR, v.v.i. (Czech Republic); Scott A. Darveau, Christopher L. Exstrom, The Univ. of Nebraska at Kearney (United States)

Cu(In,Ga)Se2 (CIGS) thin films were prepared by two-step process using DC or High Power Impulse Magnetron Sputtering (HiPIMS) of metallic precursors followed by selenization in Se or Ar+Se atmosphere. Single composite target (2”) with stoichiometry Cu0.45In0.40Ga0.15 was used for sputtering of metallic precursors. Repetition frequency of HiPIMS excitation was 100 Hz (T=10 ms) and active pulse duration 100 µs (duty cycle 1%). Maximum peak current was 18 A. Average absorbed power, cathode voltage and discharge current was in HiPIMS and DC plasma the same. Some plasma parameters were analyzed by Optical Emission Spectroscopy (OES), voltage and current waveforms were monitored by digital oscilloscope. Properties of resulting CIGS films were measured by X-ray diffraction (XRD), Raman spectroscopy, scanning electron microscopy (SEM), energy-dispersive X-ray spectroscopy (EDX) and some electrical characteristics were measured by Van der Pauw method. The basic aim of this work is to compare main properties of final layers depending on magnetron excitation mode and thermal treatment. All the CIGS films revealed chalcopyrite crystal structure with preferential (112) orientation, perfect stoichiometric composition and average resistivity about 0.15 ?•cm. Only very small influence of magnetron excitation mode on thin films properties was observed. On the other side selenization in Ar+Se atmosphere led to bigger grain size, smoother surface, better crystallinity and significantly higher level of Ga substitution.

8823-26, Session PMon

Plasmonic nanodot array optimization on organic thin film solar cells using anodic aluminum oxide templates

Kyuyoung Bae, Kyoungsik Kim, Yonsei Univ. (Korea, Republic of)

The fabrication method of plasmonic nanodots on ITO substrate has been developed to improve the efficiency of organic thin film solar cells. Metallic nanodot array on ITO substrate shows a Surface Plasmon Resonance in optical wavelength region and the Surface Plasmon Resonance helps the improvement of absorption in photovoltaic materials. Nanoscale metallic nanodots arrays are fabricated by anodic aluminum oxide (AAO) template mask which can have different structural parameters by varying anodization conditions. Structural parameters such as periodicity, radius and height of the metallic nanodots are controlled by anodizing voltage and pore widening time of AAO, and deposition time of metal. In this letter, the structural parameters of metallic nanodots, which can be controlled by the diverse structures of AAO template mask, are investigated to enhance the optical properties of organic thin film solar cells. It is found that optical properties of the organic thin film solar cells are clearly improved by finding optimization values of the structural parameters of the metallic nanodots array.

8823-27, Session PMon

Study of the chemical composition and structural properties of the CZTSe thin films

Anatoliy S. Opanasyuk, Sumy State Univ. (Ukraine); Hyeonsik Cheong, Sogang Univ. (Korea, Republic of); Aleksey E. Bolotnikov, Brookhaven National Lab. (United States); Pavel Koval, Sumy State Univ. (Ukraine); Ralph B. James, Brookhaven National Lab. (United States)

The Cu2ZnSnSe4 (CZTS?) thin films attract great attention as a new abundant and nontoxic material for photovoltaic technology instead conventional CIS, CIGS and CdTe compounds.

The CZTS? thin films were obtained by the co-evaporation of the components on the Mo coated glass substrate. The structural properties of the samples were studied by the X-ray diffraction method. In order to study chemical composition of the thin films the proton induced X-ray emission (PIXE) method was used. The ?-PIXE setup consists of proton accelerator complex “Sokol” (Institute of Applied Physics, Sumy, Ukraine) which provide formation of the proton beam proton beam with the energy of 1.5 eV and microprobe channel allowing to focus proton beam on the sample surface (spot size of about 9?6 µm). The scanning area was 200?200 µm. The chemical composition was tested for the two randomly selected points on a surface.

The X-ray analysis of the thin films revealed practically single phase tetragonal structure with the growth texture along [211]. The lattice parameters are varied in the following ranges a=(0.56640-0.56867) nm, ?=(1.13466-1.13776) nm (?/2a = 0.9983-1.0017).

As a result of a PIXE analysis the influence of the growth conditions on the samples chemical composition was determined, as well as surface distribution map.

8823-28, Session PMon

Structural and substructural features of chemically deposited zinc oxide thin films

Taisia Berestok, Anatoliy S. Opanasyuk, Sumy State Univ. (Ukraine); Aleksey E. Bolotnikov, Ralph B. James, Brookhaven National Lab. (United States); Petro M. Fochuk, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

Due to its low toxicity, Cd-free, large band-gap (Eg=3.37 eV) zinc oxide is an effective absorber of ultraviolet radiation and perspective material for use as conductive and optical cover layers of large-area solar cells. There are many methods of obtaining ZnO thin films. But recently much attention has been attracted to fabrication of this material by chemical methods because of their efficient, cost-effective and large-scale capability.

The deposition of ZnO thin films was carried out by chemical bath deposition from a zinc nitrate and hexamethylene tetramine solution. The temperature of the initial solution was 368 K. The duration of the deposition was varied in the range from 60 min to 180 min. Structural and sub-structural investigations were carried out using high-resolution scanning electron microscopy and X-ray diffraction method.

These experiments enabled us to study features of the films' structure formation and to determine basic structural characteristics (phase analysis, texture quality, lattice constants, grain size, coherent scattering domain size (CSD), and concentration of dislocations). It is shown that the films have a hexagonal structure ZnO with lattice constants of a=0.33895 and c=0.51446 nm and growth texture [100]. The values of CSD were equal to L(100) = (40-82) nm and L(101) = (30-70) nm. Regimes of the deposition of the films with optimal structural characteristic for use in the solar-energy industry were found.

8823-29, Session PMon

THIN MULTI JUNCTION SOLAR CELLS OF III-V MATERIALS TO ADVANCE SOLAR ENERGY HARVESTING

Stefania A. Castelletto, Albert Parker, RMIT Univ. (Australia)

Thin film silicon solar cells have very low collection efficiency. Surface nanostructures may significantly improve this efficiency working on the light trapping and the conversion of the light in electron flow. The most promising solutions mimic nature in the shape of the nanostructure above the silicon layer and/or use the properties of other semiconductor of better than silicon performances. Results of finite difference time domain simulations obtained with the new Lumerical software are presented in details for the composite thin film solar cells with the proposed surface textures.

8823-31, Session PMon

Characterization of semiconductor materials with lifetimes from ns to ms using time-correlated single photon counting

Volker Buschmann, Felix Koberling, Peter Kapusta, Uwe Ortmann, Tino Roehlicke, Michael Wahl, PicoQuant GmbH (Germany); Hannes Hempel, Christian Kraft, Friedrich-Schiller-Univ. Jena (Germany); Maurizio Roczen, Bernd Rech, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany); Rainer Erdmann, PicoQuant GmbH (Germany)

The luminescence lifetime of semiconductor materials can vary over a broad range from microseconds to milliseconds for indirect semiconductors like Si down to sub-nanoseconds for III/V and II/VI based thin film or organic materials. The lifetime of a given wafer sample depends on the free charge carrier dynamics and therefore strongly on the sample preparation. An important example is the influence of bulk or surface defects [1], thus the luminescence lifetime is a possible indicator for wafer quality. Luminescence of individual layers can be addressed by spectral means [2].

We have modified a recently developed setup for time-resolved photoluminescence measurements (TRPL) based on pulsed diode lasers and time-correlated single photon counting with highly sensitive single photon detectors to study the luminescence lifetime dependence of polycrystalline CdTe on activation and deposition conditions by time and spatially-resolved photoluminescence measurements.

TRPL measurements on indirect semiconductors require only a relatively low time resolution, but short dead times of the photon counting electronics are beneficial to avoid long acquisition times and dead-time induced artifacts. To address this time-range, a new photon counting unit with only a few nanoseconds dead time was integrated into the TRPL-mapping system and used to monitor the luminescence of silicon nanodots.

8823-32, Session PMon

Structural and interfacial properties of large area n- a-Si:H/i-a-Si:H/p-c-Si heterojunction solar cells

Kutsal Bozkurt, Orhan Ozdemir, Denep Y. Menda, Y?ld?z Teknik Üniv. (Turkey); Ozlem G. Pehlivan, TÜBITAK (Turkey); Okan Yilmaz, TUBITAK UME (Turkey); Alp O. Kodolbas, TÜBITAK National Metrology Institute (Turkey); Ozgur Duygulu, Middle East Technical Univ. (Turkey); Mehmet Tomak, TÜBITAK (Turkey)

Large area (72 cm2) doping inversed HIT solar cells (n-a-Si:H/i-a-Si:H/p-c-Si) were investigated by High Resolution Transmission Electron Microscopy (HR-TEM), Spectroscopic Ellipsometry (SE), Fourier Transform Infrared Attenuated Total Reflection spectroscopy (FTIR-ATR) and current-voltage (I-V) measurement. Mixture of microcrystalline and amorphous phase was identified via HR-TEM picture at the interface of i-a-Si:H/p-c-Si heterojunction. Using multilayer and Effective Medium Approximation (EMA) to the SE data, excellent fit was obtained, describing the evolution of microstructure of a-Si:H deposited at 225 °C on p-c-Si. Cody energy gap with combination of FTIR-ATR analyses were consistent with HRTEM and SE results in terms of mixture of microcrystalline and amorphous phase. Presence of such hetero-interface resulted poor open circuit voltage, Voc, of the fabricated solar cell devices, determined by I-V measurement under 1 sun. Moreover, Voc was also obtained from dark I-V analysis, revealing consistent Voc values. Efficiency of fabricated cells over complete c-Si wafer (72 cm2) was calculated as 4.7 and 9.2 %. Improvement in efficiency was interpreted due to the back surface cleaning and selecting aluminum/silver alloy as front contact.

8823-33, Session PMon

Surface photovoltage as a tool to monitor the effect of hydrogen treatment on a-Si:H/c-Si heterojunction

Luca Martini, Domenico Caputo, Rita Asquini, Giampiero de Cesare, Univ. degli Studi di Roma La Sapienza (Italy); Luca Serenelli, Massimo Izzi, Mario Tucci, ENEA (Italy)

The tendency on shrinking the mono crystalline silicon wafer thickness lower than 100 ?m is delivering the use of low temperature processes to avoid thermal stress and wafer bowing. This issues can be faced with amorphous/crystalline (a-Si:H/c-Si) silicon heterostructure in which the thin a-Si:H layers are deposited by Plasma Enhanced Chemical Vapour Deposition (PECVD) system at temperature below 300°C. Nevertheless this technology has already demonstrated its potentiality leading to high efficiency solar cell device, investigation are still running concerning the c-Si surface conditioning, amorphous materials and hydrogen plasma treatments to improve the interface quality. In this framework we propose the use of Surface Photovoltage (SPV) technique to evaluate the density of state at the heterointerface that is the most relevant issue to be controlled to achieve high performance solar cell. The SPV technique is utilized as contact-less measurement tool of the energetic distribution of the interface state density surface that imposes a band-bending at the heterointerface. The band-banding can be modulated by an external bias voltage establishing a correlation between silicon substrate preparation, resulting charge, density and energetic distribution of rechargeable interface states. In this work, after a brief description of the SPV technique adopted, the effect of hydrogen treatments performed before and/or after amorphous silicon deposition is evaluated. Defect density at the a-Si:H/c-Si heterointerface and SPV transient phenomena related to both surface recombination and crystalline silicon bulk lifetime are presented and detailed discussed to establish the effectiveness of hydrogen plasma treatments to improve the solar cell performances.

Sunday - Tuesday 25–27 August 2013

8824-1, Session 1

Towards low cost full spectrum photovoltaic systems: choice of materials, devices, system designs, and integrated manufacturing processes *(Invited Paper)*

Partha S. Dutta, Rensselaer Polytechnic Institute (United States)

The efficiency of silicon based single junction photovoltaic (PV) technology is reaching its theoretical limit of around 25% and the cost of large area panels is rapidly declining world-wide. Hence research for any future PV technologies must be focused in the direction of developing higher efficiency systems at low cost to successfully compete with alternative energy generation technologies. At the same time, using earth abundant materials and systems that could be easily recycled after it usable operating lifetime must be considered for sustainability. For developing high efficiency systems, pathways to convert the entire solar spectrum using tandem or stacked solar cells with different bandgaps are well known for decades. Space grade tandem solar cells are known to provide conversion efficiencies close to 40%, but at economies that are not feasible for terrestrial deployments. This talk will present a suite of research topics in the areas of nano- and micro scale materials synthesis, simple device designs and methodologies to integrate materials and devices into PV systems using low cost processing technologies. In particular, progress made in the areas of (a) layered semiconducting compounds that enables large area exfoliation and ease of metal contacts for effective charge transport (compared to other form factors of nano-scale materials), (b) edge illuminated devices avoiding grid shadowing effects and (c) mechanically stacked multiple bandgap devices will be presented.

8824-2, Session 1

Ultra-high efficiency compact solar modules enabled by photonic superprisms *(Invited Paper)*

Peter Bermel, Purdue Univ. (United States)

There is currently a great demand for portable, flexible solar systems offering efficiencies exceeding the Shockley-Queisser limit of 31% for unconcentrated sunlight. In this work, we present a novel approach to designing 1” diameter self-contained modules utilizing self-assembled photonic crystal superprisms for high-performance spectral splitting and light trapping by multiple distinct bandgap PV materials. Advantages of this approach include high spectral splitting performance, wide solar acceptance angles, metallic nanostructures for improved heat sinking, low material deposition costs, and amenability to large-scale manufacturing utilizing self-assembly and flip-chip integration.

8824-3, Session 1

High efficiency solar spectrum splitting using multilayer chirped high-contrast subwavelength grating

Yuhan Yao, He Liu, Wei Wu, The Univ. of Southern California (United States)

In order to harvest solar energy with efficiency beyond the state-of-the-art solar cells, spectrum splitting schemes were proposed. However, most of those systems are based on bulky geometrical optical elements and expensive optical filters, and require drastic change from convention photovoltaic setup.

We invented a new spectrum splitting system. The key element in the invention is a high-efficiency planar dispersive mirror, which will be used to replace the mirror in a solar concentrator. The dispersive mirror is based on multilayer of chirped sub-wavelength high-contrast dielectric gratings (HCGs). The sunlight will be reflected dispersively to each cell, which are arranged in parallel, according to the wavelength. Lights with short wavelength are reflected dispersively by the top HCG layer, and longer wavelengths go through top layers and are reflected by lower layers to different angles.The properly chirped HCG in each layer controls the wavefront of the 0st order diffraction. In our work, the structure and parameter for multi-layer dispersive mirrors (stacked HCGs) are designed and optimized based on numerical (FDTD and RCWA) study. For our structures, the physics behind reflection and phase shift characterization are studied. Our numerical work shows that the dispersive mirror can direct light of different wavelengths into different angles for the entire solar spectrum, maintaining very low energy loss. The dispersive mirror will be fabricated using low-cost nanoimprint lithography. Our approach does not only improve the energy harvesting efficiency, but also lower the cost by using low-cost single junction cells. Moreover, this approach has the minimum disruption to the existing infrastructure.

8824-4, Session 1

Simulation of photovoltaic performance in a thin film, hybrid heterojunction incorporating a nanoscale semiconductor spectral sensitizer

Scott Devalle, The Univ. of Arizona (United States); Jean B Kana-Kana, Materials Science and Engineering, Univ of Arizona (United States); Kelly Simmons-Potter, Barrett G. Potter Jr., The Univ. of Arizona (United States) and College of Optical Sciences, The Univ. of Arizona (United States)

Nanoscale semiconductor structures offer unique optical and electronic characteristics of significant import to enhanced solar spectral coverage and energy conversion efficiency in photovoltaics (PV). Our past work in optoelectronic CdTe-ZnO nanocomposites has identified multilength scale structural designs furnishing both tunable absorption (via quantum confinement) and effective long-range photocarrier transport. The integration of these nanostructures within established thin film heterojunction PV, however, must insure the most effective use of these materials in the context of the overall device architecture and its operation. In the present work, nanoscale CdTe was examined as a sensitizer in the context of hybrid PV heterojunctions based on ZnO and poly 3-hexylthiophene (P3HT). The role of the sensitizer and its contribution to device performance was investigated through both computational modeling of cell output characteristics and through experimental studies. The work confirms the spectral contribution of the nanophase to the heterojunction external quantum efficiency, and further demonstrates the importance of nanophase placement relative to the heterojunction plane in dictating device output. Such results provide valuable insight into carrier transport length scales and optical characteristics contributing to the design of such devices with enhanced conversion efficiency.

8824-5, Session 2

Nanostructured electrodes for organic photovoltaics *(Invited Paper)*

Nikos Kopidakis, National Renewable Energy Lab. (United States); Wounjhang Park, Univ. of Colorado at Boulder (United States)

Nanostructured back contacts offer many possibilities for improving the efficiency of Organic Photovoltaics (OPV). We discuss a simple methodology to integrate prefabricated nanostructured contacts into an OPV device, and show examples of applying it to two classes of electrodes: the first requires post-processing that is incompatible with an organic active layer and the second is a tailored nanostructure that can be used for enhanced light management in the device. The latter class of electrodes opens up new possibilities for designing photonically-active structures that can enhance the absorption of subgap photons and overcome the limitation of energy losses in the electron transfer step from the photoexcited donor to the acceptor. We will discuss the design, fabrication and characterization of photonic electrodes, their applicability to OPV and determine the spectral region where the photoresponse of the device is improved.

8824-8, Session 2

Light trapping in dye sensitized solar cells

Stephen Foster, Sajeev John, Univ. of Toronto (Canada)

The dye-sensitized solar cell (DSSC) is a promising third-generation solar cell technology, but at present lacks the power conversion efficiency to compete effectively with other solar cells on the market. In this work we demonstrate numerically that photonic crystal DSSCs can provide at least a factor of one-third enhancement in solar light absorption relative to their conventional counterparts. Our design consists of a lattice of modulated-diameter TiO_2 nanotubes filled with TiO_2 nanoparticles and interstitial regions filled with electrolyte. This provides not only light trapping and absorption enhancement, but offers improved electrical transport through the nanotube walls. The nanotube array itself forms an extended 2D photonic crystal, and the spacing and diameter of tubes in the array are chosen to promote dielectric modes that concentrate light in the interior of the tubes. Linear and sinusoidal modulation over select regions of the nanotube diameter creates a 3D photonic crystal and allow for enhanced anti-reflection and back-reflection, respectively. Further reduction of reflection losses is accomplished through the addition of triangular corrugation to the glass-air interface of the cell. Using a constant volume of dye-coated TiO_2 nanoparticles our design gives a maximum achievable photocurrent density (MAPD) of 20.8 mA/cm^2 in 2D simulations. This is a 33% improvement over the MAPD for a simple planar cell geometry, and well above the record short-circuit current density for C101-based cells. We also demonstrate that choosing a dye with a broader but weaker absorption profile compared to commonly used dyes would lead to even larger absorption enhancements.

8824-9, Session 3

Improving the light-harvesting of thin film solar cells with photochemical upconversion *(Invited Paper)*

Timothy W. Schmidt, The Univ. of Sydney (Australia)

In order to generate more cost efficient PV devices, one must look to technologies which promise to better manage the solar spectrum. One promising approach is triplet-triplet annihilation upconversion in organic molecules, whereby sub-bandgap light can be converted to usable wavelengths. I will review our latest results, applying TTA-UC to thin-film cells such as amorphous silicon, organic and dye-sensitized solar cells, and outline our strategies for achieving efficient upconversion under one sun.

8824-10, Session 3

Enhanced solar photoconversion exploiting molecular photochemical upconversion

Felix N. Castellano, Hyounsoo Uh, Bowling Green State Univ. (United States); Michael J. Therien, Jean-Hubert Olivier, Duke Univ. (United States); Andrew J. Ferguson, William Nemeth, Andrew Norman, National Renewable Energy Lab. (United States)

Over the last decade the phenomenon of triplet-triplet annihilation-assisted photon upconversion (UC) has been demonstrated for a wide variety of molecular triplet sensitizer/annihilator systems. This photophysical process exhibits great potential for the sensitization of a variety of semiconductor platforms (e.g. amorphous silicon and metal oxides) with relevance in photovoltaic (PV) and photoelectrochemical applications.

We will initially discuss efforts to photooxidize water by sensitizing nanostructured tungsten oxide (WO_3) photoanodes to sub-bandgap, non-coherent green photons at low power density, using the benchmark upconverting system palladium(II) octaethylporphyrin (PdOEP) and 9,10-diphenylanthracene (DPA) in toluene.

We will then discuss recent efforts to synthesize novel light-harvesting chromophores that (i) possess large near-infrared extinction coefficients, (ii) manifest ultrafast intersystem crossing to generate the triplet state at unit quantum yield, and (iii) possess triplet lifetimes exceeding several microseconds, which will be incorporated into molecular photon UC systems with the appropriate luminescent visible emitters. We will examine factors influencing the efficiency of the photon UC process in solution and the solid state, describe recent efforts to couple UC systems into device architectures employing transparent a-Si devices, and summarize the observed performance of the coupled UC-PV system.

8824-11, Session 3

Photonic structures for enhanced upconversion

Barbara Herter, Sebastian Wolf, Stefan Fischer, Johannes Gutmann, Benedikt Bläsi, Fraunhofer-Institut für Solare Energiesysteme (Germany); Jan Christoph Goldschmidt, Fraunhofer-Institut für Solare Energiesysteme (Germany) and Imperial College London (United Kingdom)

Upconversion of sub-band-gap photons offers a possibility to overcome the Shockley-Queisser efficiency limit for solar cells. Unfortunately, materials showing upconversion properties, still suffer from too low upconversion quantum yields (UCQY). Here, we investigate how the UCQY can be increased by embedding of the upconverter material into a photonic structure. The photonic structure has two effects: first, a local irradiance enhancement, which increases the upconversion quantum yield due to the nonlinearity of the upconversion process. Second, the local density of photonic states (LDOS) is varied due to the photonic environment. This affects the transition probabilities within the upconverter. Including these two effects shows the potential to increase the UCQY.

We present simulation results based on an FDTD-approach, where the effects of the irradiance enhancement and the LDOS are quantified. The results of these simulations are combined with a rate-equation model of the upconversion dynamics in $NaYF_4:Er^{3+}$, thus, modeling the behavior of the upconverter within the photonic structure. We show that an optimized waveguide structure can increase overall upconversion luminescence by a factor of 268 and the overall quantum yield by a factor of 9.3. For the investigated upconverter, this results in an increase of the quantum yield from 0.86?% to 8?% in the presence of the structure. The key to the successful optimization of the structure was to increase the local density of photon states at the emission wavelength of the upconverted photons.

The production of an upconverter in a suitable photonic structure is work in progress. First experimental data will be presented at the conference.

8824-13, Session 4

Nanophotonic light tapping strategies for thin solar cells *(Invited Paper)*

Mark Brongersma, Geballe Lab. for Advanced Materials (GLAM) (United States)

Nanophotonics is an exciting new field of science and technology that is directed towards making the smallest possible structures and devices that can manipulate light. In this presentation, I will show how semiconductor and metallic nanostructures can mold the flow of light well below the wavelength of light. This ability opens up the opportunity to effectively trap light in ultrathin solar and photo-electrochemical cells. I will discuss how the nanostructure sizes and shapes as well as their non-periodic arrangement on a cell can be optimized to effectively harvest solar energy from such thin cells and across the broad solar spectrum.

8824-14, Session 4

Plasmonic nanocavities: a new paradigm for ultra-thin solar cells

Andrea Cattoni, Clement Colin, Inès Massiot, Nicolas Vandamme, Jean-Luc Pelouard, Lab. de Photonique et de Nanostructures (France); Christophe Sauvan, Philippe Lalanne, Institut d'Optique Graduate School (France); Jean-François Guillemoles, Institut de Recherche et Développement sur l'Energie Photovoltaïque (France); Stéphane Collin, Lab. de Photonique et de Nanostructures (France)

Efficient light confinement in nano-scale semiconductor volumes could allow for a drastic reduction in semiconductor material consumption and for further development of third-generation solar cells.

In this talk we propose a new and versatile design for broadband light trapping in ultrathin (≲100 nm) film solar cells. The design is based on Metal/Insulator/Metal plasmonic nanocavities for which we have experimentally demonstrated omindirectional total absorption of light in sub-wavelength volumes (?3/1000) [1]. By carefully designing the resonant nanoantenna array, it is possible to obtain multi-resonant light absorption inside a semiconductor placed in the gap of the nanocavity with limited absorption by the metal. This versatile approach is applied to different solar cell materials (GaAs, CuInGaSe). We demonstrate a short-circuit current of 19.8 mA/cm2 and a theoretical conversion efficiency of nearly 20 % by using a 30nm-thick GaAs absorber layer. For CIGS a short-circuit current of 30 mA/cm2 is predicted for 100nm-thick absorbing layer with a theoretical conversion efficiency up to 17 %. The fabrication of a preliminary solar cell proof of concept based on GaAs and CIGS is detailed.

The enhanced electromagnetic field intensity together with short carrier collection paths pave the way for nano-scale second generation solar cells with arbitrarily small diffusion lengths and for

the development of third generation concepts like hot carrier or intermediate band solar cells.

Nanophotonic light trapping in polycrystalline silicon thin-film solar cells using periodically nanoimprint-structured glass substrates

Jolly Xavier, Veit Preidel, Daniel Amkreutz, Tobias Sontheimer, Daniel Lockau, Philippe Wyss, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany); Franziska Back, Eveline Rudigier-Voigt, SCHOTT AG (Germany); Bernd Rech, Christiane Becker, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany)

A smart light trapping scheme is essential to tap the full potential of polycrystalline silicon (poly-Si) thin-film solar cells. Nanophotonic periodic structures are of particular interest as they allow to substantially surpassing the Lambertian limit from ray optics in selected spectral ranges. However, large-area fabrication processes have to be applied for nanostructuring in order to permit the cost-effective production of thin-film solar cell devices. In this study, we used nanoimprint-lithography enabling the nanopatterning of large-areas at low costs and high throughput. 2D periodic crystalline silicon nanoarchitectures were fabricated by evaporation, solid or liquid phase crystallization and chemical etching of thin silicon films on Schott AF glass covered by a temperature-stable nanoimprint-textured sol-gel. In this way, periodic silicon nano-/microhole arrays with varying pitch size and hole radius could be prepared on areas up to several square centimeters featuring excellent absorption properties. Poly-Si microhole arrays with 2µm pitch and an effective thickness of 1µm exhibited 44% absorption at ?=900 nm corresponding to a light path enhancement factor above 60 in crystalline silicon, i.e. beyond the Lambertian limit. The geometrical device design has been optimized experimentally and numerically with respect to a maximum optical absorption in the poly-Si volume and minimum parasitic absorption in functional layers. The distinct growth and crystallization properties of silicon on textured surfaces have been considered in order to maintain a good electronic material quality of the poly-Si absorber. These structures inspire the design of prospective applications such as high-efficient poly-Si thin-film solar cells and large-area photonic crystals.

Solar power conversion optimization in thin-film silicon photonic crystal solar cells

Alexei Deinega, Sergey Eyderman, Sajeev John, Univ. of Toronto (Canada)

We compare efficiency of different types of photonic crystal solar cells, namely, conical pore films and nanowires. Solving both Maxwell's equations and the semiconductor drift-diffusion in each geometry, we identify optimal junction and contact position and study the influence of bulk and recombination losses on solar cell efficiency.

For conical pore photonic crystal we use p-n junction interface which is parallel to the bottom surface. For nanowires we consider radial and axial p-n junctions. We analyze photocurrent distribution inside each structure and calculate short circuit current density and open circuit voltage for different values of diffusion lengths and surface recombination at the contact. For small diffusion lengths results do not depend on surface recombination, since most of the recombination occurs at the bulk. In this case only carriers which are close enough to the junction can contribute to the photocurrent. If diffusion length is long and surface recombination rate is high, most of the recombination occurs at the metal contacts. Reducing contact area leads to improvement of solar cell efficiency. For the case of long diffusion lengths and small surface recombination, all generated carriers contribute in photocurrent.

We find that using only one micron of silicon, sculpted in the form of inverted slanted conical pore photonic crystal film, one can achieve 80-90% absorption within the whole solar spectrum and 17.5% solar power conversion efficiency when the carrier diffusion length exceeds 50 microns. This efficiency could be improved using two different types of silicon, amorphous and microcrystalline, in a top and a bottom the cell. Opportunities for "hot carrier" collection and up-conversion of infrared light, enhanced by photonic crystal geometry, facilitate further improvements in power efficiency.

8824-17, Session 5

Multiple exciton generation in quantum dots and quantum dot solar cells *(Invited Paper)*

Matthew C. Beard, National Renewable Energy Lab. (United States)

We are investigating multiple exciton generation (MEG) in quantum dot (QD) based solar cells as a way to enhance solar energy conversion by channeling excess photon energy to produce multiple electron-hole pairs rather than heat. I will discuss recent ultrafast transient absorption studies of MEG in doped and undoped PbSe QDs, couple PbSe QD arrays, and colloidal Si QDs. If time permits I will discuss strategies for incorporating both the Pb chalcogenide and Si QDs into prototype solar cells.

8824-18, Session 5

Ultrafast exciton dynamics in CdSe nanocrystals: Auger-mechanisms and confined phonons

Bryan T. Spann, Liangliang Chen, Xiulin Ruan, Xianfan Xu, Purdue Univ. (United States)

Nanocrystal sensitized solar cells have the theoretical potential to surpass the Shockley–Queisser limit via capture of hot-electrons. Time-resolved transient absorption pump-probe spectroscopy is used to investigate exciton relaxation in CdSe nanocrystal films. The effects of morphology (quantum dots vs. quantum rods), size dependent quantum confinement, and preparation of nanocrystal films are investigated. Our experiments revealed a decrease in the confinement enhanced Stark effect in the quantum rod films as well as slower intraband relaxation times compared with quantum dots of the same diameter. The slowed relaxation in quantum rods is due to the mitigation of the Auger-relaxation pathway as a result of elongating the nanocrystal. Furthermore, our study on nanocrystal size dependence also reveals reduction in the Auger-relaxation mechanism for volumetrically larger nanocrystals. Both morphologies of the nanocrystal films showed long-lived confined acoustic phonons corresponding to the ellipsoidal breathing mode, consisting of transverse and longitudinal acoustic phonons.

8824-19, Session 5

Hot carrier solar cell absorbers: materials, mechanisms, and nanostructures

Gavin Conibeer, Santosh Shrestha, Shujuan Huang, Robert Patterson, Hongze Xia, Yu Feng, Pengfei Zhang, Neeti Gupta, Suntrana Smyth, Yuanxun Liao, Shu Lin, Pei Wang, Xi Dai, Simon Chung, The Univ. of New South Wales (Australia)

An ideal Hot Carrier cell would absorb a wide range of photon energies and extract a large fraction of the energy to give very high efficiencies, up to 65% at 1sun (85% at max concentration), by extracting 'hot' carriers before they thermalise to the band edges. The key property for a hot carrier absorber is to slow the rate of carrier cooling from the picosecond timescale to at least 100s of ps. Hot carriers cool primarily by emission of LO phonons.

Multiple QW structures have demonstrated reduced carrier cooling by enhancing the phonon bottleneck, prior to optical phonon decay. Large phononic band gap materials would seem to have strong potential to block Klemens' decay of optical phonons and thus also increase phonon bottleneck. A hot carrier absorber combining both structures should give even greater reduction in carrier cooling rates as the mechanisms should not interfere directly with each other and hence their effects should be additive. A Hot Carrier cell design combining MQW with phononic band gap materials could use InN/InGaN wells and barriers. This would combine the MQW effect with phononic band gap. Later designs would incorporate the more abundant transition nitrides or group IV compounds in MQW structures with phononic band gap materials, to lead to even greater retardation of carrier cooling.

Fabrication of materials that can slow carrier cooling through enhancing phonon bottleneck is challenging. Investigation of the mechanisms in large mass difference materials and superlattice structures will be presented and options for combined devices discussed.

8824-20, Session 5

PbS quantum dot thin film solar cells using a cds window layer

Khagendra P. Bhandari, Hasitha Mahabaduge, Paul J. Roland, Neale O. Haugen, Corey R. Grice, The Univ. of Toledo (United States); Sohee Jeong, Korea Institute of Machinery & Materials (Korea, Republic of); Tieneke Dykstra, The Univ. of Toledo (United States); Jianbo Gao, National Renewable Energy Lab. (United States); Randy J. Ellingson, The Univ. of Toledo (United States)

Here we report on heterojunction thin film solar cells in which we deposit a thin PbS quantum dot (QD) layer atop a sputtered CdS n-type window layer. Fabrication of a PbS QD-based thin film consists of depositing a ~200 nm thick film of PbS QDs using a layer-by-layer (LbL) dip coating method in which the as-prepared oleic acid ligands are replaced with a short-chain molecule, 1,2-ethanedithiol. Such a thin film affords reasonable charge carrier mobilities while retaining quantum confinement. In our heterojunction devices, we sputter (via RF magnetron sputtering) an n-type window layer, onto patterned ITO and subsequently fabricate a quantum dot thin film and complete the device with a top metal contact. These solar cells generate open circuit voltage in excess of previous reports based on PbS QDs heterojunctioned with other materials. We report on investigations of the influence on device performance of CdS film thickness and PbS QD diameter, and find optimal parameters to be 70 nm CdS layer thickness and ~2.7 nm PbS QD diameter (Eg ~1.60 eV). Under standard AM1.5G illumination, we observe short circuit current as high as 13 mA.cm-2, yielding a maximum efficiency of 3.3%. We also apply photoelectron spectroscopy contactlessly, and quantitatively to measure the valence and conduction band offsets at abrupt heterojunction interfaces between CdS/PbS QDs system.

8824-21, Session 5

Super-absorption in sparse arrays of III-V nanowire optical waveguides for photoelectrochemical and photovoltaic applications

Katherine T. Fountaine, Shu Hu, Nathan S. Lewis, Harry A. Atwater Jr., California Institute of Technology (United States)

GaAs and other III-V compound nanowire (NW) arrays represent an approach to enable high-quality, lattice-mismatched growth via radial strain relaxation, and also to reduce material usage and cost of photovoltaic and photoelectrochemical devices. Even at very low areal fill fractions, GaAs NW arrays exhibit strong absorption due to coupling into radial optical waveguide modes. We report here the very strong light absorption (60-100% of incident light) and current collection properties of sparse (<5% fill fraction) III-V NW arrays grown on both GaAs and Si substrates, supported by experiments, simulations and analytical theory. These absorption characteristics indicate a 15-25x enhancement in the effective cross section of the NWs that is strongly dependent on wavelength and incidence angle.

Optical absorption and electrochemical photocurrent collection was performed for MOCVD-growth NW arrays (wire length~3um, wire diameter~150nm, pitch~600nm) as a function of wavelength (350-900nm) and illumination angle (0-60°) was measured experimentally and modeled via three-dimensional, full-field electromagnetic simulations. Experiments, electromagnetic simulations and analytical modal analysis showed excellent qualitative and quantitative agreement across the spectrum and range of incident angles. The identification of specific TE and TM optical waveguide modes that are responsible for absorption peaks was carried out via a comparison of analytical solutions using fundamental optical waveguide theory and the spatially-resolved electric field profiles of the wire cross sections obtained from electromagnetic simulations.

Ultimately, the elucidation of the mechanism responsible for the high absorption of sparse III-V NW arrays facilitates optimization of light absorption and, thus, improves III-V NW array optoelectronic performance.

8824-22, Session 5

Light trapping enhancement in ordered and disordered silicon nanowire based solar

Martin Foldyna, Ecole Polytechnique (France)

In order to reduce the fabrication cost of solar cells, the recent focus of many research groups is towards thin film solutions. To achieve high energy conversion efficiency of the thin film solar cells, the light management must be significantly boosted by an efficient light trapping scheme. One efficient way to maximize conversion efficiency of thin film solar cells is to use radial junction silicon nanowire based solar cells. The main advantages of radial junction solar cells include the high built-in field (due to the radial geometry) and efficient light trapping (due to the good absorption and scattering properties of nanowires).

In this work we compare the light trapping enhancement obtained on random nanowire based solar cells grown using plasma-assisted vapour-liquid-solid (VLS) method with the enhancement in periodic vertical nanowire arrays. Periodic arrays are modelled using rigorous coupled wave method, while the light trapping inside disordered nanowire solar cells is estimated based on the experimental data. Our results show the impact of the nanowire density and length on the light trapping enhancement in ordered and disordered nanowire solar cells. The comparison provides better understanding, needed for the optimization of silicon nanowire based solar cells fabricated using VLS method.

8824-23, Session 6

Solar light trapping in slanted conical-pore photonic crystals

Sergey Eyderman, Sajeev John, Univ. of Toronto (Canada)

We demonstrate by FDTD simulation that a solar cell with only one micron, equivalent bulk thickness, of crystalline silicon, sculpted into the form of a slanted conical-pore photonic crystal and placed on a silver back-reflector, it is possible to attain a maximum achievable photocurrent density (MAPD) of 35.5mA/cm2 from impinging sunlight. This corresponds to absorbing roughly 85% of all available sunlight in the wavelength range 300-1100nm and exceeds the limits suggested by previous “statistical ray trapping” arguments. The optimum carrier generation occurs for a photonic crystal square lattice constant of 850nm and slightly overlapping inverted cones with upper (base) radius of 500nm.

It is also shown that using only two hundred nanometers, equivalent bulk thickness, of gallium arsenide, forming a same slanted conical-pore photonic crystal packaged with SiO2 and deposited on a silver back-reflector, one can obtain a MAPD of 26.3mA/cm2, which is 90% of absorption of all available sunlight in the wavelength range 400-855nm and occurs for a photonic crystal square lattice constant of 550nm and inverted cones with radius of 300nm.

We show that our structures possess strong anti-reflective and light trapping properties and absorb light within slow group velocity modes, that propagate nearly parallel to the solar cell interface and exhibit localized high intensity vortex-like flow in the Poynting vector-field. Presented angular distribution of the MAPD indicates that in both cases there is no substantial degradation in the MAPD at least up to ? = 50o for various directions of incidence and polarizations.

8824-24, Session 6

Multilayer structures with highly directional absorptivity for solar thermophotovoltaics

Christopher H. Granier, Francis O. Afzal, Georgios Veronis, Jonathan P. Dowling, Louisiana State Univ. (United States)

Solar energy is an ideal technology for power generation because it is clean, quiet, and renewable. Photovoltaic solar cells can provide virtually unlimited amounts of energy by effectively converting sunlight into clean electrical power. However, significant improvement in the efficiency of photovoltaic solar cells is required to make them competitive with grid power. In this paper, we explore an approach to enhance the efficiency of solar cells using photonic nanostructures for solar thermophotovoltaics. Thermophotovoltaic solar cells, where solar radiation is absorbed by an intermediate absorber, which then emits thermal radiation towards a solar cell, are capable of achieving extremely high efficiency using single-junction solar cells. The theoretical efficiency of 85% far exceeds the Shockley-Queisser limit of 41% when a single-junction cell is directly exposed to sunlight. In order to approach such efficiency, however, there are very important constraints on the properties of the intermediate absorber and emitter. Here our focus is on designing photonic nanostructures that can provide broadband absorption in a narrow angular range. This is a crucial requirement for solar thermophotovoltaic systems which do not employ sunlight concentration. We consider a structure consisting of an aperiodic multilayer stack of alternating layers of silicon and silica on top of a thick tungsten layer. The layer thicknesses are optimized using a genetic global optimization algorithm in combination with a transfer matrix formalism to maximize the angular selectivity in the absorptivity for both TE and TM polarizations. Using such an approach, we design structures with highly directional absorptivity for both polarizations.

8824-25, Session 6

Minimizing light reflection from textured surfaces

Alexei Deinega, Univ. of Toronto (Canada); Ilya Valuev, Joint Institute for High Temperatures (Russian Federation); Yurii E. Lozovik, Institute of Spectroscopy (Russian Federation); Boris Potapkin, Russian Research Ctr. Kurchatov Institute (Russian Federation)

We study antireflective properties of pyramidally textured surfaces for all texture size-to-wavelength ratios. In the case when the wavelength is much smaller than the feature size of the texture, we use the geometric optics approach and ray tracing. In the long-wavelength limit we use the effective medium theory (EMT). As a main tool we use the finite-difference time-domain (FDTD) method which is valid for all texture size-to-wavelength ratios, including effective medium and geometric optics limits. In both limiting cases we compare the theoretical reflection coefficients with the results obtained using direct FDTD simulation.

It was found that the key factor, influencing the optimal size of the pyramidally textured surface, is the character of the substrate tiling by the pyramid bases. We have shown analytically, that in the case of a complete tiling (for example, when the pyramid bases are regular hexagons fully packed in triangular lattice) the EMT approximation predicts polynomial decay of the reflectance when pyramids height increases. In the geometric optics limit this decay is exponential. This leads to the fact, that the minimal reflectance can be achieved at the macroscopic sizes of the pyramids. In the case of an incomplete tiling (for example, for cones as texture elements) the reflectance approaches a constant value in the EMT limit, and in the geometrical optics limit tends to the reflectance of the bare substrate. As a result, for an incomplete tiling, which is usual for technological reasons, the minimal reflectance is predicted at the pyramid sizes of the order of the wavelength. This prediction is confirmed by the direct FDTD calculations performed in the whole sizes range. To illustrate our theoretical and computational results we compare them with the experimental data for silicon solar cells with textured surface.

8824-12, Session PMon

Down-conversion effect on GaAs single junction solar cell using CdSe quantum dots

Joon-Suh Park, Jihoon Kyhm, Hyungduk Ko, Jin Dong Song, Eunkyeom Kim, Il Ki Han, Korea Institute of Science and Technology (Korea, Republic of)

With the growing need of more effective energy harvesting, solar energy has been sought as one of the prominent candidates among the eco-friendly methods. Although many types of solar cells have been developed, the electronic conversion efficiency is limited by the material's physical properties: solar cells can only harvest solar energy from limited range in solar energy spectrum. To overcome this physical limit, we approach by using the down-conversion effect with conventional CdSe quantum dots (QDs), transforming high energy photons to low energy photons to the range the designated solar cell has higher probability of electron-hole generation. In our study, we have fabricated GaAs single junction solar cells grown by molecular-beam epitaxy (MBE) and applied CdSe quantum dots for down-conversion. We examine the effects of such application on the solar cell efficiency, fill-factor, JSC, VOC, etc. We observed noticeable increase in photocurrent and energy conversion efficiency. Also, using time-resolved photoluminescence technique, we observe the changes in decay time of CdSe QD and carrier lifetime in GaAs solar cell which occurs possibly by down-conversion effect. This work was supported by KIST Flagship Project, project number 2E23892.

Biomimetic antireflective AlInP nanostructures fabricated by lithography-free method for solar cell applications

Chan Il Yeo, Joon Beom Kim, Kwang Wook Park, Yong Tak Lee, Gwangju Institute of Science and Technology (Korea, Republic of)

III-V compound semiconductor solar cells have been considered as a promising candidate for high solar power generation due to their superior conversion efficiency. However, the high Fresnel reflection originating from the large refractive index mismatch between air and semiconductor material, limits the conversion efficiency. To improve the cell efficiency by suppressing the unwanted Fresnel reflection, a great deal of efforts has been explored using various surface structures. Recently, biomimetic antireflective nanostructures inspired from the nature called as "moth-eye" have attracted great attention due to their broadband and omnidirectional antireflection properties. To produce such antireflective structures, dry etching using etch mask patterns having nano-scale dimensions, which are usually formed by lithography method, has been widely utilized. However, the lithography based nanopatterning techniques are complex, expensive, and therefore not suitable for mass production.

In this work, we fabricated antireflective nanostructures on AlInP, which is a common material for window layer of compound semiconductor solar cells, by inductively coupled plasma etching using Ag etch mask, which was easily formed by spin-coating of Ag ink and subsequent sintering process on a hotplate (under 250°C) without any sophisticated equipments. This lithography-free method is a simple, cost-effective, and high throughput method. The fabricated AlInP nanostructures demonstrated drastically reduced solar-weighted reflectance (SWR) of 2.95% compared to that of bulk AlInP (28.75%) in the wavelength range of 300-870 nm. The incident angle dependent SWR of the fabricated AlInP nanostructure remained below 5% up to an incident angle of 50°. Therefore, the fabricated AlInP nanostructures using lithography-free method hold great potential for use in solar cells.

8824-37, Session PMon

A silicon template with a high aspect ratio nanoscale structure realized by a two-step etching method for a stamping technique

Dae-Seon Kim, Dong-Hyun Kim, Sungbae Lee, Jae-Hyung Jang, Gwangju Institute of Science and Technology (Korea, Republic of)

Subwavelength structures (SWSs) have been considered as an alternative to single-layer or multilayer antireflection coatings (ARC) to reduce the surface reflection of solar cells due to their broadband antireflective property. An array of nanoscale structures can lead to gradual changes of the effective refractive index at the surface, which contributes to decreasing the surface reflection under a wide wavelength range. The shape and aspect ratio of a nanoscale structure are crucial parameters to realize an optimized transition of the effective refractive index from the bottom of structure to the air. To realize SWS as an ARC on a solar cell, many direct lithographic approaches have been utilized on the top surface of the solar cell. These conventional methods have drawbacks associated with their complicated processes. Recently, stamping methods have been proposed due to their potential advantage of simple manufacturing. By pressing the template with a negative pattern of a nanoscale structure onto a polymeric material, the SWS is easily transferred. In this study, electron-beam lithography was utilized for the initial formation of a 350-nm-period hexagonal pattern with a 40-nm-diameter hole on a 100-nm-thick SiO_2-coated silicon substrate. Next, a two-step etching process combined with the wet etching of SiO_2 and the dry etching of silicon was carried out to create silicon templates with nanoscale structures of various appearances with aspect ratios higher than 2.5. The hexagonal pattern with an enlarged hole was then transferred to the final silicon template. By adjusting the parameters of the two-step etching condition, the aspect ratio and the shape of the structure were controlled, resulting in various silicon templates. The polymeric SWS was fabricated by silicon template and stamping technique. The fabrication details and the optical results of the polymeric SWS will also be discussed.

8824-38, Session PMon

Spectrum upconversion and downconversion in (Tm^{3+}, Yb^{3+}) and (Tb^{3+}, Yb^{3+}) co-doped fluorosilicate glass

Zhengda Pan, Richard Akrobetu, Steven H. Morgan, Fisk Univ. (United States)

We investigated the spectrum upconversion and downconversion in Tb^{3+}, Tm^{3+}, and Yb^{3+} co-doped fluorosilicate glass, aiming to reduce solar energy loss due to the sub-bandgap transmission of long wavelength photons and/or the thermalization of excess excited charge carriers by high energy photons. The rare-earth doped glasses were fabricated in a SiO_2-Al_2O_3-Li_2O-LaF_3 matrix using a melt-quench technique. Upon excitation at 980 nm, strong visible upconversion luminescence was observed between 450 nm and 840 nm, which can enhance the performance of CdTe solar cells, because the crystalline CdTe has an energy gap of 1.45 eV, corresponding to a cut-off wavelength of 855 nm. Upon blue light excitation, downconversion luminescence was observed between 920 and 1040 nm, matched well with the bandgap of the crystalline Si. Our spectrum conversion results indicate that the upconversion and downconversion efficiencies depend on the rare-earth doping concentrations as well as on the concentration of the incident light (the light irradiance). We attribute the spectrum conversions observed to the cooperative energy transfer and/or the excited state absorption mechanisms of the rare-earth ions in the glass. The luminescent glass developed can act as a spectrum convertor located on the front surface of a solar cell, therefore enhancing the light-to-electric energy conversion of a PV solar cell. The rare-earth doped glass shows promise to have high spectrum conversion efficiency and therefore may find its applications in PV solar cells for a higher light-to-electric energy conversion efficiency.

8824-39, Session PMon

High efficiency solar cell with ZnO/CdS/CdSe nanowire array

Mei-Lin Zhang, Technical Institute of Physics and Chemistry (China) and Graduate Univ. of Chinese Academy of Sciences (China); Feng Jin, Mei-Ling Zheng, Zhen-Sheng Zhao, Xuan-Ming Duan, Technical Institute of Physics and Chemistry (China)

Nowadays, a series of nano-photovoltaic devices based on ZnO nanowire array have been widely studied due to the excellent optical properties of ZnO. ZnO nanowire array can be synthesized in an easy, low cost, environmental-friendly method. The performance of solar cell with ZnO electrodes is largely depending on the morphology and crystal qualities of ZnO nanowires.

Herein, we presented the synthesis and photovoltaic application of ZnO nanowire array with three different growth methods. Based on the basic source of the hydrothermal growing solution, ZnO nanowire array was prepared by the a) ammonia solution (N), the b) hexamethylene tetramine (H) and the c) alternation of ammonia and hexamethylene tetramine (NH). Firstly, ZnO nanowire array was grown on ITO glass using the above three methods. The ZnO nanowire array with a length of about 16μm has been obtained Secondly, the ZnO/CdS core/shell heterojunction nanowire array was fabricated by depositing CdS nanocrystals on the surface of ZnO nanowires to offer an interlay to reduce the charge recombination on the ZnO nanowires. Then, the CdSe QDs were deposited on the surface of the ZnO/CdS nanowires to absorb photons and transfer charge carriers to ZnO nanowires. Finally, solar cells were constructed and optimized with polysufide electrolyte and CoS counter eletrode. The results indicate that the photovoltaic behavior depends on crystal quality and morphology of ZnO nanowire array. Hence, we observe an increasing efficiency as follows: N< NH< H. The best power conversion efficiency of 3.88% was obtained.

8824-40, Session PMon

Patterned crystalline Si solar cells for better light trapping

Dong-Wook Kim, Yunae Cho, Eunsongyi Lee, Minji Gwon D.V.M., Ewha Womans Univ. (Korea, Republic of); Joondong Kim, Kunsan National Univ. (Korea, Republic of)

Recently, there have been intensive researches on development of ultrathin Si absorber-based solar cells to realize high-efficiency and low-cost photovoltaic devices. In addition to the conventional anti-reflection coating and surface texturing techniques, patterned absorbers have emerged as an alternative light trapping structures. Through numerous attempts to design optimal patterned structures, calculation results have shown that the patterned structures exhibit omni-directional and enhanced optical absorption, compared with the planar counterparts. The efficiencies of the fabricated patterned cells, however, have not surpassed those of the conventional cells primarily due to recombination loss at the enlarged surface area.

In this study, we have fabricated and investigated photovoltaic performance of micro-patterned crystalline Si solar cells. The depth of the hole is only 2 ?m, and hence the electrical characteristics of the p-n diode does not show any signature of deterioration compared with the planar device. To investigate the optical properties of the patterned cells, we perform finite-difference time-domain (FDTD) simulations (Lumerical FDTD Solutions). The calculated field distribution clearly reveals the patterns concentrate the optical field near the surface with the help of the geometric antireflection effect due to the low optical density and grating-coupled excitation of optical modes. Comparative investigation of experimental and simulation results suggest importance of the carrier collection efficiency in the patterned cells.

8824-41, Session PMon

Nanostructured upconvertors for thin film solar cells

Rowan W. MacQueen, Timothy W. Schmidt, The Univ. of Sydney (Australia)

Photochemical upconversion involving triplet-triplet annihilation in organic molecules is invoked in order to address a higher limiting efficiency for solar cells, beyond the Shockley-Quiesser limit. In order that triplet-triplet processes dominate over the first order decay, a high concentration of sensitizer material is required. We have developed solid-state sensitizer materials for upconversion by binding metallated porphyrin molecules to silica nanoparticles. This has the advantage of achieving a high concentration while preventing unwanted triplet-triplet interactions between sensitizer molecules. Efficient quenching of phosphorescence is observed, indicating transfer of excitations to the emitter material. Initial developments towards an all solid state upconvertor will be reported.

8824-26, Session 7

Overview of optical rectennas for solar energy harvesting *(Invited Paper)*

Garret Moddel, Univ. of Colorado at Boulder (United States); Zixu Zhu, Univ of Colorado at Boulder (United States); Saumil Joshi, Bradley Pelz, Univ. of Colorado at Boulder (United States)

Although the concept of using optical rectenna for harvesting solar energy was introduced four decades ago, only recently has it invited a surge of interest, with dozens of laboratories around the world working of various aspects of the technology. In an optical rectenna a submicron antenna is connected to an ultra-high-speed diode, so that the incoming radiation is received and rectified to produce DC output power. The result is a technology that can be inexpensive, using only low-cost materials, and efficient. Conventional classical rectification theory does not apply at optical frequency, necessitating the application of quantum photon-assisted tunneling (PAT) theory to describe the device operation. At first glance it would appear that the ultimate conversion efficiency is limited only by the Landsberg limit to 93%, but a more sober PAT analysis that includes limitations due to the coherence of solar radiation leads to a result that coincides with the Trivich-Flinn limit of 44%. Innovative antenna designs are required to achieve high efficiency at frequencies where resistive losses in metal are substantial. The most commonly incorporated diode makes use of electron tunneling through ultra-thin metal/insulator/metal (MIM) diodes. The most severe constraint is that the impedance of the antenna and diodes must match for efficient power transfer. The consequence is an RC time constant that cannot be achieved with parallel-plate MIM diodes, leading to the need for real innovations in diode structures. Technologies under consideration include sharp-tip and traveling-wave MIM diodes, and graphene geometric diodes. We survey the technologies under consideration.

8824-27, Session 7

A new method for optical rectification using nanoscale rectennas

Nicholas M. Miskovsky, Paul H. Cutler, Peter B. Lerner, Scitech Associates, LLC (United States); James M. Chen, The Pennsylvania State Univ. (United States); Alexandre Mayer, Univ. of Namur (Belgium)

In this talk we present a new and viable method for optical rectification. This approach has been demonstrated both theoretically and experimentally and can be used for the development of a practical rectification device for the electromagnetic spectrum including the visible portion. This technique for optical frequency rectification is based, not on

conventional material or temperature asymmetry as used in MIM (Metal/Insulator/Metal) or Schottky diodes, but on a purely geometric property of the antenna tip or other sharp edges that may be incorporated on antennas. This "tip" or edge in conjunction with a collector anode constitutes a tunnel junction connected to the external circuit. The rectenna (consisting of the antenna and the tunnel junction) acts as both the absorber of the incident radiation and the rectifier. Using current nanofabrication techniques and the selective Atomic Layer Deposition (ALD) process, arrays of rectennas with junction-gaps of 1 nm can be fabricated, allowing rectification of frequencies up to the blue portion of the spectrum. In order to assess the viability of our approach, we review the state of development of nanoantenna structures, which can respond to and capture radiation through the visible region. In addition, we describe the state of development, both experimentally and theoretically, of tunnel junctions capable of operating in the visible region. Specifically, we review the process of rectification, and experimental data and theoretical work on optical rectification. Finally, we present operational designs for an optical rectenna and its fabrication.

8824-28, Session 7

Bounds for the rectification efficiency of solar radiation

Heylal Mashaal, Jeffrey Gordon, Ben-Gurion Univ. of the Negev (Israel)

We derive fundamental efficiency limits for the rectification (conversion of AC to DC) of incoherent broadband radiation, motivated by the paradigm of solar power conversion by rectifying antennas. For an individual full-wave rectifier, the bound is comparable to the (unrelated) efficiency bound for solar conversion via photovoltaics under high flux concentration with multi-junction cells. We also derive the efficiency boosts that can be obtained with cascaded rectifiers.

8824-29, Session 7

Coherence and thermal noise effects in arrays of nanoscale antennas

Peter B. Lerner, Nicholas M. Miskovsky, Paul H. Cutler, Scitech Solar (United States); Alexandre Mayer, Univ. of Namur (Belgium)

The fact that blackbody radiation from a radiator, which has a size comparable to the thermal wavelength ?_T=2π?c/(k_B T) has certain coherence properties has been established a long time ago. Now, with the possibility of making microscopic dense arrays of antennas smaller in scale than the optical wavelength, one might consider applications for the coherence properties of such antennas. Moreover, with possible variations in the the geometry, we analyze the nanoantenna array as a collection of blackbody radiators with some effective temperature and associated noise spectrum. This paper discusses the use of these arrays as sensors in the infrared and visible parts of spectrum and its dependence on geometry and effective temperature.

8824-31, Session 7

Step tunneling enhanced asymmetry in metal-insulator-insulator-metal (MIIM) diodes for rectenna applications

Nasir Alimardani, John F. Conley Jr., Oregon State Univ. (United States)

Thin film metal-insulator-metal (MIM) tunnel devices have experienced a renewal in interest for high speed applications such as optical rectennas for IR energy harvesting, infrared (IR) detectors, hot electron transistors, and macroelectronics. For many of these applications, desired figures of merit include high asymmetry, strong nonlinearity, and fast responsivity of current vs. voltage (I-V) behavior. The standard approach to achieving these in tunnel devices is M1IM2 diodes - the use of metal electrodes with different work functions (?M1 ≠ ?M2) to produce a built in voltage. However, the degree of asymmetry achievable using this approach is limited by the ??M. An alternative approach is to use nanolaminate pairs of insulators to introduce an asymmetric tunnel barrier so that electrons experience a different shape barrier depending on the direction of tunneling / applied bias polarity. Asymmetry may be enhanced either through resonant tunneling or step tunneling. For an appropriate choice of insulators, step tunneling can be observed. In this work, we report step tunneling enhanced properties. MIIM diodes were fabricated on smooth bottom electrodes (ZrCuAlNi or TaN) using nanolaminate pairs of insulators (HfO2, Al2O3, ZrO2) deposited via atomic layer deposition (ALD), and Al top electrodes. Conduction mechanisms were investigated as a function of temperature and field. We combine ALD nanolaminate bilayer tunnel barriers with asymmetric electrodes to produce enhanced I-V asymmetry and non-linearity in M1IIM2 devices. This result represents an advancement in the understanding needed to manufacture high quality thin film tunnel devices for microelectronics applications.

8824-32, Session 8

Prospects of graphene electrodes in photovoltaics *(Invited Paper)*

Kaustav Banerjee, Univ. of California, Santa Barbara (United States)

Transparent conductors (TC) are an essential part of modern electronics and photonics commonly found in touch panels, displays, light emitting devices, light sensors and solar cells. The market for transparent electrode is growing rapidly, and is projected to surpass $11 billion in 2016. The technical requirements for TCs in solar cell applications are sheet resistivity less than 10 ?/square and optical transparency of larger than 90%.

Few layer graphene (FLG) is a strong candidate to replace the widely used Indium Tin Oxide due to its high optical transmittance, high electrical conductivity, high-flexibility as well as impermeability to moisture (leading to improved reliability). In particular, graphene synthesis by chemical vapor deposition (CVD) (which is the only way of producing large area graphene transferrable to any substrate) allows the use of graphene as electrode material in solar cells.

In this paper, the prospects of few layer graphene for transparent conductor application in solar cells will be presented. It will discuss trade-offs between the film thickness and the optical and electrical conductivities that are needed for optimization of these structures. In the process, we will discuss methods to synthesize FLG (less than 4 layer) with high quality in a controllable manner. Furthermore, doping of FLG via various methods will be discussed that presents new opportunities in improving the performance of FLG as a TC. The integration of FLG based TCs with semiconductors is another important challenge in the development of FLG based TCs. Hence, we will discuss optimization of the interface between FLG and semiconductors including the interactions of FLG with semiconductors, which is necessary for achieving high performance photovoltaic devices.

8824-33, Session 8

Solar vapor generation enabled by nanoparticles

Oara Neumann, Alexander S. Urban, Jared Day, Surbhi Lal, Peter Nordlander, Naomi J. Halas, Rice Univ. (United States)

Solar illumination of broadly absorbing metallic nanoparticles dispersed in a liquid produces vapor without the requirement of heating the fluid volume. Energy captured by light-harvesting nanoparticles is primarily directed to the vaporization of water into steam eliminating the energy-intensive requirement of electrically heating the fluid volume.

Nanoparticle produced steam can be applied to a wide range of solar energy applications including distillation, desalination, sterilization, and sanitation. We demonstrate a high mole fraction of ethanol distillate compared with thermal-flash distillation due to the inherently non-equilibrium vaporization process using solar-powered nanoparticle heating. Additionally, the vaporization process also leads to the production of saturated steam which is ideal for sterilizing medical tools or waste. The rapid transfer of heat of saturated steam is extremely effective in denaturing proteins and may be used to destroy most known types of infectious agents, (i.e. bacteria, viruses). Complete sterilization using nanoparticle produced steam at 135°C in a 14.2 liter autoclave was verified using a standard Geobacillus stearothermophilus-based biological indicator.

8824-34, Session 8

Optoelectronic design and growth of III-V/Si tandem microwire photovoltaics

Christopher T. Chen, Daniel B. Turner-Evans, Hal Emmer, California Institute of Technology (United States); Shaul Aloni, Lawrence Berkeley National Lab. (United States); Harry A. Atwater Jr., California Institute of Technology (United States)

Tandem III-V/Si microwire arrays combine the advantages of low cost, flexible, wafer-free vapor-liquid-solid grown microwire array technology with significantly higher energy conversion efficiency potential due to better utilization of the incident solar spectrum. By tailoring the contact area between the Si microwire substrate and the III-V epilayer through selective epitaxy, a wide range of device geometries can be achieved experimentally. In this work, we consider three designs which constrain the contact area between the III-V top cell and the Si microwire bottom cell: (1) a “tipped” structure, where only the last 2 ?m of a Si microwire is coated, (2) a “spike-tipped” structure, where the Si microwire is grown to a sharp point and coated on the final 2 ?m, and (3) a “tube” structure, where the Si is etched back into a thermal oxide grown around the wire. All three designs are demonstrated using low pressure metalorganic chemical vapor deposition of Ga1-xInxP on specially prepared Si microwire substrates. Cathodoluminescence and photoluminescence are used to evaluate the material quality at nano- and macro- length scales, respectively. Scanning electron micrographs of each structure are used to create 2D coupled full field optical and device simulations using the Synopsys Sentaurus TCAD package. Current matched device tandem device designs for all three geometries are achieved, and realistic materials parameters are used to predict device performance.

8824-35, Session 8

A new method of photo-induced electrodeposition of PEDOT with silicon nanowires as electrode to form hybrid solar cells

Mingxuan Zhu, Judikaël Le Rouzo, Institut Matériaux Microélectronique Nanosciences de Provence (France); Marielle Eyraud, Lab. Chimie Provence (France); François R. Flory, Institut Matériaux Microélectronique Nanosciences de Provence (France)

Recently a new hybrid core-shell solar cell can reach more than 5% conversion efficiency. And these cells are realized by spin coating PEDOT:PSS on silicon nanowires array. The main drawback of spin coating method is bad contact quality of PEDOT:PSS on silicon wire surface, because the large size of PEDOT:PSS particles limits its penetration into the gap between wires.

Compared with spin coating, the electrochemical method can control the PEDOT film volume by determining the quantity of reaction charges during deposition. Another advantage over spin coating is tunable doping level of PEDOT that is related to quantity of anions involved into the polymer. The conformality of PEDOT coating single silicon wire can be influenced by many parameters including concentration of monomer, solvent, polarization bias, illumination intensity and so on.

Using cyclic voltammetry method, the anodic potential range for PEDOT formation is determined on silicon NW. It has been shown, by using SEM observations coupled with EDS analysis, that the PEDOT film can be successfully deposited on silicon nanowires array with electrochemical method under illumination. The illumination is necessary for PEDOT polymerization, while only little volume of polymer is fabricated in the dark.

The electro-optical measurements of such a structure will be presented and the interest of this heterojunction for nanowires silicon solar cells will thus be determined.

8825-26, Session PMon

Application of acetate, lactate, and fumarate as electron donors in microbial fuel cell

Oresta M. Vasyliv, Oleksandr I. Bilyy, Yaroslav P. Ferensovych, Svitlana O. Hnatush, Ivan Franko National Univ. of L'viv (Ukraine)

Microbial fuel cells (MFCs) are devices that use bacteria as the catalysts to oxidize organic and inorganic matter and generate current. Up to now, several classes of extracellular electron transfer mechanisms have been elucidated for various microorganisms. Shewanellaceae and Geobacteraceae families include the most of model exoelectrogenic microorganisms. Desulfuromonas acetoxidans bacteria inhabit aquatic sedimental environments and are philogenetically close to representatives of Geobacteraceae family. They are proposed to be used as a biocatalyst for MFCs because of high electron recovery (>80%) to the electric current in the process of organic matter oxidation. Two chamber MFC with volume 0.3 l was constructed with application of D. acetoxidans as anode biocatalyst. Acetate, lactate and fumarate were separately applied as organic electron donors for bacterial growth in microbial fuel cell. Bacterial cultivation in MFC was held during twenty days. Usage of lactate caused electric power production with the highest value up to 71.5 ?W on the third day of D. acetoxidans growth. Addition of fumarate and acetate into bacterial growth medium caused maximal power production up to 74.5 and 75.2 ?W respectively on the second day of their cultivation. Increasing of incubation time up to twentieth day caused decreasing of generated electric power till 20 ?W, 42 ?W and 43 ?W under usage of lactate, fumarate, and acetate respectively in anode chamber. As a conclusion, effectiveness, longevity and durability of constructed MFC on the basis of D. acetoxidans bacteria increased under addition of acetate and fumarate in anode chamber in comparison with lactate.

8825-27, Session PMon

System high voltage stress degradation test in various photovoltaic modules and encapsulant sheets

Han-Chang Liu, Wen-Kuei Lee, Mei-Hsiu Lin, Chung-Teng Huang, Fu-Ming Lin, Jen-Loong Huang, Industrial Technology Research Institute (Taiwan)

In this paper we review various PV module type, example MG-Si, poly-Si, CIGS module and encapsulant sheets performance suffer high voltage stress effect. To evaluate module durability in the presence of continuous high voltage we used three accelerated tests to qualify the HVS effect. The first one is under room temperature, 100% relative humidity, second method is room temperature and Al foil covered the front sheet and the last method is climatic chamber test at 85?and 85% relative humidity with -1000V bias applied to active layer, respectively. The I-V characteristics and Electroluminescence (EL) images have been measured after several time steps to quantify the degradation process of each module. Besides the recovery characterization was also investigation.

8825-28, Session PMon

Accelerated environmental aging and in-situ functional testing of commercial photovoltaic modules

Barrett G. Potter Jr., Kelly Simmons-Potter, The Univ. of Arizona (United States) and College of Optical Sciences, The Univ. of Arizona (United States)

Flat plate photovoltaic modules embody a complex assembly of varied material systems. Despite exposure to often adverse environmental conditions, the performance of these devices must be reliably maintained. With a functional lifetime strongly dependent on field conditions as well as on materials selection and design, an understanding of the relationship between these interrelated issues and the potential for performance degradation over the long-term is a continual goal, especially as new photovoltaic junction systems and module designs are developed.

The presentation will describe the investigation of environmental aging effects in commercially available, poly- and mono-crystalline Si PV modules. We have developed a full-scale environmental chamber equipped with single-sun irradiance capability providing illumination uniformity of 98% over a 2 x 1.6 m area. Time-dependent, photovoltaic performance (I-V characteristics) is evaluated over a compressed night-day cycle providing 6 hours of single-sun irradiance, representative of solar irradiance averages in the southwestern United States, followed by six hour dark (night) period. A total test time of 3.5 months of these cycles corresponds to year of exposure on a fielded module. Temperature and humidity maxima and minima used in the study range from 18°C, 62%Rh to 3°C, 32%Rh to simulate the coldest winter months, up to 37°C, 56%Rh to 23°C, 28%Rh to simulate the hottest summer months. Early results confirm the impact of environmental conditions on the module long-term performance. Correlation of these in-situ functional tests, a unique opportunity offered by this facility, with physical degradation of the modules is examined.

8825-29, Session PMon

Luminescence radiation spectroscopy of silicon solar cells

Radek Stojan, Jiri Vanek, Martin Mal?, Roman Gvritishvili, Lucie ?imonová, Ondrej Frantík, Brno Univ. of Technology (Czech Republic)

At present there are known many of diagnostic methods of detection large crystal lattice defects of silicon solar cells. This paper deals about results of new potential in to use one of characteristics luminescence radiation for detection defects of solar cells. So polarization spectroscopy of defect in solar cells may be used to fitting characterization of silicon solar cells. And this can lead to understand the electrical properties of defects in silicon solar cells and study of really formation defects. We extend the existing electroluminescence technology about polarization spectroscopy to yield the polarization of luminescence radiation by defect in solar cells.

Radiation emitted by the solar cell has a wave character that can interact with the silicon structures or hypothetically thin reflectance layer of solar cells. In our research we can observed the linear partially polarization luminescence light on poly-silicon crack defect. Spectral response of using CCD camera is approximately 300 to 1100 nm. Sinusoid dependence of luminescence intensity on the angle of linear polarization analyzer rotation shown this fact. The degree of polarization depends on the material, in this case the character of defect. Polarized light can be obtained in various ways. This fact opens up for potential next new questions in this widely course of study diagnostics defects silicon solar cells.

8825-1, Session 1

Degradation of transparent conductive oxides, and the beneficial role of interfacial layers

Heather M. Lemire, Kelly A. Peterson, Mona S. Breslau, Ina T. Martin, Kenneth D. Singer, Roger H. French, Case Western Reserve Univ. (United States)

Understanding transparent conducting oxide (TCO) degradation is critical to improving stability and lifetime of both organic and inorganic thin film PV modules, which utilize TCOs like indium tin oxide (ITO), aluminum-doped zinc oxide (AZO) and fluorine-doped tin oxide (FTO) as electrodes. These TCOs must retain their long-term functionality in diverse outdoor environments. In addition to bulk material degradation, interfacial degradation, a frequent avenue for failure in PV systems, is promoted by exposure to environmental stressors such as irradiance, heat and humidity. TCO samples were exposed to damp heat (85 °C, 85% relative humidity), ASTM G154, and modified ASTM G154 cycle 4 hot irradiance (70 °C, 1.55 W/m2 @ 340 nm) for up to 1000 hours. After each exposure, electrical and optical properties and surface energies of cleaned samples were determined. Yellowness, haze and resistivity of the TCO increased with exposure time, while the total surface energy decreased.

The delamination-vulnerable TCO/PV absorber interface can be engineered using interfacial layers to increase adhesion. We used allyltriethoxysilane (ATES) to modify the TCO/PV absorber interface, given its successful use in OLEDs. We characterized the electrical and optical properties, surface energies, and elemental composition of the silane on TCOs. Results demonstrate that silanization is a simple method of customizing the surface energy of the TCO, changing the water contact angle from 1° (clean ITO) to over 90° without compromising transparency or conductivity. Degradation data of TCO/silane stacks will be compared to open-faced TCO exposure results, as well as encapsulated outdoor results.

8825-2, Session 2

Predicting PV module service life *(Invited Paper)*

John H. Wohlgemuth, Sarah Kurtz, National Renewable Energy Lab. (United States); Tony Sample, European Commission Directorate-General Joint Research Ctr. (Italy); Masaaki Yamamichi, National Institute of Advanced Industrial Science and Technology (Japan)

Most PV customers want to know “if the PV modules purchased and deployed today will be able to survive for 25 years and how much they will degrade over that time”? We would like to be able to perform a set of accelerated stress tests that would determine whether a particular module type would survive for 25 years. Today we don’t know what set of tests to use. To help answer this question the PV industry created the International PV Module QA Task Force. The goals of the Task Force are to 1) Develop a QA rating system that provides comparative information about the relative durability of PV modules and 2) Create a guideline for factory inspections of the QA system used during PV module manufacturing. This presentation will discuss the QA Task Force program and the progress achieved over the first two years of the effort.

8825-3, Session 2

Characterization of defects in encapsulated solar modules using infrared lock-in thermography

Sergio Sánchez-Carballido, Juan Meléndez Sanchez, Fernando López Martinez, Emilio Olias, Univ. Carlos III de Madrid (Spain)

Infrared (IR) lock-in thermography (LIT) has been successfully used for defect detection in solar cells. Depending on the experimental setup, defects such as shunts, serial resistances, pre-breakdown regions, etc., can be qualitatively visualized or quantitatively measured. IR-LIT results improve the spatial resolution (SR) in defect visualization and the signal to noise ratio (SNR) between defects and sound regions as compared to the classic DC thermography. The same results have been accomplished on solar modules, considered as an ensemble of solar cells electrically connected. The main problem that appears in IR-LIT technique is the measurement when cells and modules are encapsulated, because most glasses used for encapsulation are opaque in the IR region. In this research the IR opacity of the encapsulating glass is treated from a thermal point of view. The solar cell has been considered as a heat source with a heating frequency actively generated by a modulated forward polarization. The encapsulation behaves as a thermal low pass filter, whose cutoff frequency has been calculated. In the experiments, a modulated forward electrical polarization has been applied to a solar module in the dark. The test sample has been a standard solar module of 36 cells connected in series. The thermal images have been acquired from the side of the external glass surface by an IR camera. A large improvement of SR and SNR has been demonstrated for shunt detection when the modulation frequency is below the cutoff.

8825-4, Session 2

Stress analysis of encapsulated solar cells by means of superposition of thermal and mechanical stresses

Sascha Dietrich, Matthias Pander, Matthias Ebert, Martin Sander, Jörg Bagdahn, Fraunhofer-Ctr. für Silizium-Photovoltaik (Germany)

Encapsulated solar cells are exposed to thermal and mechanical causing fracture, which may result in a power drop, arcing as well as hot spots in the long term. In order to minimize fracture of solar cells a fundamental understanding about the stress state is crucial.

Within this contribution mechanical stresses resulting from soldering, lamination, different operating temperatures (i.e. -30 – 75 °C) and mechanical loading are superposed, which is novel in PV science and engineering. The complex stress state in solar cells is calculated by means of finite element simulation. The generated simulation models include all details such as busbars and copper ribbons since they cannot be neglected in particular for interpreting the influence of thermal loads. A thorough analysis is given applying fundamental methods of material mechanics.

At first a systematic approach by means of uniaxial and biaxial bending is used in order to interpret the inhomogeneous multiaxial stress state of an encapsulated solar cell. This stress state has to be fully understood in order to deliver correct assumption for module design optimization and testing. Systematic studies of topology material parameters will be included in a second step. As a result generalized design measures will be given. E.g. the cell distance shall not fall below 3 mm due to strong interactions between the cells. Based on those and further definitions the stress state for a complete module will be analyzed and derivations for module design will be made in a third step.

8825-5, Session 2

Baseline testing procedures for PV modules beyond the qualification testing

Eric Schneller, Narendra S. Shiradkar, Neelkanth G. Dhere, Univ. of Central Florida (United States)

The qualification tests described in IEC 61215 for the c-Si PV modules are essentially pass/fail tests that assist in avoiding infant mortality. This paper reports on the baseline test procedure carried out on PV modules at Florida Solar Energy Center that go beyond the qualification tests and

obtain information about their degradation modes and mechanisms in the long run would allow prediction of their lifetime in various climates. The results from the baseline test procedures that have been carried out on mc-Si PV modules from three leading manufacturers are presented. Electroluminescence imaging has been used to detect and categorize the faults at the cell level. Indoor infrared imaging has been used to study the quality of electrical interconnects in the module. The infrared imaging carried out on the modules while they are undergoing outdoor exposure has provided information about the presence and distribution of hot spots in these modules. Conventionally, the insulation resistance tester has been used mostly for the dry and wet leakage test. In this study, several other tests such as Polarization Index test, Dielectric discharge test and Voltage excursion test are carried out on the PV modules. These tests have provided important information about the dielectric properties of module packaging materials that cannot be obtained using only dry/wet leakage tests. Finally a comparison of quality of Silicon cells, interconnects and dielectric/insulation properties of the packaging materials used in PV modules manufactured by the three leading manufacturers is presented.

8825-6, Session 2

Optical and electrical detection and localization of solar cell defects on microscale

Pavel ?karvada, Dinara Dallaeva, Elena Prokopyeva, Pavel Tomanek, Lubomír Grmela, Robert Macku, Brno Univ. of Technology (Czech Republic); Steve J. Smith, South Dakota School of Mines and Technology (United States)

Monocrystalline silicon wafer is still most used material for the fabrication of solar cells. The recent investigation shows that the quality of cells is often degraded by structural defects emerging during processing steps. On the other hand, there is a plenty of generally nonlocalized defects with different behavior and nature such as Schottky and ohmic shunts, edge shunts, cracks and dislocations there. Some of them are visible, other as microfractures, precipitates and other material structure inhomogeneities are often invisible. So a detection and localization of tiny local defects in the structure, as well as an assigning particular defects with corresponding degradation of photoelectrical parameters, is a key-point for solar cell reliability, lifetime and efficiency improvement. Although the breakdown can be evident in current-voltage plot, the localization of defects on the sample has to been done by microscopic investigations as well as by defects light emission measurement under electrical bias conditions.

Therefore modern scanning microscopy techniques are successfully applied in local diagnostics of defects in solar cells. The suggested method combines three measurements: electronic noise, local topography and locally induced photocurrent.

The experimental results obtained from samples where the defects were microscopically etched by focused ion beam are presented. Electrical and photoelectrical properties of sample before and after etching processing are also discussed.

8825-7, Session 3

UV aging and outdoor exposure correlation for EVA PV encapsulants *(Invited Paper)*

Charles Reid, Jayesh G. Bokria, Joseph Woods, STR Solar (United States)

A widely cited approximation in the solar industry is that "one week of xenon arc weather-o-meter exposure is equivalent to 1 year of field exposure." This statement is a generalization of test data generated in the mid 1990's as part of the NREL managed PVMaT-3 project. This approximation was based entirely upon yellowing of first generation EVA based encapsulants in two different accelerated test conditions, xenon arc and mirror accelerated outdoor aging. First generation EVA encapsulants were developed by STR under the JPL solar project 1975-1986 and are well known to exhibit yellowing (or browning) with exposure to UV and heat. This yellowing mechanism was understood and resolved with newer generation EVA encapsulation products introduced in late 1990's. Modules from the PVMaT-3 project included both older and newer generation encapsulants. Those modules were on a 2 axis tracker in Arizona from 1996 to 2012 and are now undergoing diagnostic tests. Older generation standard-cure encapsulant used in these modules exhibited severe browning over cells and the modules exhibit approximate power loss of 1% per year, but with very little drop of short circuit current (Isc). This same standard cure encapsulant material has been tested with updated xenon arc exposure methods and optical transmission tests to estimate the loss in power due only to browning and reduction in light transmission.

8825-8, Session 3

Examination of an optical transmittance test for PV encapsulation materials

David C. Miller, National Renewable Energy Lab. (United States); Jaione Bengoechea, Ctr. Nacional de Energias Renovables (Spain) and CIEMAT (Spain); Jayesh G. Bokria, Specialized Technology Resources, Inc. (United States); Michael Köhl, Fraunhofer-Institut für Solare Energiesysteme (Germany); Nick E. Powell, Dow Corning Corp. (United States); Michael E. Smith, Arkema Inc. (United States); Michael D. White, The Dow Chemical Co. (United States); Helen R. Wilson, Fraunhofer-Institut für Solare Energiesysteme (Germany); John H. Wohlgemuth, National Renewable Energy Lab. (United States)

The optical transmittance of encapsulation materials is a key characteristic for their use in many types of photovoltaic (PV) modules. Changes in transmittance over time in the field affect module performance which may concern product warranties. Because transmittance is important in product development, module manufacturing, and field power production (both immediate and long-term), an international standard has recently been proposed by the Encapsulation Task-Group within the Working Group 2 (WG2) of the International Electrotechnical Commission (IEC) Technical Committee 82 (TC82) for the quantification of the optical performance of PV encapsulation materials. Existing standards, such as ASTM E903, are general and more appropriately applied to concentrated solar power than to PV. The solar-weighted transmittance of photon irradiance, yellowness index (which may be used in aging studies to assess durability), and ultraviolet (UV) cut-off wavelength may all be determined using the proposed standard. The details of the proposed test will be described and the results of a round-robin experiment conducted to validate the test procedure using representative materials will be presented. For example, the measurement requirements (wavelength range and resolution), the requirements for the spectrophotometer (including the integrating sphere and instrument accessories, such as a depolarizer), specimen requirements (choice of glass superstrate and substrate), and data analysis (relative to the light that may be used in the PV application) were actively explored by the Encapsulation Group. The round-robin experiment investigated both intra- and inter-laboratory instrument precision and bias for five encapsulation materials (encompassing a range of transmittance and haze-formation characteristics).

8825-9, Session 3

Factors causing adhesional strength deterioration and delamination in c-Si solar cells

Neelkanth G. Dhere, Univ. of Central Florida (United States)

The dopant glass left on the c-Si cell has been known to cause

considerable loss of the adhesional strength and large-scale delamination after deployment of PV modules deployed in the harsh hot and humid coastal climate. It also caused a less severe loss of the adhesional strength and some delamination even after deployment of PV modules in the hot and dry climate. The acetic acid generated in modules using EVA encapsulant usually diffuses out through the back polymer sheet. However, in one incidence where the PV module composite was sealed with stainless steel back sheet the acetic acid generated by the EVA caused complete delamination of the EVA both from the c-Si cells as well as from the SS back sheet. There was a pungent smell of the acetic acid when the stainless steel back sheet was cut. An uneven application of the dopant can also cause large variation of dopant concentration. Significant loss of adhesion and even delamination were also observed in regions of the interfaces where high phosphorous concentrations had segregated due to chemically assisted diffusion. High concentrations of sodium from glass as well as from the coastal climate can also cause loss of adhesion and delamination. Reducing the sodium concentration in the glass combined with glass surface treatment have been found to minimize the loss of adhesion.

8825-10, Session 3

Weathering and durability of PV backsheets and impact on PV module performance

William J. Gambogi Jr., DuPont (United States); Yushi Heta, Kana Hashimoto, DuPont K.K. (Japan); James Kopchick, Thomas C. Felder, DuPont (United States); Steven W. MacMaster, Dupont Display Solutions (United States); Alexander Z. Bradley, Babak Hamzavytehraney, Vinci Felix, DuPont (United States); Tomoko Aoki, DuPont K.K. (Japan); Katherine M. Stika, Dupont CR&D (United States); Lucie Garreau-Illes, DuPont de Nemours International S.A. (Switzerland); T. John Trout, DuPont (United States)

Polymeric backsheets form the outer protective layer on the back of most crystalline and multi-crystalline silicon cell based photovoltaic modules. The mechanical, electrical, optical and chemical properties and durability of these backsheets are critical to the long term reliability, durability and safety of the photovoltaic modules. The stability of these backsheet properties is typically determined based on isolated stresses. However, impact of multiple stresses applied sequentially or simultaneously can lead to changes in materials properties that are more predictive of performance in the field. An important consideration in the development of accelerated test protocols is the level and duration of the stress. To test the weatherability of PV backsheets, key stresses include the sample temperature, light intensity and spectral power distribution and the presence and type of moisture applied. In this paper, we discuss performance of PV backsheets under these accelerated test conditions and compare changes in the materials properties to long-term outdoor performance of PV modules. We identify accelerated testing protocols that correlate with extended outdoor exposure, as well as accelerated test conditions that show no correlation with outdoor performance.

8825-11, Session 4

On differences between bathtub curves and linear degradation describing PV module degradation *(Invited Paper)*

Bolko von Roedern, von Roedern & Associates LLC (United States)

This addresses two separate issues that the human mind often confuses. The first is that not all PV module degradation data is fully and accurately interpreted. Second is the assumption that full and accurate data interpretation will necessarily lead to deeper insight and more accurate future predictions. It is however, not clear how much performance can be gained if secondary signals (like luminescence) are optimized. Often, these issues are reflected in data analyses that deal only with linear progressions, ignoring data that do not fit linear patterns. When claims are made that such data isn't public or does not exist with great enough accuracy, this may or may not reflect the real situation. While it may be instructive to understand PV losses in terms of per year (annual) loss, that might not accurately describe the actual degradation mechanism. A confusion may exists between average and individual numbers and greater accuracy and more data will not automatically guaranty deeper insight into an issue or allow more accurate future projections. The issue is whether or not more insight is gained by separation to identify the largest mechanism, or whether the correct combination of features minimizes degradation mechanisms.

8825-12, Session 4

Photovoltaic module lifetime and degradation science model development

Laura S. Bruckman, Nicholas R. Wheeler, Jiayang Sun, Roger H. French, Case Western Reserve Univ. (United States)

A better understanding of the degradation modes and rates for photovolatics (PV) modules is necessary to optimize and extend the lifetime of modules. Lifetime and degradation science (L&DS) is used to better understand degradation modes, mechanisms and rates of materials, components and systems in order to predict lifetime of PV modules. A PV module lifetime and degradation science (PVM L&DS) model was developed using statistical analysis including step analysis and structural equation models in order to elucidate statistically significant relationships between a variety of degradation modes and mechanisms. The PVM L&DS is an essential component to predict lifetime and mitigate the degradation of PV modules. Statistical analysis was used to explore the relationship of various module performance and degradation pathways from real-world and accelerated testing. The statistically signification relationships and significant model coefficients were then combined with domain analytics, incorporating materials science, chemistry and physics expertise, to produce a system of equations that model system performance based on unit degradation processes at the materials, component and system level. This exemplifies the development of a methodology to determine lifetime and degradation pathways present in modules and their effects on module performance over lifetime which can be iteratively refined.

8825-13, Session 4

Methods to evaluate the effect of water ingress: towards ultra-reliable PV modules *(Invited Paper)*

Laure-Emmanuelle Perret-Aebi, CSEM PV-Ctr. (Switzerland); Valentin Chapuis, Christian Schlumpf, Federico Galliano, Christophe Ballif, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

A durable encapsulation scheme is of paramount importance to achieve high energy yields, a long lifetime and a high reliability of the solar modules. In the PV modules, the glass and polymeric materials act as (semi-permeable) barrier layers for moisture and environmental stresses and mechanically stabilize the modules. After the cell itself, the encapsulant represents the most important material in the module in term of module reliability. Indeed, a good material selection not only increases the module production but will directly impact on the module efficiency and durability. An in-depth research should be performed to understand and evaluate the durability behaviour of PV elements exposed to atmospheric conditions. At the module level, the properties of the encapsulation polymers, their interaction with the surfaces and the module layers, as well as moisture permeation are critical. In particular, for thin film technologies, transparent conductive oxides can be sensitive both to moisture and ion migration as can occur in outdoor conditions (1,2).

Water vapor is considered as one of the most important degradation factor acting directly on the polymeric materials and corroding the metallic and glass components. Moreover, these corrosion effects are increased by the formation of acetic acid mainly driven by moisture ingress (3,4).

In addition to corrosion effects, water vapor will directly affect the adhesion of the encapsulants to the glass and the other components of the PV-module leading to delamination failures (5).

Therefore, encapsulation materials need to be evaluated to clearly understand their interaction with water in order to establish their efficiency in protecting the PV device.

We will present here various methods contributing to understand failure modes related to water vapor ingress with the final goal of going towards new design for ultra-reliable PV modules (<30 years).

• Using 2D finite-element analysis in correlation with climatic data, a model is built to simulate water and acetic acid ingress within the module through the backside encapsulants (backsheet and EVA). A comparison between various climatic region and corresponding equivalent damp heat (DH) time is given.

• We describe a new design for compressive-shear testing of polymer layers bonded to rigid substrates. We use it to characterize real interfacial adhesion of different encapsulants to glass substrate before and after exposure to water vapor (DH).

Hot spot testing of PV modules

John H. Wohlgemuth, National Renewable Energy Lab. (United States)

Reverse bias hot spots are an important failure mode for PV modules. The present hot spot test in IEC 61215 edition 2 does a poor job of identifying and testing such hot spots. The methods used to identify the specific cells to test do not result in selection of the cells most likely to fail. In addition the test method does not result in identification of the worst casr shading condition for the selected cells.

A new hot spot test procedure has been developed and has been incorporated into the draft of the third edition of IEC 61215, In the new approach the cells within each module most likely to suffer from hot spot problems are identified. The test then specifies a method for determining the worst case shading for each of those identified cells.

While the proposed new test has advantages over the old test method, there are still several questions to be answered for the proposed method:

• Is the test procedure as written easy to follow?

• Does the proposed non-intrusive method of determining worst case shadowing really identify the condition where the shadowed cell is dissipating the most energy regardless of its shunt resistance?

• How long should the hot spot exposure be conducted and should the test be continuous or cyclic?

This paper will report on a set of experiments conducted to answer these questions about the new test method and will propose any necessary changes to the test procedure.

8825-15, Session 4

Finite element analysis based model to study the electric field distribution and leakage current in PV modules under high voltage bias

Narendra S. Shiradkar, Eric Schneller, Neelkanth G. Dhere, Univ. of Central Florida (United States)

The maximum system voltage for Photovoltaic systems is 600 V in US. Some modules are designed to operate even at 1500 V, which is the limit for IEC low voltage systems. The high voltage bias between the cell circuit and frame of the module leads to a leakage current flowing through the insulation of the module to the ground. Over time, this leakage current causes Electromigration of various species to and from the cell circuit, can result in slow degradation of the performance of PV module. It is important to understand the electric field distribution and leakage current pathways in the PV modules in order to study the system voltage induced degradation of PV modules. The leakage current from the PV modules deployed outdoor and under high voltage bias strongly varies with the environmental conditions. The lumped resistance models described in literature that attempt to explain the leakage current flow through the PV module do not provide adequate information about the distribution of leakage current through different layers of insulation present in the PV modules. In this paper, a Finite Element Analysis (FEA) based model for the insulation of PV module is described that yields useful information about the distribution of electric field, potential and leakage current flowing through different layers of module. The model is also used to predict and analyze the changes in leakage current with changing environmental conditions.

8825-16, Session 5

Development of an electrical calcium test for measuring very low water vapor transmission rates *(Invited Paper)*

Michael D. Kempe, Matthew O. Reese, Arrelaine A. Dameron, National Renewable Energy Lab. (United States)

Flexible thin-film PV is being explored as a way to reduce manufacturing and installation costs and improve power-to-weight ratios. These technologies are susceptible to moisture and require flexible, transparent barriers as an alternative to rigid glass. In order to achieve lifetimes of 25+ y, it is estimated that water vapor transmission rates (WVTR) at least as low as 1•10-4 g/m2/day must be achieved.

In this work, we have developed an electrical Ca (e-Ca) test method to quantify the WVTR of high performance barrier films. The barrier under test is adhered to a metal spacer with a variable size opening. The other side of the spacer is adhered to a test card with patterned Ca lines that function as sensors. By monitoring the resistance of Ca lines, as they are consumed by reaction with water, we can measure the barrier's WVTR. This method can measure dozens of samples in parallel, and it has been demonstrated to measure barriers in the 10-7 g/m2/day range. Considering that 1•10-4 g/m2/day will transmit a 1 µm layer of water over a 20 year period, if not accurately accounted for, the smallest uptake of water in any testing component can lead to erroneous results. Therefore, validation of any of these methods is an extraordinary challenge. Here we present results evaluating the sources of noise in this system and the limitations to the accuracy of this method looking at measurement accuracy and the sources and sinks for water within this method.

8825-17, Session 5

The reliability of bypass diodes in PV modules

Neelkanth G. Dhere, Narendra S. Shiradkar, Univ. of Central Florida (United States); Vivek S. Gade, Jabil Circuit, Inc. (United States)

The operating conditions of bypass diodes in PV modules deployed in the field are considerably harsher than the conditions at which the diode manufacturers test the diodes. This has resulted in several cases of field failures of bypass diodes and has raised concerns about the reliability of PV modules as a whole. The study of modes and mechanisms of the failures encountered in bypass diodes used in PV modules has a potential to provide important information which would be useful to predict the module lifetime. This paper presents the review of the failure modes and mechanisms observed in bypass diodes and current state of the work related to reliability testing of bypass diodes. The International PV Module Quality Assurance Task Force has recommended following four potential areas of research to understand the reliability issues of bypass diodes: Electrostatic Discharge, reverse bias thermal runaway testing, forward bias overheating and transition testing of forward bias to reverse bias. As a joint collaborative effort between Florida Solar Energy Center and Solar laboratory at Jabil Inc., laboratory testing of bypass diodes on the guidelines provided by the International PV Module Quality Assurance Task Force has been initiated. Preliminary results from this work will be presented.

8825-18, Session 5

Long term endurance test and contact degradation of CIGS solar cells

Thomas Ott, Francillina Schönberger, Thomas Walter, Hochschule Ulm (Germany); Oliver Kiowski, Dimitrios Hariskos, Zentrum für Sonnenenergie- und Wasserstoff-Forschung (Germany); Raymund Schäffler, Manz AG (Germany)

is the most promising technology for thin-film solar cells with record efficiencies of 20,4% on laboratory scale and 17,8% aperture area efficiency on a 900cm? module. Another important factor besides the cell efficiency is the reliability and long term stability of the manufactured modules, which can be assessed by accelerated ageing.

In this contribution the accelerated ageing of CIGS mini modules has been investigated. Therefore, modules were dark annealed under dry heat conditions at different temperatures. During the endurance test a positive or negative bias was applied to the cells. In regular intervals the IV- and CV-characteristics were measured at room temperature. After an overall stress time of 3500h the IV-characteristics were determined under different illumination conditions (intensity, spectral illumination). Our previous publications suggest a barrier at the back contact to explain the observed parameter drifts. This contribution is focused on the influence of different bias conditions during the endurance test on the generation of a back diode and on the change of the net acceptor concentration. These parameter drifts have an impact on the open circuit voltage, fill factor and on the appearance of a cross over between dark and illuminated IV-characteristics. The interpretation of the observed parameter drifts was supported by SCAPS simulations based on the above mentioned back barrier model. As an outcome of the simulations signatures for the existence of a back barrier diode were established. IV-measurements, temperature dependent Voc measurements and SunsVoc measurements are helpful means to detect such back diodes.

8825-19, Session 5

Probabilistic design-for-reliability (PDfR) of photovoltaic modules (PVMs) *(Invited Paper)*

Ephraim Suhir, Univ. of California, Santa Cruz (United States) and Univ. of Maryland, College Park (United States); Steve Kang, KAIST (Korea, Republic of); Laurent Bechou, Univ. Bordeaux 1 (France)

Qualification testing (QT) is the major means for making a viable photovoltaic (PV) device into a reliable product. While the short-term goal of a particular manufacturer is to conduct and pass the established QT, the ultimate long-term goal of the solar industry as a whole is to make its deliverables reliable in the field. It is well known, however, that the today's PV modules that passed the existing QT often exhibit premature field failures. Are the existing QT specs adequate? Could they be improved to an extent that if the PV device, module or a system passed the QT, there is a quantifiable way to assure that its performance in the field will be satisfactory and that its projected lifetime will indeed take place? The application of the probabilistic design for reliability (PDfR) concept enables one to provide affirmative answers to this question. One effective way to do that is to conduct the appropriate failure-oriented accelerated testing (FOAT); carry out, on a wide scale, in addition to the well established FOAT models, predictive PDfR modeling to understand the physics of failure and predict the probability of failure (PoF) in the field; carry out sensitivity analyses to determine the variability of this probability and determine what should be changed to assure its acceptable level; revise the existing QT practices, procedures, and specifications; and master the PDfR methodologies, realizing that the PoF is never zero, but could be predicted, quantified, minimized, controlled, specified and even maintained at an acceptable level, using various prognostics and health monitoring (PHM) techniques and equipment.

8825-20, Session 5

Linking accelerated laboratory and outdoor exposure results for PV polymeric materials *(Invited Paper)*

Xiaohong Gu, Chiao-Chi Lin, Yongyan Pang, Jaonnie Chin, National Institute of Standards and Technology (United States)

Linking accelerated laboratory test to field performance for predicting the service life of PV polymeric materials are being investigated at NIST using the reliability-based methodology. In this study, the NIST SPHERE (Simulated Photodegradation via High Energy Radiant Exposure) was used for accelerated laboratory tests of numerous PV polymers and components, such as ethylene vinyl acetate (EVA), poly (methyl methacrylate) (PMMA), ionomers, fronsheet fluoropolymers, and backsheet materials. A factorial experiment was designed to evaluate the effects of temperature, relative humidity, and spectral ultraviolet (UV) irradiance, either applied individually or in combination, on the main degradation mechanisms of these materials. The outdoor exposure was carried out in Gaithersburg, Maryland. Multiscale chemical, optical, mechanical and morphological measurements were carried out to follow changes during accelerated and outdoor exposures. The results indicated that the effects of simultaneous multiple stresses on materials degradation closely depended on the polymer structure, composition and assembling (lamination vs. non-lamination). The UV radiation was the most important factor for the degradation of all studied materials. A synergistic effect was observed for several materials such as EVA, ionomer, and backsheets, but not for the frontsheet fluoropolymers when specimens exposed to a combination of both UV and high relative humidity. It was also found that a higher UV spectral intensity led to a higher degradation rate, but not the degradation mechanism for the studied PMMA. The implication of this work to the current test standards will be discussed.

8825-21, Session 5

Safety and performance analysis of a commercial photovoltaic installation

Babak T. Hamzavy, Alexander Z. Bradley, DuPont (United States)

Understanding how to optimize photovoltaic (PV) system performance over its life time is vital to the sustainable growth of solar. As the number

of installations and system size continues to grow, this understanding becomes increasingly important. A systematic understanding of degradation mechanisms that are induced as a result of variables such as the service environment, installation, module design, material, weather, operation & maintenance, and manufacturing is required for reliable operation throughout a system's lifetime. We report the results from an analysis of a commercial c-Si PV array owned and operated by DuPont. We assess the electrical performance of the modules by comparing the original manufacturers' performance data with the measurements obtained using a solar simulator to determine the degradation rate. This evaluation provides valuable PV system field experience and will document key issues regarding safety and performance. A review of the nondestructive and destructive analytical methods and characterization strategies that we have found useful for system, module, and subsequent material component evaluations will be presented. We provide an overview of our inspection protocol and subsequent control process to mitigate risk. The objective is to explore and develop best practice protocols regarding PV asset optimization and provide a rationale to reduce risk based on the analysis of our commercial installations.

8825-22, Session 5

A critical hurdle to widespread use of polymer based luminescent solar concentrators

Geoffrey B. Smith, Univ. of Technology, Sydney (Australia)

Luminescent solar concentrators have been studied and improved for over 30 years. Of all moderate gain solar concentrator systems they are fundamentally the most attractive from a range of geometric and optical perspectives for many solar cell materials, for daylighting via light guides, and for some bio-applications. Of most significance is their étendue advantages over mirror and lens systems in terms of best dealing with the diffuse component and varying beam directions of solar radiation. Despite this and some attempted commercial ventures they have yet to achieve their potential. This paper addresses what is for the dominant class of such concentrators, those involving fluorophore doped polymers, especially PMMA, a core residual problem. Their long-term stability outdoors is insufficient. This is not due to UV effects and dye quenching, which can be controlled, but to fast local photothermal interactions between the activated dye molecules and the host material. Production of char like nanoscale absorbers may result. These absorb over a broad-band and though very dilute lower output transport efficiency in practical sizes. Data which led to this conclusion is presented, plus possible solutions. Other improvements in LSC polymer technology only have practical value if this core problem is first mitigated.

8825-24, Session 6

Experimental analysis, simulation and design guideline to suppress moisture ingress into thin-film PV module under continuously varying environment

Namsu Kim, Changwoon Han, Korea Electronics Technology Institute (Korea, Republic of); Dohyun Baek, Jaehoon Lee, DongSeop Kim, Samsung SDI Co., Ltd. (Korea, Republic of)

Recently, encapsulants without sealing material are being considered, especially ionomer, as one of candidates for glass-to-glass PV module structure to lower material and manufacturing cost. In this work, permeation properties such as diffusion and solubility coefficients of encapsulant and sealing materials were investigated and experimentally determined. Permeation characteristics of different combinations of encapsulants and sealing materials are evaluated under different local weather conditions. Results from simulating the vapor transport through different combinations over an expected lifetime will be presented. Based on experimental and simulating results, design guidelines to minimize moisture ingress are suggested based on the choice of encapsulant and sealing materials for each weather condition.

8826-1, Session 1

Hyperdoping of semiconductors by pulsed laser melting: in pursuit of intermediate-band photovoltaics *(Invited Paper)*

Austin J. Akey, Christine B. Simmons, Joseph T. Sullivan, Jonathan Mailoa, Massachusetts Institute of Technology (United States); Daniel L. Recht, Harvard School of Engineering and Applied Sciences (United States); Michael J. Aziz, Harvard Univ. (United States); Tonio Buonassisi, Massachusetts Institute of Technology (United States)

Laser-assisted hyperdoping of semiconductors has the potential to create a new class of materials with an impurity band inside the host material's band gap. This impurity band would enable the utilization of sub-gap light, potentially improving the efficiency of photodetectors and photovoltaics while retaining the desirable properties of existing devices. Hyperdoping, realized using ion implantation followed by pulsed laser melting to rapidly resolidify the implanted region, allows dopants to be retained at concentrations well above the equilibrium solid solubility limit. We are pursuing an approach involving impurities and pairs of impurities with states deep inside the band gap that are expected to broaden into one or more impurity bands at very high concentrations. We will show evidence that boron and sulfur are retained at hyperdoping levels following co-implantation into silicon and pulsed laser melting, and that gold is retained at much higher levels than other transition metals. Investigations of the suitability of these materials for photovoltaic applications and the character of the intermediate bands formed will be discussed using quantitative metrics. The extension of the hyperdoping technique to other intermediate-band materials systems will also be presented.

8826-2, Session 1

New laser-based approaches to improve the passivation and rear contact quality in high efficiency crystalline silicon solar cells *(Invited Paper)*

Carlos Molpeceres, María Isabel Sánchez-Aniorte, David Munoz-Martin, Miguel Morales, Sara Lauzurica, Juan José García-Ballesteros, Univ. Politécnica de Madrid (Spain); Pablo Ortega, Isidro Martín, Mónica Colina, Cristóbal Voz, Gema López, Ana-Belén Morales, Ramón Alcubilla, Univ. Politècnica de Catalunya (Spain)

Laser processing has been the tool of choice last years to develop improved concepts in high efficiency (HE) crystalline silicon solar cells. Different approaches for emitter formation by means of laser-doping techniques, and the extensive application of laser-firing techniques for rear contact formation mainly on p-type substrates, has lead to a general acknowledgement about the dominant role of laser technology in the quest of industrially viable concepts for HE solar cell production. Nowadays, substantial efforts are underway to optimize these processes minimizing the induced damage in the material inherent to the laser irradiation process.

In this work we present two recent developments made by our groups to improve, using lasers, the passivation and contact quality on the rear side of two different concepts of high efficiency crystalline solar cells. In both cases we analyze in detail the influence of the laser irradiation parameters on the final contact quality. First, we discuss the possibility of using standard laser-firing techniques in heterojunction silicon solar cells in an approach fully compatible with the highly demanding low temperature processing concepts associated to these devices. Secondly, and bearing in mind that a real challenge in rear contact formation is to reduce the damage induced by the laser irradiation, we present a new strategy, in fact an evolution of the standard laser-firing approach, to contact the rear side of p-type c-Si solar cells by means of laser processing of dielectric stacks containing Al2O3 before rear metallization. This approach, less aggressive than the standard approach of irradiation after the rear metallization, is applied to 2?2 cm2 solar cells leading to photovoltaic conversion efficiencies well beyond 20% on 0.5 and 2.3 ? cm substrates.

8826-3, Session 1

Investigation of metal contacts for silicon solar cells using laser transferred 8 µm thick Al foils

Longteng Wang, Univ. of Virginia (United States); David E. Carlson, Carlson PV Consulting (United States); Mool C. Gupta, Univ. of Virginia (United States) and National Institute of Aerospace (United States)

Laser transfer process for contact formation of silicon solar cells has been studied previously in our laboratory. The All-Laser-Transferred Contacts (ALTC) cell was demonstrated with initial efficiency of 15.1%. However, the thickness of laser transferred metal film was around 500 nm and was prepared by the vacuum evaporation process, which could increase the total series resistance. Also, the use of the vacuum evaporation process for preparing the coated glass increases the fabrication cost. Laser transfer of thick aluminum foil (8 µm) would lower the metal contact resistance and decrease the fabrication cost. A high-power nanosecond pulsed laser with wavelength of 1064 nm was used for laser transfer of aluminum foil. The initial demonstration was performed by laser transfer of aluminum foil through a passivation oxide (100 nm) layer to contact p-type silicon. The transfer of thick Al foil layer mounted on glass to Si substrate was carried out while Fraunhofer ISE group mounts the foil on Si substrate and fires it. We are able to laser transfer 8 micron thick Al foil with our current laser. With higher power laser, thicker foil could be transferred. Point and line metal contacts were investigated. The results of optical and scanning electron microscope images, contact resistance and electrical cell parameters will be reported. Studies are focused on the effect of laser transfer parameters on the optimization of cell performance.

8826-4, Session 1

Towards increased efficiency in solar energy harvesting via intermediate states *(Invited Paper)*

Eric Mazur, Kasey C. Phillips, Benjamin Franta, Yu-Ting Lin, Meng-Ju Sher, Harvard Univ. (United States)

Shining intense, ultrashort laser pulses on the surface of a crystalline silicon wafer drastically changes the optical, material and electronic properties of the wafer. The process has two effects: it structures the surface and incorporate dopants into the sample to a concentration highly exceeding the equilibrium solubility limit. This femtosecond laser "hyperdoping technique" enables the fabrication of defect- and bandgap engineered semiconductors, and laser texturing further enhances the optical density through excellent light trapping. Hyperdoped silicon opens the door for novel photodectors and for Earth-abundant, semiconductor-based solar energy harvesters with the potential for both low cost and high photoconversion efficiency.

The same technique can be used to form nanostructured and doped

TiO2 and non-stoichiometric TiN films. We show that oxygen, nitrogen, and chromium incorporation occurs in these films when the laser fluence exceeds the ablation threshold. Our research offers an innovative approach to alter the surface and structure of TiO2 to generate new materials with applications in visible-light watersplitting.

8826-5, Session 1

Role of process parameters on laser fired contact geometry and resistance

Ashwin S. Raghavan, Todd A. Palmer, Edward W. Reutzel, Tarasankar DebRoy, The Pennsylvania State Univ. (United States)

The evolution of the laser fired contact geometry of a silicon wafer with an aluminum metallization layer is studied using a transient numerical heat transfer and liquid metal flow model. This model considers time dependent alloy composition, the very large heat of fusion in aluminum-silicon alloys, and Marangoni convection of molten alloy driven by spatial gradients of temperature. The effects of laser processing parameters on the evolution of concentration fields produced are examined for a wide range of pulse durations and power densities during laser processing with various aluminum metallization layer thicknesses. The computed results of fusion zone geometry and concentration profiles are compared with the corresponding experimentally determined results. After the model is validated with experimental results, sensitivity of several laser parameters, such as the pulse duration, power, and power density, on the contact geometry and temperature and concentration profiles are examined.

8826-6, Session 1

Pulsed laser annealing of polycrystalline CdTe

Brian J. Simonds, Brian van Devener, The Univ. of Utah (United States); Christos S. Ferekides, Univ. of South Florida (United States); Michael A. Scarpulla, The Univ. of Utah (United States)

CdTe is an important photovoltaic material used in the majority of all thin film modules manufactured today. It has been shown that CdTe is an extremely stable material that is largely stoichiometric across a range of deposition techniques. Here, we show that pulsed laser annealing can be used to affect the stoichiometry of thin film CdTe. A KrF excimer laser with a wavelength of 248nm and pulse duration of 25ns is used to deliver various energy fluences between 0 and 200 mJ/cm2 to an unintentionally-doped polycrystalline CdTe film. The surface melting threshold is observed to be between 50-100 mJ/cm2 as evidenced by scanning electron microscopy and is seen to be confined only to the film surface. We show with x-ray diffraction that the structure of the bulk is largely unaffected by these treatments. To measure the stoichiometry at the surface we use x-ray photoemission spectroscopy while the bulk is measured with secondary ion mass spectrometry. The stoichiometry changes as a function of laser fluence over a depth of several microns even though the penetration depth of the 248nm excitation is <10nm. To help explain this, we present a full, 3D heat flow model which predicts temperatures vs. time and depth which helps us construct hypotheses which can align the seemingly disparate results from our work and the literature.

8826-8, Session 2

Solution based solar cells on flexible substrate assisted by laser *(Invited Paper)*

Seung Hwan Ko, KAIST (Korea, Republic of)

Laser processing of solution processed solar cell has attracted tremendous attention due to its economic and simple process nature. Solution process can remove expensive vacuum deposition processes and laser process can remove any high temperature processes. Thus, laser assisted solution process can fabricate solar cells on a heat sensitive polymer substrate. This kind of solar cells can be applied to light weight, low cost solar cells on plastic substrate and further can be fabricated by roll-to-roll process.

8826-9, Session 2

Comparison of two picosecond laser sources for SiNx ablation with subsequent nickel silicide formation by excimer laser annealing (ELA) for industrial high efficiency silicon solar cells

Samuel Gall, Commissariat à l'Énergie Atomique (France)

The front side contacting of c-Si solar cells with a two-step nickel-copper (Ni-Cu) metallization requires local openings in the Anti-Reflective Coating (ARC) layer followed by the formation of a nickel silicide seed layer in the ARC trenches and subsequent metal plating. This work aims at correlating the nickel silicide formation by Excimer Laser Annealing of a thin PVD-Ni layer with the silicon surface properties resulting from ARC ablation. Using a ps-range laser source emitting at 532nm with a repetition rate of 200kHz, the first ablation process targets the selective removal of SiNx while inducing only slight changes to the surface topography and properties of an initial 100?/• n+ POCl3 emitter. The second ablation process involves a ps-range source emitting at 355nm with a repetition rate of 80MHz and targets the simultaneous formation of a selective emitter solar cell structure. Thermal effects induced by the 80MHz high cadency SiNx ablation process lead to a partial melting of the pyramids at textured silicon surface and a redistribution of the emitter profile. Nickel silicide formation in the ARC trenches resulting from the irradiation of a 50nm PVD-Ni layer with a XeCl Excimer laser (308nm, 150ns pulse duration) is investigated for each ablation process. After removal of the unreacted Ni using selective wet etch chemistry, the phase, thickness and uniformity of the nickel silicide is compared to a reference process where NixSiy is directly formed with same XeCl laser on textured silicon featuring same as-diffused 100?/• emitter. The influence of post-ablation surface topography and emitter properties is discussed. Both ablation processes target thin 20µm self-aligned NiSi line that can contribute to the industrial manufacturing of high efficiency silicon solar cells.

8826-10, Session 2

Optimal irradiance for sintering of inkjet-printed Ag electrodes with a 532 nm CW laser

Yoon Jae Moon, Heuiseok Kang, Kyungtae Kang, Jun Young Hwang, KITECH (Korea, Republic of); Seung Jae Moon, Hanyang Univ. (Korea, Republic of)

Industrial solar cell fabrication generally adopts printing process to deposit the front electrodes, which needs additional heat treatment after printing to enhance electrical conductivity. As a heating method, laser irradiation draws attention not only because of its special selectivity, but also because of its intense heating to achieve high electric conductivity which is essential to reduce ohmic loss of solar cells.

In this study, variation of electric conductivity was examined with laser irradiation having various beam intensity. 532 nm continuous wave (CW) laser was irradiated on inkjet-printed silver lines on glass substrate and electrical resistance was measured in situ during the irradiation. The results demonstrate that electric conductivity varies nonlinearly with laser intensity, having minimum specific resistance of 4.1 x 10-8 Ωm at 529 W/cm2 irradiation. The results is interesting because the specific resistance achieved by the present laser irradiation was about 1.8 times lower than the best value obtainable by oven heating, even though it was still higher by 2.5 times than that of bulk silver. It is also demonstrated that the irradiation time, needed to finish sintering process, decreases

with laser intensity. The numerical simulation of laser heating showed that the optimal heating temperature could be as high as 300 oC for laser sintering, while it was limited to 250 oC for oven sintering. The nonlinear response of sintering with heating intensity was discussed, based on the results of FESEM images and XRD analysis.

8826-11, Session 3

Pump-probe investigations and numerical simulation of the confined laser ablation of thin film systems used for photovoltaic *(Invited Paper)*

Heinz P. Huber, Jürgen Sotrop, Hochschule für Angewandte Wissenschaften München (Germany); Stephan Rapp, Technische Univ. München (Germany); Matthias Domke, Hochschule für Angewandte Wissenschaften München (Germany)

The transient behaviour of the laser lift-off of thin film systems, initiated by glass substrate side or by film side irradiation with a 660 fs laser pulse, is investigated from the femtosecond to the microsecond range. For this purpose, a pump-probe microscopy setup is utilized to measure the transient relative reflectivity change of the irradiated spot at the molybdenum/glass interface. Moreover, the setup enables to measure the dynamic mechanical movement of the film by interferometry. In addition, a multi-physics and multi-time scale simulation was performed to simulate the electron and lattice temperature, the phase transitions, and the mechanical movement of the film. The experiment and the simulated data suggest that the film bulging is mainly driven by a shock wave created by a volume expansion of about 10 % that occurs during the phase transition from solid to liquid. The acceleration of the removed thin films is in the order of 1010 m/s?. The films display a dome formation at a constant velocity of about 70 m/s. The mechanical motion continues for approximately 20 ns. Then intact disk or fractured film particles are sheared-off, if the tensile stress limit is exceeded.

8826-12, Session 3

Study of the laser scribing of molybdenum thin films fabricated using different deposition techniques

Neelkanth G. Dhere, Univ. of Central Florida (United States); Aravinda Kar, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States); Eric Schneller, Juliana Shimada, Florida Solar Energy Ctr. (United States)

Thin film solar cells, specifically CuIn1-xGaxSe2-ySy (CIGS) based devices, provide an alternative to Silicon based solar cells with the potential for lower production cost while maintaining comparable conversion efficiencies. In order to realize these lower production costs, the implementation of a monolithically integrated device is essential. Monolithic cell interconnections require three independent scribes commonly referred to as P1, P2 and P3. The P1 scribe is performed on the cell back contact and is required to electrically isolate adjacent cells. Molybdenum thin films remain the most suitable back contact for CIGS thin film solar cells, due to their high melting point and low reactivity. Laser scribing has been adopted for performing this scribe due to successful processing for a wide range of laser pulse lengths and wavelengths. This paper reports on the effect of the molybdenum thin film deposition technique, and the resulting film properties, on the characteristic of the laser scribe. Films were deposited using DC magnetron sputtering over a range of working gas pressures and powers as well as in single and multilayer configurations. It was found that the residual stress within the film led to significantly different laser ablation processes. This required independent tuning of the laser processing parameters to create a clean, defect free scribe for different samples. Experimentation was carried out using both film side and glass side processing. It was determined that processing these films from the glass side led to a reduction in cracks and delamination originating from the scribe. The processing conditions that produced successful scribe lines for the various films are presented and discussed.

8826-14, Session 3

Pulsed laser scribing of earth-abundant Cu2ZnSnS4 thin film solar cells

David J. S. Hwang, Di Liu, Stony Brook Univ. (United States); Makarand A. Karmarkar, Michael A. Scarpulla, The Univ. of Utah (United States)

Beam shaping imaging system for laser microprocessing with scanning optics

Alexander V. Laskin, AdlOptica Optical Systems GmbH (Germany); Nerijus ?iaulys, Gintautas ?lekys, ALTECHNA R&D (Lithuania); Vadim V. Laskin, AdlOptica Optical Systems GmbH (Germany)

Laser beam shaping systems converting Gaussian to flattop or other irradiance profiles are used in various solar cell manufacturing laser technologies to enhance their performance. Scanning over whole working field with using popular 2- and 3-axis galvo mirror scanners is very often important part of microprocessing systems. Therefore, combining of beam shaping optics with scanning heads is an important technical task in field of solar cells manufacturing. As the beam shaping optics it is suggested to apply field mapping refractive beam shapers piShaper having some important features: low output divergence, high transmittance, extended depth of field, capability to work with TEM00 and multimode lasers, as result providing a freedom in building various optical systems. De-magnifying of flattop laser beam can be realized with using imaging technique; the imaging optical system to be composed from F-theta lens of scanning head and additional collimating system to be used right after a piShaper. One of the problems in this approach is implementation of compact design of the collimating part. As a solution it is suggested to apply a specially designed Beam Shaping Unit being based on piShaper and locating between a laser and a scanning head; the functions of that combined system are: conversion from Gaussian to flattop laser beam irradiance profile, compact collimator design, alignment features, easy adaptation to a laser and a scanning head used in particular equipment. There will be considered design features of refractive beam shapers piShaper and Beam Shaping Unit, examples of optical layouts to generate flattop laser spots, which sizes span from several tens of microns to millimetres. Examples of real implementations and results of material processing will be presented as well.

8826-17, Session 4

Laser drilling up to 15,000 holes/sec in silicon wafer for PV solar cells

Rahul Patwa, Hans J. Herfurth, Fraunhofer USA, Inc. (United States); Guenther Grupp Mueller, Khan Bui, SolarWorld Americas LLC (United States)

One way to realize a back contact solar cell design is to 'wrap' the front contacts to the backside of the cell [1]. This result in significantly reduced shadowing losses, possibility of simplified module assembly process and reduced resistance losses in the module; a combination of measures, which are ultimately expected to result in lower cost per watt of PV modules. A large number of micro-vias need to be drilled in a silicon wafer through which the front and rear contacts can be connected. Laser drilling was investigated using a pulsed disk laser was used which provided independent adjustment of pulse width, repetition rate and laser power. To achieve very high drilling rates, synchronization of laser beam with two-axis galvo scanner was established using a FPGA controller.

A design of experiments (DOE) was developed and executed to understand the key process drivers that impact the average hole size, hole taper angle, drilling rate and hole quality. Laser drilling tests were performed on wafers with different thicknesses between 120 µm and 190 µm. The primary process parameters included the average laser power, pulse length and pulse repetition rate. The impact of two laser spot sizes (34 µm and 80 µm) on the drilling results was compared.

The results show that the average hole size can be varied between 30 – 100 µm by changing processing parameters such as laser power, pulse length, repetition rate and spot size. In addition, this study shows the effect of such parameters on the hole taper angle, hole quality and drilling rate.

Using optimized settings, 15,000 holes per second are achieved for a 120 µm thick wafer with an average hole diameter of 40µm.

Rapid laser scanning based texturing of silicon surfaces for enhanced solar cell performance by improved light trapping

David J. S. Hwang, Matthew Quigley, Di Liu, Stony Brook Univ. (United States); Hee K. Park, Dong X. Yu, YUCO Optics Corp. (United States)

Extensive research in micro/nanoscale surface engineering has developed for many energy applications. The laser-texturing has proven to be a useful technique to improve solar light trapping performance in solar cell devices. However, state-of-the-art laser texturing methods still have limitation in realizing reasonable manufacturing cost and scalability. In addition, laser-textured surfaces are lack of nice structural connectivity with base material systems, frequently requiring subsequent chemical etching steps to overcome the addressed issues.

In this study, we will present recent evaluation results on a cost effective surface texturing method based on rapid scanning of nanosecond laser pulses. In contrast to conventional laser-assisted methods, we have achieved highly uniform and controllable texturing means over arbitrary scanning area on silicon surfaces. Detailed texturing mechanisms such as effect of unit laser spot size on the local thermo-capillary-driven textured structures, continuing texturing trend over the extended surface area, and effect of molten depth controlled by laser parameters, will be discussed based on advanced in-situ and ex-situ characterization techniques. It will be also shown that the resulting surface structures exhibit superior crystallinity assisted by simultaneous annealing mechanism in the course of rapid scanning of nanosecond laser pulses. The detailed effect will be visualized by experimental analysis using electron microscopes and optical microscope and spectroscopy. Finally, potential towards practical manufacturing capabilitiy will be considered in conjunction with reasonable manufacturing cost and scalability.

8826-19, Session 4

Optical and electrical properties of SnO2 thin films after ultra-short pulsed laser annealing

Davide Scorticati, Univ. Twente (Netherlands); Andrea Illiberi, TNO Science and Industry (Netherlands); Johann Z. P. Skolski, Univ. Twente (Netherlands) and M2i (Netherlands); Ton C. Bor, Wojciech Ogieglo, Michel Klein Gunnewiek, Aufried T. Lenferink, Cornelis Otto, G. R. B. E. Römer, Univ. Twente (Netherlands); Frank Grob, TNO Science and Industry (Netherlands); Dirk F. de Lange, Univ. Autónoma de San Luis Potosí (Mexico); Bert A. J. Huis in 't Veld, Univ. Twente (Netherlands) and TNO (Netherlands)

Ultra-short pulsed laser sources, with pulse durations in the ps and fs regime, are commonly exploited for cold ablation. However, operating ultra-short pulsed laser sources at fluence levels below the ablation threshold can be used for fast and selective thermal processing. This is especially advantageous for the processing of delicate thin films. A precise control of the heat affected zone (as small as tens of nanometers, depending on the material and laser parameters) can be achieved, thus enabling the treatment of the upper surface of thin films with negligible effects on the rest of the film and no thermal damage on sensitive substrates below. By applying picosecond laser pulses, the optical and electrical properties of a 900 nm thick SnO_2 film, grown by an industrial CVD process on boroflat-glass, were modified. The treated film showed a higher transmittance of light in the visible and near infra-red range, as well as slightly increased electrical sheet resistance. Changes in optical properties are attributed to thermal annealing, as well as to the occurrence of Laser-Induced Periodic Surface Structures (LIPSSs) on the surface of SnO_2 films. The latter were found to be superimposed on the morphology of the as deposited film. The increase of electrical resistance was attributed to the generation of laser induced defects during the fast heating-quenching cycle. These results can be used to further improve the performance of SnO_2-based electrodes for solar cells and/or electronic devices.

8827-1, Session 1

Topological optimization of nonlinear optical quantum wire networks *(Invited Paper)*

Richard Lytel, Shoresh Shafei, Mark G. Kuzyk, Washington State Univ. (United States)

Spatially extended molecular structures comprised of interconnected quantum wires are modeled as quantum graphs with one-dimensional electron dynamics. Their nonlinear optical responses can approach the fundamental limits for structures containing specific topological motifs. Graphs comprised of composites of star vertices exhibit the largest response, whereas an isolated closed-loop graph (ie, a molecular ring) has a small response regardless of the geometry (shape) of the loop. Combinations of loops with stars produce some of the largest nonlinearities ever predicted by any model and approach the potential optimization limits determined by the Thomas-Reiche-Kuhn sum rules for any quantum system.

We present the results of a comprehensive study of the topological dependence of the nonlinearities of quantum graphs and show exactly how first and second hyperpolarizability of a graph depend upon its topological class and how the hyperpolarizability tensors vary with graph geometry. We solve an arbitrary graph for its eigenvalues and eigenstates, use these to compute the complete set of transition moments, and employ a sum-on-states to get the hyperpolarizability tensor components. We invoke their rotation group properties to calculate the best shape for each ensemble member of thousands of random graphs with identical topology. We perform Monte Carlo calculations for loops, bent wires, stars, and combinations of these and show how graphs with stars share universal scaling behavior near the maximum nonlinear responses. We articulate a set of design rules for quantum-confined, quasi-one dimensional systems that may be realized using molecular elements and nanowires.

8827-2, Session 1

Optimizing hyperpolarizability through the configuration space of energy spectrum and transition strength spanned by power law potentials

Sean Mossman, Mark G. Kuzyk, Washington State Univ. (United States)

Our work seeks to determine what makes a large nonlinear response beyond the trivial strategy of making larger molecules. Various techniques have been applied to purportedly probing the full configuration space in hopes of finding the largest nonlinear-optical response. An important result of such studies: the off-resonant nonlinear optical response depends strongly on the nature of the energy spectrum and oscillator strength of the dominant transition. Given the persistent small gap between the best molecules and the calculated fundamental limit, speculations for the need of exotic and perhaps even unphysical Hamiltonians have been proposed.

Our approach is to focus on the class of power law potentials spanning many fundamentally interesting systems including hydrogen-like atoms, harmonic oscillator, particle in a box and electric multipoles -- systems that are analytically tractable. Smooth variation of the exponent covers all these classes as a subset of a much larger configuration space, providing the opportunity to characterize their nonlinear optical properties in terms of one parameter.

We focus on identifying universal properties associated with the largest first and second hyperpolarizabilities, including the nature of the energy spectrum and transition moments as the exponent is smoothly varied over the full domain. We find a discontinuity in the energy density spectrum for the exponent -2, a peculiar and fascinating potential known to have many bound states but no ground state. Our results will be related to measurable properties of real systems and the importance of the 1/x2 potential to nonlinear optics will be discussed.

8827-3, Session 1

From fundamental limits to quantum networks: a path from science to applications

Shoresh Shafei, Richard Lytel, Mark G. Kuzyk, Washington State Univ. (United States)

The theory of the fundamental limits of the first and second hyperpolarizabilities has taken us closer to understanding the major factors that determine the maximum attainable nonlinear-optical (NLO) response of molecular systems and discovering the properties required of a material to exhibit efficient nonlinear response. The goal is to apply this understanding to developing new approaches and strategies for designing structures with large nonlinearities that can be ultimately used in future technologies.

A comparison of this theory with experiments on many molecules reveals a large gap between the two. Efforts to understand the origin of the gap and finding new classes of materials with efficient nonlinear response have been based on Monte Carlo techniques that probe a large enough part of the configuration space to generate hypotheses. A class of systems that are amenable to such analysis is nonlinear optical quantum graphs, which can be viewed as artificial materials with controllable properties where a combination of confinement, geomerty and topology can lead to ultra large hyperpolarizabilities. Calculations of their hyperpolarizabilities already show values that approach the fundamental limit. Our present work focuses on extended our calculations to real systems such as quantum wires as the fundamental building blocks. To do so, we account for band structure on the nanoscale using Bloch's Theorem of many-particle wavefunctions, and calculate the hyperpolarizabilities, which can then be compared with experiment both in theory validation and in guiding the development of new materials.

8827-4, Session 1

Shape engineering to promote head-tail interactions of electro-optic chromophores

Cheng Zhang, Lianjie Zhang, South Dakota State Univ. (United States); Stephanie J. Benight, Univ. of Washington (United States); Lewis E. Johnson, Bruce H. Robinson, Univ. of Washington (United States); Benjamin C. Olbricht, Univ. of Delaware (United States); Robert A. Norwood, College of Optical Sciences, The Univ. of Arizona (United States); Larry R. Dalton, Univ. of Washington (United States)

Alignment of dipolar chromophores lies at the heart of organic electro-optic materials research. Among all the factors (e.g., external electric field, temperature, conductivity, etc.) affecting alignment efficiency or order parameter, interchromophore electrostatic interaction has been the focus of attention in the last decade. The strength of dipole interaction is highly dependent not only on dipole moment but also on chromophore shape and chromophore number density. Antiparallel interaction is dominant in the solid state of conventional EO chromophores (long and flat) and prevents electro-optic coefficient (r33) from scaling with chromophore concentration. Despite the great amount of research along various approaches to enhancing alignment, order parameters of organic EO materials are still low (0.13-0.2 v.s. 1 for a perfect alignment). Antiparallel interaction can be selectively attenuated by attaching bulky groups to the middle part of chromophore. However, it is synthetically

challenging to provide sufficient steric protection without causing severe reduction of chromophore concentration. In this paper, we will present the first realization of atom-economic steric protection of chromophore against H-aggregation in all directions and show evidences for the dominance of head-tail interaction over antiparallel interaction of a highly dipolar chromophore. With the novel shape, the EO coefficients of guest-host films of the chromophore do not show attenuation with increasing concentration up to 100 wt%. The dominance of head-tail interaction also enabled fabrication of optical quality thick films from the neat chromophore and allows poling induced alignment to retain at temperatures above the poling temperature – a phenomenon never observed for other chromophores.

8827-5, Session 1

Multilayer optical data storage by photobleaching of organic fluorophores *(Invited Paper)*

Cory W. Christenson, Brent M. Valle, Anuj Saini, Chris Ryan, Case Western Reserve Univ. (United States); Christoph Weder, Univ. de Fribourg (Switzerland); Joseph Lott, Univ. of Minnesota (United States); Eric Baer, Kenneth D. Singer, Jie Shan, Case Western Reserve Univ. (United States)

The capacity of optical data storage media has failed to keep up with magnetic media, limiting their application. This is mainly due to the inability to economically scale three dimensional optical media. We have recently reported optical data storage in 23 layers in a periodic bilayer polymeric film having 300nm thick writing layers separated by 3micron thick buffer layers at diffraction limited resolution using a 405 nm Blu-ray laser (Adv. Mater. 24 (38), 5222-6, 2012). The production of these films using a low-cost and highly scalable technique based on multilayer polymer co-extrusion promises large capacity optical data storage media up to the petabyte scale.

The writing process is based on photobleaching organic fluorophores incorporated as dopants into the active polymer layers. For example, 2.0 wt.% of the fluorescent chromophore 1,4-bis(?-cyano-4-octadecyloxystyryl)-2,5-dimethoxy-benzene (C18-RG) is doped into PETG, with PVDF buffer layers. We report here on investigations of the writing dynamics by pulsing a 405nm diode laser from 20ns durations and up. We find that both photochemical and thermal effects contribute to the photobleaching, with thermal effects and excited state absorption becoming dominant at higher powers. We interpret our results in terms of thermally activated rates and thermal diffusion. Photochemical processes are described by a multilevel model including both singlet and triplet manifolds, as well as ground state and excited state absorption. Different dyes and excitation wavelengths are also compared. Results are discussed in terms of the needs for long term optical data storage.

8827-6, Session 2

White fluorescent nano-fibers prepared by periodic organic hetero-epitaxy *(Invited Paper)*

Guenther Schwabegger, Johannes Kepler Univ. Linz (Austria); Francesco Quochi, Univ. degli Studi di Cagliari (Italy); Gerardo Hernandez-Sosa, Karlsruher Institut für Technologie (Germany); Tatjana Djuric, Technische Univ. Graz (Austria); Giovanni Bongiovanni, Univ. degli Studi di Cagliari (Italy); Antje Vollmer, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany); Martin Oehzelt, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany) and Humboldt-Univ. zu Berlin (Germany); Ingo Salzmann, Humboldt-Univ. zu Berlin (Germany); Roland Resel, Technische Univ. Graz (Austria); Norbert Koch, Humboldt-Univ. zu Berlin (Germany) and Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany); Helmut Sitter, Clemens Simbrunner, Johannes Kepler Univ. Linz (Austria)

Para-hexaphenyl (p-6P) or ?-sexithiophene (6T) form crystalline organic nano-needles by epitaxial growth on various substrates [1,2]. It turned out that p-6P in combination with muscovite mica represents an outstanding material combination. In particular, the low substrate surface symmetry in combination with the resulting molecular alignment is the key to well ordered, parallel aligned nano-fibers providing highly polarized blue fluorescence and laser action [3].

To preserve the morphological properties of p-6P based nano-fibers and simultaneously tune their emission wavelength, periodic organic hetero-epitaxy was utilized. Multilayer structures of p-6P and 6T have been prepared by hot wall epitaxy and analyzed by AFM, fluorescence microscopy, UPS, XRD and time resolved spectroscopy.

We demonstrate that organic hetero-epitaxy can be applied to produce multilayered nano-fibers with high crystallinity, well defined epitaxial relationship along different material phases, molecular azimuthal order, and long-range morphological homogeneity. It could be shown, that it is possible to precisely control and tune the highly polarized PL emission of the nano-fibers from the blue to the green and orange spectral regime by a variation of the 6T concentration. Remarkably, it is possible to prepare nano-fibers emitting white polarized light. Furthermore, it was recently shown that such nano-structures are capable of laser emission in the green and orange spectral regime [4].

8827-7, Session 2

Waveguiding properties of individual electrospun polymer nanofibers

Yuya Ishii, Ryohei Kaminose, Mitsuo Fukuda, Toyohashi Univ. of Technology (Japan)

Optical circuits are needed to achieve high-speed, high-capacity information processing. An optical waveguide is an essential element in optical circuits. Electrospun polymer fibers have diameters in the nanometer range and high aspect ratios, so they are prime candidates for small waveguides. In this work, we fabricate uniform electrospun polymer nanofibers and characterize their optical waveguiding properties. Poly(methyl methacrylate) (PMMA) solutions of different concentration that contain a small amount of Nile Blue A perchlorate (NBA) are electrospun. Uniform PMMA/NBA fibers with an average diameter of 540 ± 60 nm are obtained from the 10 wt% solution. The fibers are covered with transparent cladding and their ends cut vertically. A laser beam with a wavelength of 533 nm is irradiated onto the fiber from the direction vertical to the fiber axis so it scans along the fiber. Photoluminescence (PL) spectra at the end face of individual fibers are then measured. The PL spectra exhibit a red shift as the distance (d) between the end face and irradiating point of the laser beam increases because of reabsorption of PL that is guided in the fiber. Measurements of five individual fibers reveal the PL intensity at the end face decreases with a ratio of ~10-?d where the loss coefficient (?) is 7.3–32 cm-1. In conclusion, we demonstrate optical waveguiding in electrospun single nanofibers and evaluate their ?.

8827-8, Session 2

Low loss photonic structures realised by solution processing at low temperatures

Andrew Strang, Imperial College London (United Kingdom); Manuela Russo, Imperial College London (United Kingdom) and ETH Zurich (Switzerland); Walter R. Caseri, ETH Zurich

(Switzerland); Donal D. C. Bradley, Imperial College London (United Kingdom); Natalie Stingelin-Stutzmann, Imperial College London (United Kingdom) and ETH Zurich (Switzerland); Paul N. Stavrinou, Imperial College London (United Kingdom)

Photonic structures that can be produced by solution processing are attracting increasing interest in the scientific and industrial community due to the advantages straight-forward procedures such as those adapted from bulk "plastic" manufacturing. Key for realising photonic structures from solution, and at low temperatures, is the development of versatile, high refractive index, low loss material systems. In this work we employ an organic/inorganic hybrid material that was developed by Russo et al. and is processable from an aqueous solution: titanium oxide hydrate cross-linked polyvinyl alcohol (PVA). The material's refractive index can be tuned from 1.5 to greater than 1.8, yet without inducing significant optical losses. The refractive index can be further increased to over 2.1 by thermal annealing, showing that the refractive index of these hybrids can be tuned over a similar window as the best materials previously reported, but without reducing the material's transparency. We attribute this highly beneficial feature of these novel materials to the fact that they are molecular hybrids rather than nanocomposites that suffer from nanoparticle aggregation even at relatively low loadings. As an initial demonstration of this material's use in photonic structures we present solution-processed distributed Bragg reflectors (DBRs), fabricated to a desired optical response, which achieve close to 100% reflectance over a pre-designed optical stop-band. We demonstrate experimentally and through modeling of such structures that the hybrid material exhibits unprecedentedly low optical losses and excellent interfacial quality when integrated in multilayer stacks using deposition techniques commonly employed in the manufacturing of commodity "plastic" products.

8827-9, Session 2

Straightforward electro-optic polymer/TiO2 waveguide modulators *(Invited Paper)*

Feng Qiu, Shiyoshi Yokoyama, Kyushu Univ. (Japan)

Electro-optic (EO) polymers and their devices have received considerable attention in the photonics applications. Based on Pockels effect in EO polymers, a variety of EO waveguide modulators have been realized, such as all polymeric modulators, hybrid sol-gel SiO2 / EO polymer modulators, and EO polymer / silicon slot modulators. An ideal EO modulator should possess high poling efficiency, low VπL, simple fabrication process and low propagation loss. In this work, we have presented a phase modulator and a ring-resonator modulator, both of which are based on an EO polymer/ TiO2 system. This system can be realized by a straightforward fabrication process, which consists of a sputtering, a photolithography, and two times spin-coating. The r33 of our EO polymer in the waveguide was improved to 120 pm/V due to the function of the TiO2 layer, which was 80% higher than that in a thin film. Combining high r33 and short interelectrode gap, the phase modulator had a low VπL of 4V?cm, corresponding to 2 V?cm in a push-pull MZI structure; the ring-resonator had an on/off ratio of 8dB, a Q-value of 4500, and a resonance peak shift of 1.5pm/V. In addition, the propagation losses were ~3dB/cm and ~1.8 dB/cm for the phase modulator and ring-resonator, respectively. The straightforward fabrication process, low VπL, and low propagation loss make our modulators suitable for industrial productions.

8827-12, Session 3

Multi-scale multi-material plasmonic composites for enhanced linear and nonlinear optical response *(Invited Paper)*

Pieter G. Kik, Seyfollah Toroghi, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

Metal-organic and metal dielectric composites are well known to show optical properties that differ dramatically from those of their constituents. A new class of related composites, that of cascaded plasmonic metamaterials, has been predicted to produce field enhancement factors and nonlinear optical response which vastly exceeds that observed in systems. In these materials the coupling of surface plasmons on adjacent metal nanospheres with significantly different sizes can lead to effective multiplication of field enhancement factors. Thus far, research has focused on systems containing only a single material, and it is non-trivial how to extend this to more materials. Here we investigate the linear and nonlinear optical response of dielectric-Ag-Au composites containing Au and Ag nanospheres of different sizes in the 5 - 100 nm size range through numerical simulation. It is shown that careful engineering of inter-particle spacing and particle size differences enables the achievement of multiplicative cascading in these materials. The spherical nature of the metallic elements and their physical separation makes these structures ideal for high power applications. Internal field enhancement factors are shown to exceed those of isolated nanoparticles by over an order of magnitude. Effective enhancement factors for nonlinear optical absorption and refraction will be presented, and possible fabrication methods of these multiscale materials will be discussed.

8827-14, Session 3

Non-Markovian theory of collective plasmon-molecule excitations in nanojunctions combined with classical

electrodynamic simulations

Boris D. Fainberg, Holon Institute of Technology (Israel); Alexander J. White, Michael Galperin, Univ. of California, San Diego (United States); Boris Apter, Holon Institute of Technology (Israel)

Intersite dipolar energy-transfer interaction influences on electron transport through molecular wires in nanojunctions [1]. Such interactions can compensate Coulomb repulsions (CR) for particular relationships between their values [2]. This effect of exciton compensation of Coulomb blocking can be observed by varying the exciton coupling that can be achieved by controlling the plasmonic response of metallic contacts. Exploiting their tunability feature, wavelength specific designs for optimal energy transfer can be realized. We have applied the pseudoparticle nonequilibrium Green function formalism [3] to the study of coupling between plasmons and excitons in nonequilibrium molecular nanojunctions. The formalism treats on-site CR, inter-site exciton and plasmon-exciton couplings exactly, and is shown to be especially convenient for exploration of plasmonic absorption spectrum of nanopolaritonic systems with combined electron and energy transfers. We demonstrate the sensitivity of the exciton-plasmon Fano resonance to junction bias, CR and inter-site exciton coupling. We evaluate the local field and exciton coupling enhancement, along with the energy transfer to metal, using the dressed interaction [4] and FDTD calculations near plasmonic nanostructures. Our study opens a way to deal with nanopolaritonic systems in nonequilibrium molecular devices.

Optical properties of nanopatterned light-emitting organic-inorganic composites and fibers

Luana Persano, Andrea Camposeo, Pompilio P. Del Carro, Marco Polo, Ripalta Stabile, Consiglio Nazionale delle Ricerche (Italy); Anna Maria Laera, Vincenzo Resta, Leander Tapfer, ENEA (Italy); Dario Pisignano, Univ. del Salento (Italy)

Polymeric and nanocomposite micro- and nanostructures are widely exploited in different fields. Properly designing and combining their constituents is a direct and effective way to obtain new materials with tailored or improved properties. However, nanopatterning and interfacing nanostructures with devices at macro-scale remain challenging. Here we present a few model technologies that we developed, concerning the realization of light-emitting organic–inorganic composites gently shaped to obtain fluorescent nanostructures. Both in-situ and ex-situ nanocrystal synthesis approaches have been pursued and the optical properties of the resulting features have been investigated. We demonstrate line narrowing induced by amplified stimulated emission and assess the gain performances by the variable stripe length method.

8827-16, Session 3

Recent advances in two-photon 3D laser lithography with self-Q-switched Nd:YAG microchip lasers *(Invited Paper)*

8827-17, Session 3

Hybrid gold nanoparticles for fluorescent imaging and photodynamic therapy

Patrice L. Baldeck, Lab. Interdisciplinaire de Physique, CNRS, Univ. de Grenoble (France) and Lab. de Chimie, CNRS, Univ. Lyon (France)

We will review our work on hybrid Gold nanoparticles (GNP) that are coated with polymers bearing photoactive molecules optimised for their fluorescence or PDT activity. Our first goal in using GNP is to load a large density of photoactive molecules onto a biocompatible nanoplatform. Our second goal is to optimize the molecule GNP interaction to improve the photoactive properties.

In this project GNP have typical dimensions in the 50-100 nm that are suitable for in vivo imaging and therapy. Their geometrical shapes included spheres, rods, bipyramids and stars. The spherical shape is efficient only when a spacer is used to maintain a minimum distance between the photoactive molecule and the metallic surface. However, more elongated shapes, or tipped shapes can be used for a direct grafting of photoactive molecules if their transition dipole moments are maintained perpendicular to the surface (J-aggregate type of interaction between the GNP and molecules). We will report on optical spectroscopy, fluorescence imaging, cell uptake, cytotoxity, and PDT action of several type of polymers coatings and photoactive dye loading.

8827-18, Session 3

Recent advances in optical power limiting of nanoarchitectured materials

Jayan Thomas, Panit Chantharasupawong, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

Optical properties of nanomaterials and nanostructured materials have gained significant research interest. For example plasmonic nanostructures and graphene optics were targets of several recent studies. Plasmonic materials have been extensively studied and used in various applications, for instance, bio-sensing, photovoltaic, and cancer treatments. Graphene materials, on the other hand, have been found to be promising in various applications due to its excellent electrical and optical properties. Recent advances in optical nonlinear properties of novel materials like nanoparticle and graphene oxide will be discussed. In the first part of the talk, the size dependence of optical nonlinearity, at the surface plasmon wavelength, in atomically engineered particles will be presented. Its potential application as a resilient optical limiting material will be discussed. It has been found by our group that functionalization of graphene oxides by means of fluorination can lead to improvement of their nonlinear optical properties. A well adopted technique for measuring nonlinear absorption of both solid and liquid samples is an open aperture Z-scan, which is a transmission based measurement. In the second part of the talk, we will present a measurement technique called OPAZ scan to perform optical Z-scan and photoacoustic Z-scan simultaneously in one experimental run. We have found that simultaneous measurement of the optical and photoacoustic Z-scan signals offers considerably better understanding of the mechanism responsible for the optical nonlinearity. Moreover, when these two sets of information are collected simultaneously, erroneous conclusions can be avoided. OPAZ scan enabled us to recognize the nonlinear processes within a mixture of nonlinear scattering species and nonlinear absorbers.

8827-19, Session 3

Hybrid nanostructured biocomposite for organic photonic

Stefano Toffanin, Tamara Posati, Susanna Cavallini, Wouter A. Koopman, Marco Natali, Istituto per lo Studio dei Materiali Nanostrutturati (Italy); Anna Sagnella, Valentina Benfenati, Roberto Zamboni, Istituto per la Sintesi Organica e la Fotoreattività (Italy); Michele Muccini, Istituto per lo Studio dei Materiali Nanostrutturati (Italy)

Hydrotalcite-like (HTlc) compounds are layered solids with peculiar physical and chemical properties given their structural anisotropy. The intercalation of guest species possessing chromophoric groups into host layered nanoparticles gives rise to nanostructured materials with photophysical properties which are strongly affected by the geometrical and chemical environment experienced by the dye [1].

In particular, organic conjugated small-molecules are well-indicated candidates for the functionalization of HTlcs given their interesting optical and photonic properties, such as efficient optically pumped lasing in the solid state.

Natural biopolymers recently emerged as a highly promising candidates for realizing biocompatible photonic components. Indeed, we have recently demonstrated that dye-doped silk thin films can be implemented for organic lasing onto nanostructured grating, thus opening new perspectives for the applications of optically active silk in biophotonics and organic optoelectronics [2].

Here, we present the heterogenization of a chromophore with lasing properties on inorganic lamellar nanoparticles when dispersed in biopolymers. We report on the photonic properties of the new functionalized nanocomposite once deposited onto optical active substrates. A detailed photoluminescence time-resolved spectroscopic investigation is carried out for determining the specific photophysical processes and dye localization within the hybrid organic-inorganic nanostructures.

The performance analysis of an electro-optic polymer modulator

Guofang Fan, Qi Wang, Technical Institute of Physics and Chemistry (China); Yuan Li, Shanghai Institute of Measurement and Testing Technology (China); Lihua Lei, Shanghai Institute of Measurement and Testing Technology (China) and Tongji Univ. (China); Guangming Xu, Haohui Ren, Xinhou Liu, Zhen Zhen, Technical Institute of Physics and Chemistry (China)

In this paper, we present a detailed analysis about the electro-optic (EO) polymer modulators using a full vectorial finite difference (FVFD) mode solver for an optical waveguide and a finite-element method (FEM) for a microwave electrode. A detailed discussion has been presented to describe a modulator about performance parameters: Vpai L, ?fL, Nm, ?c and zc with the design parameters, where VpaiL is the product of the half-wave voltage Vpai and the electrode interaction length L, the parameter ?fL is the product of the 3 dB optical bandwidth ?f ?and the electrode interaction length L, ?c is the conductor loss and Zc is the characteristic impedance.

Design of Mach-Zehnder interference modulators composed of enhanced electro-optic active polymers *(Invited Paper)*

Guangming Xu, Jialei Liu, Zhen Zhen, Xinhou Liu, Technical Institute of Physics and Chemistry (China)

Organic electro-optic polymer has relatively low dielectric constant and especially high electro-optic coefficient, which is one of the perfect materials for making modulators with low loss and high bandwidth. In this paper, we firstly synthesized a novel chromophore based on 4-(diethylamino) salicylaldehyde, which was used as an electron donor and had one reactive site to introduce rigid isolated benzyl group. Polymers doped with the innovative chormophore showed good thermal stability and high electro-optic activity, which were adopted as core materials and used to design Mach-Zehnder interference (MZI) modulator. In the second part of the paper, we combined cladding materials and core materials and designed a low loss MZI optical waveguide. We used tapered waveguides at the input and output ports of MZI to reduce the coupling loss with fibers and tapered multimode Y-branches to equally split or combine optical signals. By simulating the transmission of optical modes in tapered structures, we calculated the optical loss of MZI waveguides and optimized the waveguides structures. Finally, we respectively designed the modulators with 50GHz 3dB bandwidth using the coplanar waveguide electrodes (CPWE) and the micro-strip electrodes (MSE), which are two typical traveling wave electrodes in microwave applications. We detailed analyzed the influence of electrodes structures on the microwave response and compared the CPWE and MSE when applied to polymer modulators. Fabrication of the modulators is under development. Modulators made of organic electro-optic polymers have great application prospects in the fields of information procession and communication needing high speed and high bandwidth.

Photoluminescence characteristics of dye-doped polymer nanofibers excited by surface plasmon polaritons

Ryohei Kaminose, Yuya Ishii, Takuma Aihara, Ayumi Takeda, Mitsuo Fukuda, Toyohashi Univ. of Technology (Japan)

One-dimensional nanostructures are attracting considerable attention because of their subwavelength size and unique optical properties including light confinement, guiding, and amplification. Electrospinning is a simple and versatile technique to produce polymeric fibers with diameters in the nanometer range, and allows light-emitting nanofibers to be prepared simply by adding organic dyes to raw polymer solutions (Y. Ishii and H. Murata, J. Mater. Chem. 22, 4695 (2012)). The photoluminescence (PL) of such fibers excited with external light sources has been thoroughly investigated, but PL arising from surface plasmon polariton (SPP) excitation has not been reported. In this work, we use SPPs to excite dye-doped electrospun polymer nanofibers by attenuated total reflectance. Uniform electrospun polymer nanofibers composed of poly(methyl methacrylate) (PMMA) and Nile blue A (NBA) with an average diameter of 540 ± 60 nm are prepared. The PMMA/NBA fibers are placed on an Au thin film deposited on a semi-cylindrical prism. A laser beam with a wavelength of 633 nm is then irradiated onto the Au film with different incident angles (?), and PL from the fibers and reflectance are measured. The highest intensity PL is obtained at ?=44°, where reflectance showed its minimum value because of excitation of SPPs. Our results confirm that SPPs can excite dye-doped electrospun polymer nanofibers.

Design considerations for monolithic beam formers based on electro-optic polymer phase modulators and strain-induced optical waveguides

Richard S. Kim, Attila A. Szep, Nicholas G. Usechak, Air Force Research Lab. (United States)

The fabrication and characterization of a 1?4-element integrated beam former based on electro-optic (EO) polymer phase modulators (PM) is summarized including findings related to waveguide loss, near- and far-field diffraction patterns, and the maximum steering angle achievable. Based on this device, two alternate designs are proposed to improve performance: an unequally spaced 1?4-element and an equally spaced 1?8-element beam former both based on EO polymer PMs. Models of these alternative designs indicate that waveguide propagation loss and strong grating lobes, both of which degraded the performance of the initial device, can be substantially improved. The proposed approach explored by the 8-element beam former introduces novel components including strain-induced optical waveguides, hybrid integration of active and passive polymers, modified waveguide diffraction aperture, and directional coupler thermo-optic (TO) switches.

Investigation of third order nonlinear optical properties in s-indacene-1,3,5,7(2H,6H)-tetraone based D-pi-A-pi-D chromophores by z-scan

Robert D. Breukers, Ayla P. Middleton, Stefaan Janssens, Sebastiampillai G. Raymond, Andrew J. Kay, Callaghan Innovation (New Zealand)

Recently there has been much interest in two photon absorbing chromophores for two photon initiated polymerisation1and reversible multistage redox systems.2 Centro-symmetric D-π -A-π -D chromophores also have potential in photonic applications such as optical communication and switching, due to their third-order optical nonlinearity.3 Variations can be made to the donor, the acceptor and the conjugated spacer such that it is possible to fine tune the electronic structure of the chromophore for particular applications4 and this enables the development of smart materials.

Here we describe the synthesis and characterization of a novel range of symmetrical two photon absorbing dyes based on a D-π -A-π -D architecture utilizing s-indacene-1,3,5,7(2H,6H)-tetraone based acceptors. Dialkyl-aniline based donors were synthesized and the effect of conjugation length on the optical properties of the chromophores was investigated in an effort to tailor these materials for photonic applications. Conjugated linkers containing thiophene and pyrrole moieties were investigated. The third order nonlinear optical properties of these materials were investigated by z-scan. We report our z-scan data, which shows these materials have high third order optic nonlinearity. The ability to tune the nonlinear optical properties by varying the structure of the molecules is also discussed.

Surface-emitting liquid crystal laser using nanostructured, transparent, and conductive films

Na Young Ha, Kyung Won Yoon, Ajou Univ. (Korea, Republic of)

An organic dye laser has received considerable attention because of a broad and continuous tunability in the visible region, an intrinsic low threshold, and an easy processing. Particularly, a distributed feedback (DFB) structure is one of the preferred resonators to achieve such organic lasers. For a given period of the DFB grating, the second-order diffracted light makes a counter-propagating mode, resulting in optical feedback for lasing action. Lasing can be out-coupled to the surface normal direction by first-order Bragg diffraction.

Indium-tin-oxide (ITO) films have been widely used as transparent conducting electrodes of optoelectronic devices such as displays and solar cells due to high optical transmission and good electrical conductivity. Recently, we fabricated ITO films with one-dimensional periodic nanostructures by all-solution processing of ITO nanoparticles and a nanoimprint lithography (NIL) method. The NIL used in this study is a promising technique for quick, simple, and low-cost surface patterning with submicron resolution. The experimental transmission spectra from the nanostructured ITO films with various periodicities showed specific transmission dips due to light diffractions. Here, we use this nanostructured ITO film as a DFB resonator, transparent electrode, and alignment layer of nematic liquid crystals. Dye-doped nematic liquid crystals are introduced into the DFB resonator. In addition, the electro-optic performance of the lasing device based on nanostructured ITO electrodes is demonstrated successfully. The present lasing device provides various opportunities in photonic device application and its simple fabrication process can be readily used for large area geometries from the viewpoint of practical application.

Determination of refraction nonlinear index, for effect thermal, of solutions with nanoparticles of gold

Antonio de Jesus Olivares-Vargas, Mónica Trejo-Durán, Edgar Alvarado-Méndez, Univ. de Guanajuato (Mexico); Delfino Cornejo-Monroy, Univ. Autónoma de Quéretaro (Mexico); Ruth Ivonne Mata-Chavez, Julián Móises M. Estudillo-Ayala, Univ. de Guanajuato (Mexico); Victor M. Castaño-Meneses, Univ. Nacional Autónoma de México (Mexico)

The research of nonlinear optical properties of materials for the manufacturing of opto-electronic devices, had a great growth in the last years. The solutions with metal nanoparticle present nonlinear optical properties. In this work we present the results of characterizing, analyzing and determining the magnitude and sign of the nonlinear refractive index, using the z-scan technique in solutions with nanoparticles of gold, lipoic acid and sodium chloride. We studied 5 different solutions. We used a continuous Argon laser at 514 nm with variable power, a lens of 18 cm and a chopper. Three different power of laser and two frecuencies of chooper were used to analize the five solutions. We studied how the presence of lipoic acid and sodium chloride modified the nonlinear optical properties of the Au-nanoparticles solution in water. We determined the nonlinear refractive index in each case and we found it was in the order of 10 E-7. These materials have potential applications mainly as optical limiters.

8827-25, Session PWed

Effects of energy offsets and molecular packing on exciton and charge carrier dynamics in small-molecule donor-acceptor composites

Keshab R. Paudel, Brian H. Johnson, Afina Neunzert, Mattson Thieme, Oregon State Univ. (United States); John E. Anthony, Univ. of Kentucky (United States); Oksana Ostroverkhova, Oregon State Univ. (United States)

Understanding of exciton and charge carrier dynamics in organic donor-acceptor (D/A) heterojunctions is important for development of organic solar cells, light-emitting diodes, and photorefractive applications. Thus far, most effort has been directed towards studies of D/A materials with polymer donors and fullerene acceptors, while small-molecule D/A bulk heterojunctions (SMBHJ) remained relatively unexplored. We present a study of SMBHJs based on high-performance solution-processable functionalized fluorinated anthradithiophene (ADT-R-F) and pentacene (Pn-R-F8) derivatives. Here R is a side group which dictates molecular packing in the solid state without affecting optical and electrochemical properties of molecules themselves. We chose one of the ADT derivatives, ADT-TES-F, which exhibits a 2D pi-stacking “brickwork” packing, as the donor, and ADT-TIPS-F (2D “brickwork”), ADT-TSBS-F (1D “sandwich-herringbone”), Pn-TIPS-F8 (2D “brickwork”), and Pn-TCHS-F8 (1D “sandwich-herringbone”), as acceptors. We measured photoluminescence (PL) and photoconductivity, at time scales from sub-nanoseconds to many seconds after photoexcitation, at various acceptor concentrations, under various experimental conditions. This enabled us to establish effects of (i) LUMO energy offset between the D and A molecules and (ii) molecular packing at the D/A interface and in the acceptor domains on exciton and charge carrier dynamics. Differences in molecular arrangement in the acceptor domains both in ADT/ADT and ADT/Pn D/A composites resulted in pronounced differences in charge carrier photogeneration and recombination dynamics. In ADT/Pn D/A composites, exciplex formation at D/A interfaces was observed; exciplex contribution to the overall PL and photocurrent was determined to depend on the D/A distance, which is affected by the side-group R of Pn acceptors.

Phase-shifted gratings in azo doped polymers and their analysis by coupled-wave theory

Yutaka Kawabe, Toshio Yoshikawa, Kazuhiro Tada, Kodai Fukuzawa, Toshiro Imai, Chitose Institute of Science and Technology (Japan)

Phase (index) grating inscription in azo-dye doped polymers is an interesting phenomenon because of its high diffraction performance and applicability to real-time 3D displays.[1,2] Although several these materials investigated in preceding studies worked without external electric field in symmetric optical alignments, some of them showed an asymmetric phase shift of periodic modulation of refractive index from the interference fringe formed by irradiation beams, resulting in energy exchange between two coupled beams. The mechanism of the behavior was usually attributed to the molecular motions triggered by trans-cis isomerization, but their details were still unknown. Therefore, experiments on temporal evolution of the process and their translation into physical meaning are necessary.

In order to investigate the evolution of grating inscription and phase shift, several methods have been developed. In this study, we analyzed the coupled wave equations proposed by Kogelnik, and derived general solution applicable to both phase and amplitude gratings with arbitrary phase relationship. We showed that the analysis based on the equation can give a direct evidence of the phase shift between the phase and amplitude gratings if it exists.

This method was applied to the fringe pattern inscribed in thick films of PMMA doped with an azo-carbazole dye, NACzEtOH and its derivatives, and was compared with other experimental results obtained by conventional means.

Optical fiber waveguides using DNA-based solutions as core materials

Bjorn Paulson, Woohyun Jung, Tavakol N. Baresari, Kyunghwan K. Oh, Yonsei Univ. (Korea, Republic of)

We present spectral analyses of optical fiber waveguides containing DNA-based solutions as the optical core material, as well as separately measured optical dispersion curves for said solutions. DNA-lipid biopolymers have shown a high refractive index and potential for amplifying the optical nonlinearity of certain nonlinear optical dyes when used in solid thin-films and in gel-cuvette waveguides. Here we demonstrate the optical potential of DNA and DNA-lipid biopolymers in solution. Using an Abbe refractometer and CW light sources, we measure the visible (complex) refractive indices of high-refractive-index and low-viscosity DNA-based solutions, including DNA-toluene solution, DNA complexed with cetyltrimethylammonium (DNA-CTMA) in n-butanol, DNA-CTMA-ethanol solution, and DNA-CTMA-hexafluoroisopropanol solutions. Refractive indices are presented for several length distributions of DNA, at several concentrations. We also demonstrate DNA-based solutions in their liquid form as the core for optical fiber waveguides, with the silica glass of the optical fiber serving as a cladding, and the light guided down the DNA-based liquid core such that there is high biopolymer-light interaction. The waveguides used are a step-index waveguide based on a filled hollow optical fiber and a liquid-filled photonic crystal fiber, with their transmission spectra measured by optical spectrum analyzer.

Nonlinear optical properties of DNA and betanin natural dye doped silica sol-gel glasses

Vishnu Kavungal, Madambi K. Jayaraj, Anand B. Puthirath, Cochin Univ. of Science & Technology (India)

Sol-gel process is a technique for developing amorphous or crystalline materials from a liquid phase at room temperature. It involves the formation of inorganic oxides from silicon - alkoxide with addition of a solvent and catalyst undergoes hydrolysis followed by polycondensation resulting in a final product in the form of glass or crystalline material that can be casted as a thin film. The specific research for non-linear optical materials prepared by sol-gel technology has been achieved by the preparation of semiconductor nanoparticle such as CdS, CdSe, CdTe, CuCl, CuBr, Bi2S3 and PbI2, metal nanoparticle and organic dyes doped glasses. The third order susceptibilities of these materials are quite high and depend on the concentration of the dopant.

In the present work we prepared silica sol-gel glass doped with DNA and betanin dye and studied the nonlinear optical absorption using a single beam open aperture Z-scan method. A Q-switched Nd: YAG laser (Spectra PhysicsLAB-1760, 532 nm, 7 ns, 10 Hz) was used as the light source. A 20 cm converging lens was used to focus the laser beam. Using a translation stage attached to a stepper motor the sample was moved in a spatially varying intensity region on either side of the focal point. The incident and transmitted energies can be measured simultaneously using two probe heads of the energy ratio meter. Reverse saturable absorption (RSA) at 532nm is observed for DNA and saturable absorption (SA) for betanin dye. In DNA-betanin doped system, by increasing the concentration of DNA, SA behavior of betanin dye is switch to RSA. And also observed that by increasing the input laser power density SA behavior of betanin dye switched over to RSA.

Shape and morphology tuning of p-phenylenediacetonitrile-based fluorescent nanoparticles

Karolis Kazlauskas, Gediminas Kreiza, Vilnius Univ. (Lithuania); Egle Arbaciauskiene, Aurimas Bieliauskas, Algirdas ?ackus, Kaunas Univ. of Technology (Lithuania); Saulius Jursenas, Vilnius Univ. (Lithuania)

Fluorescent organic nanoparticles (FONs) consist of specific molecules capable of inhibiting fluorescence concentration quenching while causing aggregation-induced emission due to suppressed intramolecular torsions, which are usually accompanied by intramolecular planarization and/or specific head-to-tail molecular arrangements in the aggregates. A special attention to the FONs is paid for their potential applications in solid-state light emitters, fluorescent labels and sensors [1,2].

In this work, formation of the p-phenylenediacetonitrile-based FONs as well as their properties were studied systematically as a function of different alkyl and aryl side-groups linked to the molecule backbone. The FONs were formed by a simple reprecipitation method in the tetrahydrofuran(solvent)/water(non-solvent) mixtures at different solvent/non-solvent ratios, from 1:0 to 1:49. Dynamic light scattering and electron microscopy results demonstrated the possibility to tune FON sizes from 50 up to 1000 nm, whereas fluorescence quantum efficiency and optical spectroscopy measurements indicated the possibility to vary emission efficiency by a couple orders of magnitude, and moreover, alter shape and morphology of the nanoparticles in a controlled manner. Particularly, the selected p-phenylenediacetonitrile compounds bearing long alkyl side-moieties were shown to form highly-fluorescent crystalline one-dimensional nanowires and weakly-fluorescent amorphous spherical nanoparticles just by slightly tuning solvent to non-solvent ratio in the tetrahydrofuran/water mixture. The influence of different side-groups on the phenylenediacetonitrile molecule packing in the FONs and their fluorescence turn-on behavior is discussed.

Fabrication and characteristics of thin-film waveguides based on DNA biomaterials

Woohyun Jung, Bjorn Paulson, Yonsei Univ. (Korea, Republic of); Jun Young Son, Sungkyunkwan Univ. (Korea, Republic of); Tavakol N. Baresari, Yonsei Univ. (Korea, Republic of); Sung Ha Park, Sungkyunkwan Univ. (Korea, Republic of); Kyunghwan K. Oh, Yonsei Univ. (Korea, Republic of)

In the development of optoelectronic devices, deoxyribonucleic acid (DNA) has been a representative material which has received much recent attention as a promising research area. We constructed thin-film waveguides based on DNA-Biopolymer materials and DNA monolayers grown by a self-assembly process. Using solid state DNA-CTMA as a core, and PDMS as cladding, we manufactured and measured the spectral profile of slab waveguides using CW light sources, including thermo-optic coefficients and birefringence. We also report on an optical phenomenon of DNA monolayers grown by a self-assembly process. Discrete 2D nanocrystal structures of DNA were prepared on a light-guiding substrate. The high evanescent field interaction between the guided light supplied via optical fiber and DNA monolayers enabled the systematic investigating of the optical properties of DNA nanocrystal structures. In particular, light guided down the fiber and received by an optical spectrum analyser enabled spectral analysis, while morphology studies of the self-assembly DNA were performed by atomic force microscopy. We expect that biomaterials such as DNA-lipid complexes will have a unique application in optical devices compared with traditional fossil fuel-based polymers.

Synthesis and characterization of ring-protected electro-optic chromophores

Lianjie Zhang, Jianyuan Sun, Logan P. Sanow, Cheng Zhang, South Dakota State Univ. (United States)

Antiparallel interaction among dipolar chromophores is the dominant force in the solid state of conventional EO chromophores (long and flat). This interaction is responsible for the formation of acentric aggregates and prevents electro-optic coefficient (r33) from scaling with chromophore concentration. Antiparallel interaction can be selectively attenuated by attaching bulky groups to the middle part of chromophore. However, it is synthetically challenging to provide sufficient steric protection without causing severe reduction of chromophore concentration. In this paper, we will present the synthesis and characterization of atom-economic ring protection of chromophores against H-aggregation in all directions and show the effect of ring protection on optical properties of the chromophores in solution and film.

8827-32, Session PWed

Synthesis and electro-optic properties of the chromophore-containing NLO polyarylate polymers

Haohui Ren, Chengcheng Peng, Shuhui Bo, Guangming Xu, Guofang Fan, Hui Zhao, Zhen Zhen, Xinhou Liu, Technical Institute of Physics and Chemistry (China)

Base on the same two monomers, diphenolic acid (DPA) and isophthaloyl chloride (IPC), three chromophore-containing nonlinear optical (NLO) polyarylate polymers were prepared. A tricyanofuran (TCF)-acceptor type chromophore group was in main-chain (mPAR-chr1), side-chain (sPAR-chr1) and side-chain with a 1,1-bis(4-hydroxyphenyl)-1-phenyl-2,2,2-trifluoroethane (BPAPF) group (sPAR-F-chr1), respectively. The obtained polymers were characterized and evaluated by UV-Vis, 1H NMR, DSC and TGA. The polymer mPAR-chr1 and sPAR-F-chr1 showed excellent film forming ability. All the polymers exhibited good electro-optic (EO) activity. The relationship between EO coefficients (r33) and the chromophore concentration of the three polymers were also characterized and discussed. There were no obvious differences found in EO activity between mPAR-chr1 and (sPAR-chr1) polyarylates with the same chromophore. The fluorinated block polyarylate sPAR-F-chr1 has the largest r33 value in these three polyarylates which is 52 pm/V at the wavelength of 1310 nm (which is almost twice the r33 value of normal polymers contained the same chormophore at the same content), when the concentration of chromophore 1 is 18wt.%. 85% of the r33 value was retained in the sPAR-F-chr1 after being heated at 85oC for 600 hours. The polymer sPAR-F-chr1, with good solubility, high Tg (above 200 oC) and side functional group at the same time, may probably be a practical NLO material.

8827-33, Session PWed

Effects of molecular charge density polarization on chi(1) and chi(2): a computational study of 2-methyl-4-nitroaniline (MNA) and 4-(N,N-dimethylamino)-3-acetamidonitrobenzene (DAN)

Tomasz Seidler, Jagiellonian Univ. in Krakow (Poland) and Univ. of Namur (Belgium); Katarzyna Stadnicka, Jagiellonian Univ. in Krakow (Poland); Benoît Champagne, Univ. of Namur (Belgium)

Molecular crystals are materials with prospective second-order NLO properties. Their design faces the problem of optimum molecular alignment in the crystal structure. Among these, the prototypical MNA and DAN, which crystallize in non-centrosymmetric space-groups owing to molecular asymmetry have been characterized using experimental and theoretical approaches.

When applying the Rigorous Local Field Theory developed by Hurst & Munn[1] the chi(1) and chi(2) values are underestimated with respect to experiment[2]. Indeed, these derivatives have large ground-state dipole moments and the resulting polarizing electric field should be taken into account, which has been achieved only in a few studies[3]. In this contribution, a cheap computational method is presented. It allows for the precise calculation of chi(1) and of chi(2) with the crystal structure as the only experimental input and with inclusion of the molecular dipole polarization.

From this theoretical investigation we observe that experimental chi(1) and chi(2) values can be reproduced and analyzed in terms of intermolecular interactions when i) the effects of the uniform dipole electric field are accounted, ii) the geometries of the constituting molecules are optimized with quantum-chemistry methods, and iii) the molecular electric properties are calculated by combining MP2 static response with TDDFT frequency dispersion within the multiplicative scheme.

Responsive cholesteric liquid crystals *(Invited Paper)*

Timothy J. Bunning, Jonathan P. Vernon, Air Force Research Lab. (United States); Nelson V. Tabiryan, Svetlana V. Serak, BEAM Engineering for Advanced Measurements Co. (United States); Vincent P. Tondiglia, Mariacristina Rumi, Kyung Min Lee, Michael E. McConney, Timothy J. White, Air Force Research Lab. (United States)

Novel combinations of photosensitive materials and electro-optic fluids open up the coupling of stimuli-driven modulations of the optical properties of liquid crystal cells. We present here recent work on the ability to control the optical properties of electro-optic cholesteric liquid crystal cells using light. This talk will focus on the surface driven photo-modulation of aligned, bulk cholesteric liquid crystal cells.

8828-2, Session 1

Light-driven supramolecular chiral materials: photoinduced control of liquid-crystalline helical structures and non-destructive erasable molecular memory for photonic applications *(Invited Paper)*

Masuki Kawamoto, Natsuki Shiga, RIKEN (Japan); Kazuto Takaishi, Seikei Univ. (Japan); Takafumi Sassa, RIKEN (Japan); Takashi Yamashita, Tokyo Univ. of Science (Japan); Yoshihiro Ito, RIKEN (Japan)

Light-driven supramolecular chiral materials composed of an azobenzene moiety as a photoresponsive part and a binaphthyl moiety as a chiral part were designed and investigated. The materials exhibited reversible change in a dihedral angle of the binaphthyl moiety when photoisomerization of the azobenzene moiety was induced upon photoirradiation. We developed two types of optically active azobenzenes, acyclic and macrocyclic materials, as bistable chiral materials to be used for chiroptical phototriggers.

Acyclic chiral materials exhibited dynamic molecular motion induced by light and temperature. The chiral materials were dissolved in nematic (N) liquid crystals (LCs) to produce a chiral N phase with a helical structure. Helical pitch length of the chiral N LC decreased when temperature increased, because a molecular twisting motion of the binaphthyl moiety occurred in the LCs. On the other hand, length of the helical pitch increased upon photoirradiation, and then the resulting LC mixture was found to show photoswitching between chiral N and N phases upon trans-cis isomerization of the azobenzene moiety without the molecular twisting motion.

Light-driven chiral macrocycles exhibited specific suppression of cis–trans thermal back isomerization of the azobenzene moiety. The lifetime of the material at 298 K is 52.6 days, which is extremely long compared with those of azobenzene derivatives previously reported. Because of these desirable characteristics, the non-destructive molecular memory of the compounds was explored. When the chiral macrocycles were irradiated at 365 and 436 nm, the molecular twisting motion could be induced by trans–cis and cis–trans photoisomerization of the azobenzene moiety, respectively. In contrast, optical rotation was monitored by irradiation at 589 nm without any substantial changes, because the chiral compounds were inactive toward photoisomerization at this wavelength.

8828-3, Session 1

Electrically variable liquid crystal lenses for auto focus applications *(Invited Paper)*

Tigran V. Galstian, Univ. Laval (Canada)

Over the 120 years of liquid crystal research and development, we have seen at least one successful consumer electronic product incorporating those materials; the flat panel LCDs. Huge investments have been done to build corresponding manufacturing infrastructures, which is an excellent platform to help to introduce new applications. Until recently, only the polymer dispersed liquid crystal windows might benefit from these infrastructures. However, new electrically variable devices, such as switchable windows or lenses, are being actively developed now (using liquid crystals). In fact, liquid crystal lenses are already available to the public (Skype certified auto focus webcams sold by Amazon and Best Buy).

In this review talk, I will present the today's most important area of application of electrically variable lenses; the auto focus in mobile cameras. I will describe the currently available voice coil motor solutions and also the alternative approaches, such as the liquid or deformable lenses. I will then focus on various geometries used to obtain electrically variable liquid crystal lenses. I will present some of most advanced approaches in this area. I will conclude by describing some other potential applications of those lenses, including in biomedical devices.

8828-4, Session 1

Photorefractive effect in ferroelectric liquid crystals containing oligo-thiophene chiral compounds *(Invited Paper)*

Takeo Sasaki, Yumiko Naka, Tokyo Univ. of Science (Japan); Masashi Ikegami, Satoshi Kajikawa, Tokyo Univ of Science (Japan)

The photorefractive effect in photoconductive ferroelectric liquid crystals (FLCs) that contain photoconductive chiral compounds was investigated. Terthiophene and quaterthiophene compounds with chiral structure were chosen as the photoconductive chiral compounds and mixed with an achiral smectic C liquid crystal. The mixture exhibited the ferroelectric chiral smectic C phase. The photorefractivity of the mixture was investigated by two-beam coupling experiment. It was found that the FLC containing the photoconductive chiral compound exhibit a large gain coefficient of over 800 cm-1 and a fast response time of 1.4 ms.

8828-5, Session 2

Liquid crystal lasers *(Invited Paper)*

Juergen Schmidtke, Univ. Paderborn (Germany)

During the past decade, photonic band edge lasers based on cholesteric liquid crystals (CLCs) have attracted considerable interest. We give a review of various aspects of these self-assembled, tunable, coherent light sources:

The heat which is dissipated during the pumping process disturbs the cholesteric order, which is detrimental to lasing performance. We show, that stabilization of the cholesteric order -- either by crosslinking of reactive mesogens, or by application of an electric field along the helical axis of a system with negative dielectric anisotropy -- reduces the threshold and increases the slope efficiency of laser emission.

We demonstrate broad-band mechanical tuning of a LC laser based on a cholesteric elastomer, as well as high-precision fine tuning by electric-field induced distortion of the cholesteric helix.

Discontinuities in the chiral photonic structure give rise to additional resonant modes with small spatial extension and high quality factor. We prepared a phase jump in the cholesteric helix by stacking two layers of a highly crosslinked CLC polymer. The resulting photonic defect mode can be used for the generation of low-threshold laser emission (lasing threshold one order of magnitude lower than in conventional CLCs).

We demonstrate uniform alignment and narrow-band emission of a CLC between polydimethylsiloxane (PDMS) substrates. The formation of a CLC monodomain is promoted by using conventional substrates (coated with rubbed polyimide as alignment layer) as mold for casting the PDMS substrates. With PDMS being the standard material for the fabrication of microfluidic devices, this opens a simple and flexible route for system integration of LC lasers for lab-on-a-chip applications.

Liquid crystal chiroptical polarization rotators for the near-UV region: theory, materials, and device applications *(Invited Paper)*

Debra J. Saulnier, Brittany N. Taylor, Kelly McNabb, Kenneth L. Marshall, Terrance J. Kessler, Stephen D. Jacobs, Univ. of Rochester (United States)

The helical structure of a chiral nematic liquid crystal (CLC) material produces a number of interesting optical properties, including selective reflection and optical rotatory power. To take advantage of the high optical rotation near the selective reflection peak in the UV, either large concentrations of chiral components or those possessing very large helical twisting powers (HTP) are necessary. It is difficult to find chiral twisting agents that do not degrade UV transmission. We report what we believe to be the first experimental observation of extraordinarily high optical rotation (> 30°/?m) in the near UV for a long pitch (13.84 ?m) CLC mixture composed of the low-birefringence nematic host ZLI-1646 doped with a low concentration (e.g., 1 wt. %) of the chiral dopant CB15. This experimental finding was verified theoretically using a mathematical model developed by Belyakov, which improves on de Vries' original model. Optical rotation far from the selective reflection region is taken into account by considering the nonlinearity of the optical rotation as a function of LC layer thickness. Using this model, the optical rotation at ?=355 nm for the 1% CB15/ZLI-1646 mixture was determined computationally, with the results in good agreement with experimental data obtained by evaluating a series of wedged cells using an areal mapping, Hinds Exicor 450XT Mueller Matrix polarimeter.

This finding now opens a path to novel LC optics for numerous near UV applications. One such envisioned application for this class of materials is in UV Distributed Polarization Rotators (UV-DPR's) for high-peak-power lasers.

8828-7, Session 2

Lasing effect in blue phase liquid crystal *(Invited Paper)*

Tsung-Hsien Lin, National Sun Yat-Sen Univ. (Taiwan)

Blue phases (BPs) are highly chiral mesophases with highly fluid three-dimensional (3-D) cubic defects structures. They exist between the isotropic phase and the cholesteric phase, and can be classified as BPIII, BPII, and BPI in order of emergence attended by the decrease in temperature. Owing to their self-assembly feature, the blue phase can be regarded as a 3-D photonic crystal. This presentation show the lasing effects in blue phase liquid crystal. In the first section, we report on the relationship between the output directions of BP band-edge laser and the rubbing (alignment) directions. The 3-D periodic structure enables band-edge lasing in blue phase liquid crystals. The rubbing direction may dominate the crystal direction and thus determine the lasing directions. In the second section, we report on the switchability and the tunability of BP random laser devices, including coherence, mode stability, excitation threshold and lasing spectrum. On account of their self-assembly, polycrystalline texture appears upon cooling from the isotropic liquid. Even though the BPLCs are optically isotropic on a macro scale, discontinuous grain boundaries among platelets still cause weak light scattering. Random distributed micron-scaled platelets contribute to coherent random lasing in the BP due to the discontinuity across grain boundaries; whereas the cholesteric phase exhibits only incoherent type. Both types can be switched to each other at room temperature based on the thermal hysteresis effect. Mode-stability, the randomness of lasing wavelengths, is found to be determined by the platelet size and the addition of polymer network.

8828-8, Session 2

Tunable metamaterial in the terahertz regime using liquid crystals *(Invited Paper)*

Robert G. Lindquist, Daniele Lo Forti, Abubaker Tareki, Junpeng Guo, The Univ. of Alabama in Huntsville (United States)

Researchers at the University of Alabama in Huntsville are investigating tunable materials for phase and polarization management in the terahertz regime. Since these materials are not available in nature, artificial materials using liquid crystals for tuning need to be engineered. In this effort, the metamaterials comprise of a layers of Teflon, films of liquid crystal and patterned gold. By using a stratified structure, the LC films can be kept relatively thin and thus have a modest (0.1s) response time. However, the transmission properties of electrodes become a critical issue especially in the In the terahertz regime. We have investigated several patterned electrodes utilizing plasominc effects to optimize transmission and polarization properties.

8828-9, Session 2

Photoalignment change in pi-conjugated dye-doped LC system *(Invited Paper)*

Motoi Kinoshita, Atsushi Shishido, Tokyo Institute of Technology (Japan)

Liquid crystals (LCs) have unique properties such as self-organizing nature, cooperative motion, anisotropy in optical, electrical and magnetic properties, and alignment change by external stimuli. The key technique to use LCs for application is how to control their alignment precisely. Especially in recent years, many researchers have developed ways of controlling LC alignment by light instead of using rubbed polyimide film or electric field. In this study, photoalignment behavior of LC system containing various pi-conjugated dye was explored.

8828-10, Session 3

Surface plasmon polaritons in metal-liquid-crystal nanostructures *(Invited Paper)*

Ying Gu, Qihuang Gong, Peking Univ. (China); Iam Choon Khoo, The Pennsylvania State Univ. (United States)

Surface Plasmon polaritons (SPPs), originated from the collective oscillations of free electrons in metal, have the applications in SERS, nanosensors, nanowaveguides, solar cells, nonlinear optics and quantum optics. The existence or occurrence of SPPs is greatly relative to the dielectric permittivity of dielectric surrounding the metal. The tunability of permittivity tensor of liquid crystal (LC) can effectively modulate the properties of SPP.

By orienting the optical axis of LC, we found the large spectral tunability of narrow geometric resonances of arrays of metallic nanoparticles [1]. In Plasmon-LC wavguides, by varying its optical axis, we obtained two kinds of mode transformation: mode recombination, accompanied by dramatically extended propagation lengths at the cutoff angles, and mode alternation, associated with an obvious shift of the electromagnetic energy flux from one insulator to the other [2], as well as the quasiguided

SPPs [3]. Finally, we investigated the effects of dielectric anisotropy on SPPs in three-layer anisotropic-dielectric-metal nanostructures [4]. The numerical results indicate that the propagation length of conductor-gap-dielectric mode and its cutoff thickness changed greatly varying the optical axis. These findings may have prospective applications in actively-modulated plasmon-based nanodevices and tunable single surface plasmons sources.

Liquid-crystalline self-assembling nanoparticles with dendrimeric outer corona *(Invited Paper)*

Kiyoshi Kanie, Tohoku Univ. (Japan)

Nanoparticle (NP)-based periodic structure formation has attracted a considerable attention in material science, because new synergistic functions could be derived from the periodic structure. Among organic soft materials, liquid-crystalline (LC) organic dendron is one of the most representatives to form spherical dendrimer-like structures by the self-assembling property. Such spherical assembly spontaneously forms a self-organized periodical structure. Thus, we focused our attention on introduction of such self-organization ability into inorganic NPs. As dendrons, we synthesized phenetyl ether-type dendrons G1-G3 with an amino-group at the apex. G1-G3 themselves show thermotropic LC phases. The dendrons are attached as the outer corona, through amidation, to the carboxylic groups at the surface of the inner aliphatic corona encapsulating the NP. Purpose-designed CO2H-modified monodisperse gold NPs A1-A3 were synthesized uisng 12-dodecanethiol (DT) and 16-mercaptohexadecanoic acid (MHA). The DT/MHA molar ratio was fixed to 1/1, 3/2, and 4/1 for A1, A2, and A3, respectively. SAXS measurement revealed that G2-modified A2 showed an LC hexagonal columnar phase at 130 ?C and formed a simple cubic (SC) LC phase at 150 ?C. The dendron-modified gold NPs G/A can be regarded as organic-inorganic hybrid dendrimers with thermotropic LC behaviour. The effects of dendron generation and surface coverage by dendrons on the mode of self-organization of NPs were also investigated. The technique also applied to CdS NPs.

8828-12, Session 3

Conformation and chirality in liquid crystals *(Invited Paper)*

John L. West, Lei Zhao, Kent State Univ. (United States)

Molecular conformation plays a critical role in determining the helical twisting power, HTP, of chiral additives in a liquid crystal host. We studied the relative population of different conformers for chiral additives based on an isosorbide benzoate ester core. Molecular modeling revealed two lowest energy states with very different conformations for this core. A simple Boltzman distribution shows that substantial changes in the relative population will occur for conformers with free energy differences of 1-2 Kcal/ mole. For lower energy differences the conformers will maintain an essentially statistical distribution of the temperature range of interest while for larger differences in the free energy the lowest energy conformer will dominate at all temperatures of interest. If the conformers have very different helical twisting powers (as expected from the molecular modeling for the isosorbide cores) this will translate in to a large temperature dependence of the HTP. A clear isosbestic point in the ultra-violet absorption spectra confirms two stable conformers for one of the isosorbide benzoate esters. This is confirmed also by proton NMR. Combined with the molecular modeling, these spectra reveal how the relative populations of these two conformations change with temperature and how this is related to the helical twisting power. Temperature dependent changes in conformation can explain many of the observed anomalous responses of HPT to temperature.

8828-13, Session 3

Electrical-switched positive and negative refraction in nanosphere dispersed liquid crystal metamaerial

Grzegorz Pawlik, Wroclaw Univ. of Technology (Poland); Wiktor Walasik, Institut Fresnel (France); Karol Tarnowski, Antoni C. Mitus, Wroclaw Univ. of Technology (Poland); Iam Choon Khoo, The Pennsylvania State Univ. (United States)

We discuss the concept of reversible electrical switching between positive and negative refraction in nanosphere dispersed liquid crystal (NDLC) metamaterial for TM polarization. The proposed design offers an interesting possibilities of real-time control using external electric field of positive-negative refraction and reflection for the Poynting vector at infrared frequencies. Exemplary switching parameters and physical composition of the material are theoretically demonstrated. Finite Element (FE) simulations (Comsol) confirm this effect.

8828-14, Session 4

Defect and domain patterning in mechanically adaptive liquid crystal polymer networks

Timothy J. White, Michael E. McConney, Jeong Jae Wie, Vincent P. Tondiglia, Kyung Min Lee, Air Force Research Lab. (United States); Angel Martinez, Ivan I. Smalyukh, Univ. of Colorado at Boulder (United States)

The ability to dictate the self-organization of liquid crystalline polymer networks to form monolithic films composed of complex defect and domain patterns is reported. Using photoalignment materials and spatio-temporal control of intensity and polarization of the patterning light source – we report on the thermally and optically generated mechanical response observed in glassy, liquid crystal polymer networks. The thermally or optically generated strain within the films can yield outputs including adaptive topography or self-folding.

8828-15, Session 4

One-dimensional photonic crystals containing memory-enabling liquid-crystal defect layers *(Invited Paper)*

Po-Chang Wu, Wei Lee, National Chiao Tung Univ. (Taiwan)

Incorporating liquid crystal (LC) as a defect layer in a photonic crystal (PC) leads to the electrically tunable optical spectrum in defect modes within the photonic band gap. Such a superior feature makes the hybrid structure potential for designing various types of optical devices. Recently, we have demonstrated several types of photonic structures based on one-dimensional (1-D) PC containing memory-enabling LC (MELC) as a defect layer. The optical state remains unchanged after removal of applied voltage in the memory state. The defect modes of a PC/MELC cell can be switched to not only the voltage-sustained states but the memory or optically stable states. Owing to the fact that the spectral properties of defect modes in a memory state persist without applied voltage, the device will support the green society of tomorrow.

The wavelength tunability, amplitude tunability and optical multistability of the defect modes permit the 1-D PC/MELC cell to be alluring for photonic device applications such as low-power-consumption multichannel filters, light shutters or electrically controllable intensity modulators without any polarizers.

In this invited talk, our recent development of various one-dimensional PC/LC hybrid cells for photonic applications will be presented. Special attention will be paid to the optical and spectral properties of multilayer PC structures containing a bistable chiral-tilted homeotropic nematic (BHN) layer, a bistable chiral-splay nematic (BCSN), a bistable dual-frequency cholesteric LC (DF-CLC) layer, a tristable polymer-stabilized cholesteric texture (PSCT), and a tristable smectic-A liquid crystal as a defect layer.

8828-16, Session 4

Electro-optic and spectroscopic studies of liquid crystals functionalised with ferroelectric nanoparticles *(Invited Paper)*

Malgosia Kaczmarek, Nina Podoliak, Oleksandr Buchnev, Mark Herrington, Univ. of Southampton (United Kingdom); Jean-Francois Blach, Jean-François Henninot, Marc Warenghem, Univ. Lille Nord de France (France)

Ferroelectric nanoparticles, dispersed in nematic liquid crystals, can lead to significant changes in the host's physical properties, namely birefringence, dielectric anisotropy and clearing temperature. Such functional liquid crystals are complex systems, where the dynamics is governed by different relaxation processes, including liquid crystal switching, the nanoparticle reorientation, and the liquid crystalline relaxation around nanoparticles. Our recent work demonstrated the impact of nanoparticles on some fundamental parameters, such as elastic constants, viscosity and response time.

We report on the results obtained with two different types of ferroelectric nanoparticles, BaTiO3 and Sn2P2S6, dispersed in a low birefringence liquid crystal LC18523 and in low ionic content and high birefringence liquid crystal TL205 (Merck). The electro-optic study showed that ferroelectric nanoparticles cause a significant increase of the dielectric anisotropy and also reduce the splay elastic constants. Both of these effects lead to a decrease in the threshold voltage up to a factor of 1.8. Liquid crystal switching behaviour in twisted cells was also used to estimate dynamic parameters, such as rotational viscosity for the suspensions, indicating its increase by a factor of up to 3.2.

Furthermore, the interaction between the organic and inorganic elements of the functionalised liquid crystals colloids was investigated using spectroscopic ellipsometry and Raman scattering. New, intense bands of the Raman signal were detected for the liquid crystals functionalised with two different types of ferroelectric nanoparticles, indicating strong interaction between the liquid crystal molecules and the nanoparticles.

8828-17, Session 4

A biosensor of high-density lipoprotein of human serum on a liquid crystal and polymer composite film *(Invited Paper)*

Yi-Hsin Lin, Kai-Han Chang, Wei-Lin Chu, Yu-Shih Tsou, National Chiao Tung Univ. (Taiwan); Li-Ching Wu, Chien-Feng Li, Chi Mei Medical Ctr. (Taiwan)

High-density lipoprotein (HDL) is one of the major carriers of cholesterols in the human blood. The high level of HDL in human body has beneficial effects to cardiovascular diseases and reducing the risk of Alzheimer's disease. Recently, we have developed a switchable surface, liquid crystal and polymer composite film (LCPCF), and also developed many applications based on LCPCF, such as lenses, electro-optical switches, and sperm testing devices. In this paper, a biosensor for the concentration of high-density lipoprotein in human serum on the LCPCF is demonstrated. The sensing mechanism is based on a polar-polar interaction between orientation of LC directors and HDL in human serum. From the experiments, the concentration of HDL in human serum with a change of polarity affects the orientations of LC directors at the interface between LCPCF and human serum. In addition, the surface free energy of LCPCF can be changed with the applied voltage due to the electrically tunable orientations of LC directors anchored among the polymer grains of LCPCF. As a result, the droplet motion of human serum on LCPCF under applied voltages can sense the concentration of HDL in human serum even though the surface tension of human serum remains the same with the concentration of HDL. The impact of this study is to design an inexpensive, fast, and portable biosensor for sensing the diseases related to high-density lipoprotein in human blood.

8828-18, Session 4

Nanosecond electro-optic switching of a liquid crystal

Volodymyr Borshch, Sergij V. Shiyanovskii, Oleg D. Lavrentovich, Kent State Univ. (United States)

Electrically induced changes in optical properties of liquid crystals (LCs) represent a broad platform for modern technologies. The most widely used is the Frederiks effect, i.e. collective reorientation of molecules caused by dielectric anisotropy of the LC. Its Achilles' heel is a slow (millisecond) relaxation from the field "on" to the field "off" state. We present an electrooptic effect in a LC with the response time shorter than 100 ns to both the field on and field off driving. The effect is caused by electric field induced modification of the order parameter (EMOP) and does not require molecular reorientation.

To demonstrate the concept of EMOP, we use a nematic LC with negative dielectric anisotropy. The electric field is perpendicular to the director. Although the field does not reorient the molecules, it causes two other effects. First, it changes the components of dielectric tensor at optical frequencies (optic tensor). Second, it modifies the director fluctuations. The two effects have very different response times, nanoseconds for EMOP and milliseconds for director fluctuations. The principal difficulty is to eliminate the slow contribution of director fluctuations to the optical response. We achieve it by using a special oblique scheme of light propagation. As a result, the nematic cell shows a fast response, around 30 ns, to both the field on and field off driving. By separating the uniaxial and biaxial contributions to EMOP we show that the relaxation time of the latter is around 1 ns. The work was supported by DOE grant DEFG02-06ER46331.

8828-19, Session 5

Liquid crystal tunable optical vortices *(Invited Paper)*

Yan-Qing Lu, Wei Hu, Nanjing Univ. (China)

We present a technique for producing tunable optical vortices by using liquid crystal (LC) fork gratings. To write gratings in to LC cells, a home-made micro-lithography system with a digital micro-mirror device (DMD) as dynamic mask forms arbitrary micro-images on photoalignment layers and further guides the LC molecule orientations. The current resolution of 5 ?m is realized, while it is still improvable. Arbitrary fine photo-patterning fork gratings with various pitch sizes, prongs and LC alignments are thus obtained. The diffraction properties for both infrared and visible lights are studied. Clear optical vortices with designed topological charges are obtained showings in different diffraction orders. When a voltage is applied on the cell, index re-distribution is induced due to the realignment of LC molecules, and then the optical vortices become tunable. Dynamic switching between Gaussian modes and vortex beams are thus achieved. These advantages make the device appealing for single-molecule optical tweezers, orbital angular momentum multiplexing in optical communications and even future quantum computing.

8828-20, Session 5

Low-voltage tunable photonics devices: grove on thin porous structures containing liquid crystals *(Invited Paper)*

Luigino Criante, Istituto Italiano di Tecnologia (Italy) and Univ. Politecnica delle Marche (Italy); Francesco Scotognella, Politecnico di Milano (Italy)

Future key technologies in the field of electronic switches and processes replacement by all optical devices have to mix the achievement of very high density integrated optic devices with a significant electro-optic tuning capability. To reach these technological challenges high operation speed, power dissipation and low voltage circuit design are the problems out for solution. The porous materials infiltrated with liquid crystal give a great potential for tunable photonic devices due to their tunable physicochemical properties. It shows both practical and fundamental interest and it may open the way to satisfy all new technology requirements.

In this study we present the fabrication and the optical characterization of a very thin but efficient photonic crystal made by metal oxide nanoparticles, infiltrated with the nematic liquid crystal (E7) by drop casting in a simple and fast procedure. The real time analysis of the photonic band-gap during the infiltration shows a red shift (60 nm) due to the increase of an effective refractive index of the multilayer. The effect of an applied electric field has been studied and we report a blue shift of 8 nm with only 8 Vrms, corresponding approximately to an electric field of 3.4 V/µm, one order of magnitude smaller with respect to previously reported tunable liquid crystal infiltrated photonic crystals. The performances obtained - improvement through the choice of the most suitable liquid crystals for lower voltage operation - could be very interesting for realization of low cost and portable switching devices for high density integrated optics.

8828-21, Session 5

Large color tuning of polymer stabilized negative dielectric anisotropy cholesteric liquid crystals

Kyung Min Lee, Air Force Research Lab. (United States) and Azimuth Corp. (United States); Vincent P. Tondiglia, Lalgudi V. Natarajan, Air Force Research Lab. (United States) and SAIC (United States); Michael E. McConney, Air Force Research Lab. (United States) and Azimuth Corp. (United States); Timothy J. Bunning, Timothy J. White, Air Force Research Lab. (United States)

We report on the electro-optical responses of polymer stabilized CLCs upon application of DC fields by varying chiral dopants. Red-tuning of the cholesteric notch (~400nm at 70V DC) was observed in cells containing chiral LC monomer (SL04151) or achiral LC monomer (RM257) with chiral dopants R1011 and R811 combined with negative dielectric nematic LC ZLI-2079. Interestingly, broadening or tuning of the notch was seen when a combination of R1011 and R811 chiral dopants was used with achiral monomer RM257. Surprisingly, only notch tuning was observed when the chiral LC diacrylate monomer (SL04151) was used for the polymer stabilization. The mechanism involving ion transport leading to the deformation of the template polymer network as the precursor leading to the tuning or broadening will be discussed.

8828-22, Session 5

Liquid crystal near-IR laser beam shapers employing photoaddressable alignment layers for high-peak-power applications *(Invited Paper)*

Kenneth L. Marshall, Debra J. Saulnier, Univ. of Rochester (United States); Haiqing Xianyu, Svetlana V. Serak, Nelson V. Tabiryan, BEAM Engineering for Advanced Measurements Co. (United States); Christophe Dorrer, Univ. of Rochester (United States)

Spatial beam shaping is used in high-peak-power laser systems for improved efficiency and performance. The low near-IR laser-damage threshold (230 mJ/cm2 at 1054 nm, 2.4 ns, 5 Hz) of the commercial liquid crystal-on-silicon (LCOS) programmable spatial light intensity modulators (PSLIM's) currently used on OMEGA EP limits their use to the low-fluence areas located in the front end of the long-pulse beamlines. Other limitations of these devices include both a relatively small device clear aperture (12 mm ? 16 mm) and low-pixel density (600 ? 792). In previous work, we demonstrated that passive near-IR LC beam shapers with laser damage thresholds ≥30 J/cm2 at 1054 nm (both 1-on-1 and N-on-1 testing at 1 ns) are achievable using coumarin alignment layers patterned by contact photolithography. We report on efforts to apply this technology to near-IR LC beam shapers to make them capable of being switched optically between two different patterned alignment states. Such reversible switching is accomplished using low-energy polarized UV and visible light incident on a "command surface" containing photoswitchable azobenzenes or spiropyrans, with pattern writing conducted using polarized UV photolithography or by raster scanning with a pulsed UV laser. Pattern erasure is achieved using either visible light or UV light with a different polarization orientation than used to write the pattern. The ability to reversibly write and erase patterned optical states "on-demand" in an assembled device combines the high resolution and high laser-damage resistance of current passive photopatterned LC beam shapers with the flexibility and in-system write/erase capability of the PSLIM device without requiring conductive coatings that compromise the laser-damage threshold.

8828-23, Session 5

The science (and art) of switching diffractive waveplates *(Invited Paper)*

Nelson V. Tabiryan, Sarik R. Nersisyan, Svetlana V. Serak, BEAM Engineering for Advanced Measurements Co. (United States); Timothy J. White, Timothy J. Bunning, Air Force Research Lab. (United States); Diane M. Steeves, Brian R. Kimball, U.S. Army Natick Soldier Research, Development and Engineering Ctr. (United States)

Diffractive waveplates present modulation of optical axis orientation at high spatial frequencies induced and supported by conditions at the boundaries. Their electro-optical and all-optical tuning and switching characteristics are as complex as in cholesteric liquid crystals where the modulation is supported by intermolecular forces. We will discuss the specifics and will outline the conditions for tuning and switching different varieties of diffractive waveplates avoiding long transients and hysteresis typical to liquid crystalline materials with complex orientation state.

8828-24, Session 6

Novel siloxane based smectic A liquid crystal materials: formulation, structures, and optical device applications *(Invited Paper)*

D. P. Chu, W. A. Crossland, A. B. Davey, Mykhaylo N. Pivnenko, Huan Xu, Andriy Dyadyusha, John R. Moore, Univ. of Cambridge (United Kingdom); Terry V. Clapp, Dow Corning Ltd. (United Kingdom); Jonathan P. Hannington, Dow Corning Corp. (United States)

An overview of the recent development of novel siloxane based smetic A liquid crystal materials developed for optical device applications. Flexibility in formulation, robust and stable smetic A phases, excellent uniformity and extremely long lifetime will be presented.

8828-25, Session 6

3D microscope system by using a liquid crystal lens and an LED ring illumination

Marenori Kawamura, Shunsuke Ishikuro, Akita Univ. (Japan)

When microscopic three-dimensional (3D) objects are observed by using a conventional microscope, the focused and defocused images can be obtained in same area. It is remarkable that the effect of focused and defocused images depends on the magnification of the objective lens (numerical aperture; NA) since a depth of field is inversely proportional to the NA of the lens. When the positions of the camera or the object is moved in the depth direction, the variation of the image magnification with focus occurs.

In our group, many types of optical devices using nematic liquid crystal (LC) materials with a large birefringence and dielectric anisotropy have been developed. Prof. Susumu Sato proposed an optical device such as an LC lens with a circularly hole-patterned electrode for tuning a focal length without any mechanical movements.

In this study, we propose a three-dimensional (3D) microscope system for tuning a focal plane in a depth direction by using a an LC lens and a light emitting diode (LED) ring illumination without any mechanical movements. The focal length of the microscope imaging system is controlled by applying the voltage to electrodes of the LC lens with double circularly hole-patterned electrodes and external flat transparent electrode. The objects can be selectively illuminated by using a light emitting diode (LED) ring illumination with controllable switching each LED. The continuous microscopic images are taken by changing the position of the focal plane. The all-focused images and depth mapping properties of the microscopic objects are obtained by processing our proposed image digital filter from contentious focal images.

8828-26, Session 6

Viewing angle compensation of various LCD modes by using a liquid crystalline polymer film *(Invited Paper)*

Takuya Matsumoto, Suzushi Nishimura, JX Nippon Oil & Energy Corp. (Japan)

We have developed liquid crystalline retardation films to improve quality of images of LCDs such as their viewing angle performance and coloration. We could achieve to make many types of optical retardation film by using rod-like liquid crystalline polymer. The resulting liquid crystalline polymer film has several advantages over conventional uni- or biaxial stretched retardation film. Optical well-controlled structures such as twisted nematic, homogeneous nematic, hybrid nematic and homeotropic structures could be stabilized for ideal compensation of various LCD modes such as STN, TN, ECB, VA and IPS modes.

Twisted nematic film is effective to cancel coloration of STN mode that is a fatal drawback for color representation.

Short pitch cholesteric film of rod-like liquid crystalline polymer, is equivalent to Negative-C plate, that can expand the viewing angle of VA LCDs.

Hybrid nematic film is quite unique film because the film works not only as a wave plate but also as a viewing angle compensator for TN and ECB modes.

Homeotropic film, positive-C plate, allows In-Plane-Switching (IPS) and Circularly-Polarized Vertical-Alignment (CPVA) LCDs to have excellent viewing angle performance. And our homeotropically aligned liquid crystalline film called “NV film” is the thinnest retardation film. The thickness of the liquid crystalline layer is a mere 1 micrometer.

Homeotropic film is useful to expand the viewing angle of not only LCDs but also OLED Displays. NV film can expand the viewing angles of the circular polarizer for antireflection of OLED Displays, in combination with a quarter wavelength plate.

8828-27, Session 6

Microseconds-nanoseconds-femtoseconds all-optical switching with liquid crystals

Shuo Zhao, Kuan Lun Hong, Iam Choon Khoo, The Pennsylvania State Univ. (United States)

We present the results of recent studies on mechanisms suitable for microseconds through nanoseconds to femtoseconds all-optical switching in liquid crystals, and compare the performance with other materials. In particular, we show that their microsecond-nanoseconds responses are ideal for nonlinear transmission and optical limiting action in temporal regimes where other nonlinear absorbers do not function.

8828-28, Session 6

Tunable photonic devices based on liquid crystals and composites *(Invited Paper)*

Rita Asquini, Antonio D’Alessandro, Univ. degli Studi di Roma La Sapienza (Italy)

Tunable photonic switches and filters employing liquid crystals (LC) and LC-composites can be used in several application fields as optical communications, sensors and imaging systems. Their excellent electro-optic, thermo-optic and nonlinear optical responses can be exploited for realizing components in guided-wave microstructures operating at low optical and electric powers.

In this review we discuss various integrated optics structures proposed and/or experimentally demonstrated for optical processing, including routers, Bragg filters and all-optical switches.

A compact (160 um long) two-way router in a nematic liquid crystal (NLC) waveguide was designed and demonstrated in the near infrared with voltage modulation as low as 0.21 V.

Wavelength-tunable voltage-controlled Bragg reflectors were analyzed in different geometries: one has a reflectivity above 80% in a 14 nm range (1530-1550 nm) with bias voltages from 2.5 to 3.0 V; another exploits coplanar comb electrodes to achieve an extended tuning range of about 104 nm (1521-1625 nm) with reflection above 50% for voltages from 2.9 to 10.2 V.

Tunable gratings realized with microstripes of polymers and NLC on glass waveguides were also characterized in the 1.55 ?m spectral window, demonstrating electro-optic filters adjustable over 4 nm for bias fields of about 3 V/?m. An all-optically tuned filter was also demonstrated in dye-doped NLC with tunability over 6.6 nm when illuminating at optical power densities not exceeding 1.43 W/cm2.

8828-29, Session 6

Phototropic liquid crystals comprising one component

Anna M. Sobolewska, Joanna Zawada, Stanislaw J. Bartkiewicz, Wroclaw Univ. of Technology (Poland); Zbigniew Galewski, Univ. of Wroclaw (Poland)

Liquid crystals (LC) are materials which due to their unique properties are widely used in everyday life. Traditional LCs are classified as thermotropic (TLC), which means that the temperature generates the mesophase, or lyotropic (LLC), in which mainly the concentration affects the phase transition. In the last few years research is being conducted on a new class of LCs in which the phase transition is induced by the light. Such materials are called phototropic liquid crystals (PtLC) and they open a new way for applications of liquid-crystalline materials in photonic devices fully controlled by the light. However, most of PtLCs have been realized by the doping a classical LC with a photochromic dye. The photochemical reaction of the photochromic molecule dispersed in a LC matrix induces changes in the alignment of the liquid-crystalline host which can lead to the phase transition, called as a photochemical phase transition.

Here we report a novel approach in which the liquid-crystalline and photochromic properties are accomplished in a single-component azobenzene-based liquid crystal. Using the phenomenon of the light control phase transition we demonstrate its application in optical memories. We were able to realize optical ROM and RAM types of memories using one material.

Defect structures in liquid crystals bounded by microwrinkles *(Invited Paper)*

Takuya Ohzono, Jun-ichi Fukuda, Yoshiko Takenaka, National Institute of Advanced Industrial Science and Technology (Japan)

Spatially confined liquid crystals (LCs) exhibit non-uniform alignment, often accompanied by self-organized topological defects of non-trivial shape in response to imposed boundary conditions and geometry. Here we show that a nematic LC, when confined in a sinusoidal microwrinkle groove, exhibits a new periodic arrangement of twist deformations and a zigzag line defect [1]. This periodic ordering results from the inherent LC elastic anisotropy and the antagonistic boundary conditions at the flat LC-air and the curved LC-groove interfaces. The periodic structure can be tuned by controlling the groove geometry, which demonstrates the importance of boundary conditions and introduced asymmetry for the engineering of topological defects. The temperature dependence of the structure also shows nontrivial transformation of the defects [2]. Moreover, the kinks in the zigzag defects can trap small particles, which may afford a new method for manipulation of colloids. Our system, which uses easily fabricated microwrinkle grooves, provides a new microfabrication method based on the arrangement of controllable defects, which can be applied for other LC phases [3].

Topological reorientation of liquid crystals with optical vortices *(Invited Paper)*

Mohamed El Ketara, Charles Loussert, Etienne Brasselet, Univ. Bordeaux 1 (France)

The optical reorientation of liquid crystals is a research topic for a long time since the discovery of the optical Fréedericksz threshold in the early eighties. A few years ago, the concept of topological optical reorientation has been introduced, namely the writing of orientational patterns endowed with topological features. Surprisingly, this can be achieved by using "regular" Gaussian beams whereas the seemingly more obvious case of "singular" beams, optical vortices, also works. In this presentation, a review of the results obtained so far will be given and our latest results regarding topological patterning induced by optical vortices will be presented.

Properties of the self-deforming Nx phase in mesogenic dimers *(Invited Paper)*

Vitaly P. Panov, Jagdish K. Vij, Reshma Balachandran, Trinity College Dublin (Ireland); Volodymyr Borshch, Oleg D. Lavrentovich, Kent State Univ. (United States); Maria-Gabriela Tamba, Georg H. Mehl, The Univ. of Hull (United Kingdom)

An overview of the most recent experiments performed to reveal the structure of the Nx phase will be given. This new phase provides typical for nematics X-ray diffraction pattern and is found at temperatures below the conventional nematic phase in odd-chain hydrocarbon linked mesogenic dimers.

The materials in the Nx phase form self-deformed striped pattern parallel to the rubbing direction in planarly aligned rubbed cells with a well-defined period. The period is found to depend on the cell spacing. The self-deformation stripes appear without any external electromagnetic field or thickness gradient across the cell.

Although the materials are composed of non-chiral molecules, the low temperature nematic phase exhibits fast linear optical response of the order of a few microseconds. This response is reminiscent of the phase exhibiting chirality.

Moreover, at high fields some of the materials form striped domains with opposite direction of the optical response. These are normal to the rubbing direction and their periodicity exhibit voltage and frequency dependence.

The Freedericksz transition in this phase also shows unusual properties and has proven to be of the first order.

The experiments to be presented include polarized microscopy observation, birefringence mapping and optical contrast spectroscopy. Possible causes of the phenomena will be discussed.

Tuning SmAPf mesogen structure for different applications

Eva D. Korblova, David M. Walba, Jan Porada, Maria Kolber, Joseph E. Maclennan, Matthew A. Glaser, Renfan Shao, Yongqiang Shen, Cheol S. Park, Noel A. Clark, Univ. of Colorado at Boulder (United States)

We recently described the first SmAPf mesogen W586, which exhibits analog electrostatic V-shaped switching and analog phase modulation in LC cells. This was followed with directed design and synthesis of a very high polarization SmAPf mesogen exhibiting V-shaped switching with optical latching. Here we report the design, synthesis, and characterization of new SmAPf mesogens, with the goal of controlling properties important in various applications, including phase modulation depth, ferroelectric polarization, and electronic second order nonlinear optics (NLO).

In order to increase the maximum phase modulation depth (change in birefringence $\partial(\Delta n)$ achievable in V-shaped switching, mesogens possessing a diphenylthioether in the center of the bent core were prepared. It was expected that this structure would decrease the "bite angle" between the two "wings" of the core compared to the known m-disubstituted aromatic rings, and that this would increase the ∂(Δn) achievable in V-shaped switching. Other SmAPF mesogens were designed to adjust spontaneous polarization in the SmAPf phase. It was anticipated that this could be achieved by changing the orientation of phenylbenzoate ester linking groups along the core. Other work involving design of mesogens for electronic second order nonlinear optics has also been undertaken.

The characterization and EO properties of the new materials of will be discussed. Results suggest the SmAPf phase constellation shows great promise for application in fast phase-only EO modulators.

New LC materials with small absorption for photonic devices in THz range *(Invited Paper)*

Janusz R. Parka, Military Univ. of Technology (Poland)

During last few years many interesting applications of liquid crystal materials in THz range are expected. The properties of different liquid crystal materials are widely investigated in this range.

From application point of view the most important of liquid crystal materials is obtaining the low tangent of losses in wide frequency range with relatively high coefficient of tunability. These properties can be changed and adjusted to dedicated applications. Our last investigations shown that is possible to modified the structure of LC molecules to reduce the tangent of losses to value about 10-3 with tunability about 40%. New LC materials consisted of fluorinated atoms with low loss tangent and high transparency in 0.3 – 3 THz were spectrally characterized and used in tunable phase shifter and phase grating. Fluorinated liquid crystal compounds have low absorption in the THz band in comparison with commercially available LCs like 5CB. The properties of these device have been described.

Effects of UV curable liquid crystals on electro-optical properties of polymer stabilized liquid crystal displays (PS-LCDs) *(Invited Paper)*

Toru Fujisawa, DIC Corp. (Japan)

It is a recent attractive approach to use polymer/liquid crystal composite for the breakthrough of the performance of a LCD. The applications of UV-curable liquid crystals such as the light scattering LCD using polymer network liquid crystals (PNLC) and polymer stabilized V-shaped ferroelectric LCD (PSV-FLCD) are reviewed, and the effects of UV curable liquid crystals on electro-optical properties of PSV-FLCD are discussed. The cross linked liquid crystalline polymer formed from a small quantity of UV curable liquid crystals plays an important role to exhibit several interesting properties such as a fast relaxation time with the increase of molecular interaction between the liquid crystal molecules and the polymer network. Moreover, the switching mechanism of FLCs is altered with a unique process combining a UV irradiation and an applying AC voltage. A biaxial alignment of FLCs is changed into a uniaxial alignment resulting in V-shaped switching in FLCDs and the drastic improvement on relaxation time from 500 micro seconds to 25 micro seconds is observed. By the increase of applying voltage in situ-polymerization, a uniaxial alignment is attained even in a 5 micro meters of thicker cell being independent from surface stabilization.

All-optical recording of liquid crystal microlenses based on light induced anchoring modification in conventional dye-doped nematic cells *(Invited Paper)*

Liana Lucchetti, Univ. Politecnica delle Marche (Italy)

We describe a simple method to obtain tunable microlenses in cells with pixel-free electrodes filled with the nematic LC 5CB doped with methyl red. The lens-like refractive index distribution is generated by the joint action of a laser beam with Gaussian intensity distribution and an external dc voltage (V) lower than the Freedericks threshold.

Lenses are obtained in conventional planar cells with not patterned electrodes. A linearly polarised pump beam from a cw He-Cd laser is focused on the sample surface. The beam waist on the sample is 100 ?m. A dc voltage below the electric Freedericksz threshold is applied perpendicular to the cell substrates.

The presence of microlens in the irradiated region is highlighted by the appearance of the Self-Phase-Modulation (SPM) rings in the far field. The ring pattern appears when the optical and the electric fields are simultaneously present. The SPM pattern is also visualised by means of a low power probe He-Ne beam, polarised parallel to the pump and microlens formation is demonstrated by the observation and modulation of the red ring pattern when the pump beam is switched off. Microlenses are electrically tunable requiring a very small variation of V, can be erased by an external bias exceeding the electric Freedericks threshold and can be renewed by lowering again the external voltage.

Experimental results are well fitted by a model based on the light-induced decrease of the LC surface anchoring energy.

In-situ hologram correction in SLM setup *(Invited Paper)*

Vincent Carrat, Univ. of Virginia (United States); Bruno Viaris de Lesegno, Laurence Pruvost, Lab. Aimé Cotton (France)

Liquid crystal modulators suffer from defects that need to be compensated for demanding phase modulation applications like cold atoms manipulations. By adding another wavelength in an existing SLM phase modulation setup, we developed a robust method to get the birefringence map of the modulator. In this way we are able to see and correct the defects in-situ without disturbing the running experiment.

The phase modulation is applied to a red laser beam and we monitor the birefringence map with an infrared beam. The monitoring beam is initially linearly polarized with a 45° angle between the polarization plane and the neutral axis. The outgoing polarization is elliptical and we analyze it with an polarizer and a CCD camera to measure the birefringence map. After a comparison between the measured and desired birefringence map, the defects are corrected by modifying the addressing hologram. Furthermore, the correction is done in one step, and the response time of the procedure is limited by the frame rate of the camera. For these reasons we can control time-dependent defects like those introduced by a powerful read-out beam or thermal drifting.

This method allows us to measure and correct the defects of the SLM with spatial and phase resolutions comparable to the interferometric methods. As the method relies on polarization, vibration isolations and alignments are not critical which supplies robustness. Furthermore, this method provides an in-situ measurement, which simplifies the correction required for day to day defects or aging. Finally the demonstrated method provides feasibility to a closed-loop phase correction.

Active electrical and optical tuning of silicon photonic devices

Joanna N. Ptasinski, Univ. of California, San Diego (United States) and Space and Naval Warfare Systems Pacific (United States); Sung W. Kim, Lin Pang, Univ. of California, San Diego (United States); Iam Choon Khoo, The Pennsylvania State Univ. (United States); Yeshaiahu Fainman, Univ. of California, San Diego (United States)

Silicon photonics is a rapidly evolving field allowing for optical devices to be made cost effectively using standard semiconductor fabrication techniques and integrated with microelectronic chips. Active tuning of silicon photonic devices has been demonstrated using thermal, electrical and optical means in the form of injection of free carriers through two-photon absorption. This work explores active electrical and optical tuning of silicon photonic devices using silicon strip waveguides combined with nematic liquid crystal (NLC) claddings. Simulation studies are presented.

Design and simulation of optical sensor based on 2D photonic crystal

Indumathi T. S., Visvesvaraya Technological Univ. (India)

Here case study for different fluids is done since the different fluid has different density and there will be variation in the dielectric constant which results in shift in the frequency from the standard value.

We analyze band structure of the immersed liquid crystal and see the waveguide existence in the band structure. This is compared with our already existing prototype. If in case the shift was matching with the existing prototype, then we see the corresponding density of the liquid. Since each liquid has its own density we can easily find which was the fluid given to us.

In Figure, we see all the waveguide modes for the given liquid The shift in waveguide was downward because the dielectric constant was increasing from our standard structure. The gap between kerosene and heptanes was very small. This is because the dielectric constant was very close to each other. But the distinct feature between them could be clearly identified upto four decimals. It is 0.2491 for kerosene, 0.2404 for heptane. So we can see that our device is sensitive even for the smallest variation in dielectric constant.

Here it is reported that the numerical and simulation study indicates proposed structure is appreciably sensitive to the refractive index of the liquid. Normally the defect will be a disadvantageous but here the defect is a boon. By creating a defect such as point defect or line defect in photonic crystal it provides number of applications such as pressure sensor, biochemical sensing etc.

Influence of small particles on electrooptic effects in liquid crystals

Tahir D. Ibragimov, Gazanfar M. Bayramov, Institute of Physics (Azerbaijan)

It is known that optical properties of small particles depend on surrounding medium. In this work such medium is liquid crystal (LC) whose dielectric and optic properties along light propagation can be operated by application of electric field. We considered following problems:

- Christiansen effect in the small particles-liquid crystal system. It was shown possibility of tunable selective filtration and modulation of infrared radiation as at the electric field application with invariable frequency, and changing frequency at invariable voltage (an use of dual-frequency LC).

- Influence of conducting and dielectric particles on electrohydrodynamic instability (EHDI) in nematic LC. It was shown that the occur¬rence of silver particles in LC reduces the threshold voltage of the EHDI formation in a static field, and then it is more at low frequencies and less at high ones than in the pure LC. Meanwhile, the limiting frequency of the EHDI disappearance increases. While aluminum oxide particles reduce the threshold voltage of the EHDI occurrence at low frequencies on greater value than silver particles and they increase it at the high frequencies. A presence of particles changes rise and decay times in comparison with the pure LC. It is connected with an increase in viscosity and a reduction of elastic properties of LC and also overcoming the additional obstacles (particles) by ions.

- Influence of particles of centrosymmetric and noncentrosymmetric materials on Clark-Lagerwall effect in ferroelectric LC. It has been shown that time characteristics of a cell with LC-Al2O3 are a little bit worsened in comparison with a cell with pure LC. It is caused by increase of the rotational viscos¬ity of the ferroelectric LC with addition of small particles Al2O3. Time characteristics of the Clark–Lagerwall effect in the LC-SrTiO3 cell essentially surpass time characteristics of the cell with pure LC because the transition from the deformed UP-state to the DOWN-state demands overcoming much lower energy than the transition from the pure UP-condition to the DOWN-state.

High efficient polymer dispersed liquid crystal for ultra-bright projected image

Shun-Ling Hou, National Taiwan Univ. (Taiwan)

Head-up display (HUD) commonly uses liquid crystal to generate images. However, the intensity of the light decreases a lot because of passing through the polarizers. Therefore, polarizer-free display is a way to enhance the light efficiency. We demonstrate the feasibility of using Polymer Dispersed Liquid Crystal (PDLC), which consists of polymer and liquid crystal, as an optical switch to fabricate a simple see-through projected display device. Due to the unique E-O characteristics of PDLC, it can be a role to define the projected image shape. In our device, we use the ultra-bright collimated LED as a backlight source so that the projected image can also be seen clearly in broad daylight. Besides, PDLC do not need to utilize polarizers. It is achieved to obtain very high light efficiency (~70%). In this paper, we show some results of projected images with various colors (RGB) that can be applied to see-through projected display. From our experiment result, the see-through projected display device by PDLC can achieve high contrast ratio (~1000:1) and response time is about 15~20 ms. The driving voltage is around 20~25 V. Further improvement can be achieved by optimizing the LC material/monomer concentration or others parameters.

Effect of in-plane electric fields on the optical properties of cholesteric liquid crystals

Mariacristina Rumi, Vincent P. Tondiglia, Lalgudi V. Natarajan, Timothy J. White, Timothy J. Bunning, Air Force Research Lab. (United States)

A considerable body of knowledge has been developed on the general behavior of cholesteric liquid crystal (CLC) materials in electric fields,

but not all aspects have been fully explored and many of the device configurations have limitations in spectral bandwidth, tunability, response time, or dynamic range. One approach that has been reported to achieve tunability in optical filters based on CLCs with a positive dielectric anisotropy and in the planar homogeneous state involves the application of electric fields perpendicular to the axis of the CLC helix. The field leads to a progressive unwinding of the helix and a corresponding red-shift in the position of the reflection band of the CLC. We will discuss how intrinsic properties of partially unwound helices and extrinsic factors related to cell parameters and the vicinity of regions with different liquid crystal textures manifest in a decrease in reflectance and in band broadening with increase in the field strength for the Bragg reflection of this type of devices.

Nonlinear optics with blue-phase liquid crystals

Iam Choon Khoo, Kuan Lun Hong, Shuo Zhao, The Pennsylvania State Univ. (United States)

Blue-phase liquid crystals with their 3-D photonic crystal structure and optical anisotropy allow polarization-free nonlinear optical switching. The freedom from surface alignment requirements also facilitate/enable integration in complex nano-structures/geometries to devise tunable metamaterials and nano-structured optical waveguides and ring-resonators. Recent experimental feasibility demonstrations of exemplary structures will be presented.

Liquid-crystal micro-lens array with variable focusing and deflecting functions

Marenori Kawamura, Jyunki Teragaki, Akita Univ. (Japan); Susumu Sato, Akita Research Institute of Advanced Technology (Japan)

Liquid crystal (LC) devices with a single circularly hole-patterned electrode at the diameter of millimeter and/or micro size have been proposed by Prof. Susumu Sato. The LC device such as an LC lens with a radially-varying refractive gradient-index distribution can be realized by the LC molecular reorientation caused by an axially symmetrical electric field in the circularly hole-patterned electrode. The wave-front passing through the hole-patterned aperture of the LC lens possesses a quadratic function property. The LC lens has a very wide variable range of the focal length from the negative to positive lens properties and preserves its optical quality over the entire focus range by applying the voltages. Both a beam steering and anamorphic lens property in addition to the variable focusing function can also be controlled when the circularly hole-patterned electrode is divided into several parts and the applied voltages to the each electrode are different values.

In this study, we propose an LC micro-lens array with two-divided and hexagonal hole-patterned electrodes for varying a focal length and a beam deflection angle. The distribution of the refractive index in the hexagonal region of the LC microlens-array can be controlled by applying the voltage to the electrodes. The optical properties such as the focal length and beam deflection can be estimated by the induced refractive index distributions.

8828-45, Session PWed

Electro-optical properties of nematic liquid crystal cells in the infrared wavelength region

Marenori Kawamura, Akita Univ. (Japan); Susumu Sato, Akita Research Institute of Advanced Technology (Japan)

Liquid crystals (LCs) have optical and electrical properties such as a large tunable birefringence and dielectric anisotropy. The LCs have been extensively used in display devices and some optical tunable applications mainly in the visible wavelength region. The optical properties of LCs in the infrared region can also be changed by applying an electric field. Then, new optical devices working in the infrared region can be produced by using the LC materials. In this study, we fabricate nematic LC cells such as a homogenous and twisted nematic LC cells by using silicon wafer substrates, and evaluate their electro-optical properties at the infrared wavelength from 8 to 14 microns. The birefringence of the LC materials at this wavelength can be estimated by applying the voltage to the homogenous LC cell under crossed polarizers where the LC director is set to be 45 degrees to the polarization direction, and its value is slightly smaller than that in the visible region. The transmission light intensity through the TN LC cell is measured under crossed and parallel polarizers as a function of the voltage to the LC cell. The twisted nematic effect in the infrared region can also be obtained as well as that in the visible region.

An electrically tunable endoscopic system by adding a liquid crystal lens to enlarge and shift depth-of-field

Hung-Shan Chen, Yi-Hsin Lin, National Chiao Tung Univ. (Taiwan)

Conventional endoscopic systems consisting of several solid lenses suffer from a fixed and limited depth of field (DOF). For practical applications in throat or stomach diagnoses, we have to mechanically change the distance between the solid lenses of a lens module in order to change the focusing plane and DOF. In this way, the endoscopic systems are bulky. In 2011, S. Kuiper at. al., proposed a electrowetting-based liquid lens for capsule endoscopes to improve the focusing properties. However, the depth-of-field in the endoscope still needs to be discussed and designed. In this paper, an electrically tunable endoscopic system by adding a liquid crystal lens to enlarge and shift depth-of-field is demonstrated and discussed. The liquid crystal lens with an operation of two modes, positive and negative lenses, can not only extend but also shift the depth of field of the endoscopic system. The optical mechanism and limitation of the electrically tunable endoscopic system is discussed. We believe this study can be extended in the applications of industrial and medical endoscopes.

8828-48, Session PWed

An electrically tunable optical zoom system with separated focusing and zooming functions

Ming-Syuan Chen, Po-Ju Chen, Yi-Hsin Lin, National Chiao Tung Univ. (Taiwan)

An electrically tunable optical zoom system using liquid crystal (LC) lenses is important for many applications due to the advantages of light weight, low power consumption, and no mechanical moving elements. Recently, we have demonstrated the electrically tunable-focusing optical zoom system using two LC lenses and the optical mechanism is based on the concept of a confocal telescope. The object can be continuously zoom in and zoom out with object distance from 10cm to infinity. However, the focusing and zooming functions in the previous optical zoom system are not separable. The zoom ratio decreases with the objective distance. In this paper, we demonstrated an electrically tunable optical zoom system with separated focusing and zooming functions. The optical mechanism and design rules are discussed. The focusing distance and magnification of the image can be controlled separately by focusing LC lenses and zooming LC lenses. As a result, the zoom ratio is independent of objective distance and only depends on the tunable range of the lens power of the LC lenses. This study helps designing many applications with an optical zoom function, such as cell phones, cameras, holographic projectors and pico projectors.

8828-49, Session PWed

Beaming and filtering at terahertz frequencies in liquid crystal filled metallic grating

Daniele Lo Forti, The Univ. of Alabama in Huntsville (United States); Domenico de Ceglia, Maria A. Vincenti, National Research Council, ARMDEC (United States); Michael Scalora, U.S. Army Aviation and Missile Command (United States); Robert G. Lindquist, The Univ. of Alabama in Huntsville (United States)

The increasing interest of the scientific community in the terahertz frequency range is motivated by the unique property of sub-millimeter waves to penetrate any nonmetallic materials such as fabric and plastic, and sense objects distinctive signatures. Furthermore because of its low photon energy, terahertz radiation can be used in medical applications for accurate imaging without damaging tissues. For these reasons there is a growing need of devices dedicated to control the radiation in this frequency range. Current established technology uses non-tunable mesh-like filters and mechanical mirrors to filter and manipulate energy at these frequencies. We study electrically-controlled beaming and filtering abilities of sub-wavelength metallic gratings. The geometry consists of a finite array of metallic slits separated by spacers and filled with liquid crystal. We exploit the Fabry-Perot like resonances of the slits to filter THz radiation. An external voltage is then applied across the metallic grating in order to generate an electro-optic torque force on the liquid crystal molecules and change the dielectric constant inside the slits. This results in a large tuning effect on the Fabry-Perot resonances. We also show that a linear voltage distribution across the grating induces a linear phase delay and a beam-steering of terahertz radiation impinging at grazing incidence.

8828-50, Session PWed

Thermal degradation of the distributed-feedback cavity in cholesteric liquid crystal lasers

Andrii Varanytsia, Peter Palffy-Muhoray, Kent State Univ. (United States)

Cholesteric liquid crystals due to their birefringence and self-assembled periodic structure are known to form a distributed-feedback cavity and show mirrorless lasing. In this work, cholesteric liquid crystal laser emission was studied from two different liquid crystal hosts doped with the same laser dye. For both systems the lasing thresholds were measured and energy output was studied under a pump power significantly higher that lasing threshold. When the pump power was increased, a shift of lasing wavelength was observed. One of systems demonstrated a rapid decrease of emission after the pump energy reached a threshold value. This phenomenon was associated with thermal degradation of distributed-feedback cavity in cholesteric liquid crystal host caused by absorption of pump energy and heating. The local change of temperature of the host material can change the cholesteric liquid crystal pitch and shift the position of the selective reflection band. Further heating of the system can move the selective reflection band away from fluorescence of the laser dye and at some point the system loses the ability to lase. Emission from cholesteric liquid crystal lasers was studied at different pump powers and at different temperatures. From the obtained results, we were able to estimate the local increase of temperature of the cholesteric liquid crystal host caused by optical pumping. The estimated heating correlates well with study of temperature dependence of position of selective reflection band in cholesteric liquid crystal hosts.

Effect of liquid crystal structures on liquid crystal based biosensor for cholic acid detection

Sihui He, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States); Wenlang Liang, Univ. of Central Florida (United States); Jiyu Fang, Univ. of Florida (United States); Shin-Tson Wu, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

The concentration level of bile acids is a useful indicator for the diagnosis of liver diseases since individual suffering from liver diseases often has a sharp increase in bile acid concentration. Here we present a nematic liquid crystal (LC) based biosensor for the detection of cholic acid (CA). The orientations assumed by nematic LCs in contact with water are sensitive to the molecules at the LC/aqueous interface. The adsorption of sodium dodecyl sulfate (SDS) to the LC/aqueous interface resulted in homeotropic (untilted) LC alignment. Subsequent adsorption of CA to the SDS-laden interface resulted in a reorientation of the LC from homeotropic alignment to a tilted alignment. This transition took place above a certain concentration of CA, which we define as the detection limit of CA. By studying this system with nematic LC 4', 4-alkylcyanobiphenyls (nCB, n=5-8) where n is the alkyl chain length, we found the detection limit increases with the increase of chain length. Binary mixtures of nCB and other LCs were also studied. In general, the detection limit decreases with the increase of dipole moment. These studies pave the way for the optimization of LC-based biosensors in terms of the choice of LC material.

Efficient simplified OLEDs using high-work-function polymeric anodes *(Invited Paper)*

Tae-Hee Han, Su-Hun Jeong, Min-Ho Park, Seong-Hoon Woo, Tae-Woo Lee, Pohang Univ. of Science and Technology (Korea, Republic of)

Organic light-emitting diodes (OLEDs) have potential applications in large area, full-colour, high resolution flat-panel displays, future flexible displays, and solid-state lighting. Although device efficiencies and operational lifetimes of vacuum-deposited small-molecule OLEDs have been significantly increased, state-of-the-art OLED device structures have been developed to have more functional layers than did earlier OLEDs. These functional layers facilitate charge injection, transport and blocking in the devices and thus to help balance injection and transport of holes and electrons to the emitting layer for efficient radiative recombination. Another important role of these functional layers in multilayered OLEDs is to prevent an exciton quenching near electrodes. The standard fabrication method for small-molecule OLEDs is vacuum deposition, which has high costs of materials and processing to fabricate multilayered structures, and so has been a critical impediment to mass production at a low cost. Therefore, achieving simple structured OLEDs while maintaining their original luminous current efficiency (CE) has become a major challenge that must be solved before wide industrial application of OLEDs can be economically feasible.

Our idea to simplify structure to realize highly efficient OLEDs that uses a molecularly-controlled, high-work-function hole injection layer (HIL) on the anode or high-work-function anode, which enable efficient blocking of exciton quenching as well as efficient hole-injection and efficient electron-blocking at the same time. Our HILs develops a gradient work function (WF) by self-organization of a perfluorinated ionomer in conducting polymer films (We call “GraHIL”). This single-layered small molecule OLED has much greater CE (~20 cd/A) than do standard multilayered small molecule OLED devices that use conventional well-known hole injecting small-molecule, as a HIL (CE ~12 cd/A). The dramatic improvement in simplified OLEDs is achieved because that molecularly controlled GraHIL meets all the requirements for realization of simplified small-molecule OLEDs. From our studies regarding exciton quenching, we find that the self-organized surface layer of our GraHIL having efficient hole-injection/electron-blocking capability can prevent the severe quenching of excitons at the HIL/emitting layer interface without needing a hole transporting layer. We extended our work to a new flexible polymeric anode material which has easy work-function tunability and thus makes ohmic-contact between the anode and an overlying organic layer even with a high ionization potential. We finally demonstrated indium-tin-oxide-free flexible solid-state lighting devices using white fluorescent OLEDs.

8829-3, Session 1

Highly efficient new emitting materials based on dual core concepts for blue fluorescence OLEDs *(Invited Paper)*

Beomjin Kim, Seungho Kim, Jaehyun Lee, Hwangyu Shin, The Catholic Univ. of Korea (Korea, Republic of); Daisuke Yokoyama, Junji Kido, Yamagata Univ. (Japan); Jongwook Park, The Catholic Univ. of Korea (Korea, Republic of)

New blue fluorescent emitting materials for OLEDs based on dual core concept were synthesized and TPAPTP exhibited higher quantum efficiency (7.51 %) without doping and 2 times longer life-time than MADN, the commercial material.

8829-4, Session 1

Materials design for highly efficient delayed fluorescence *(Invited Paper)*

Chihaya Adachi, Kyushu Univ. (Japan)

Although typical organic molecules are simply composed of carbon (C), hydrogen (H), nitrogen (N) and oxygen (O) atoms, carbon’s unique bonding manners based on sp3, sp2 and sp hybrid orbitals enable very complicated molecular architectures, leading to amazing functions in a wide variety of creatures and industrial products. In the last two decades, the allure of unlimited freedom of design with organic molecules has shifted a significant part of the research effort on electronics from inorganic into organic materials. In particular, great progress has been achieved in the development of organic light-emitting diodes (OLEDs). The successive progress of 1st generation OLEDs using fluorescent molecules and 2nd generation OLEDs using phosphorescent molecules solidified organic materials as a very attractive system for practical electronics.

In this study, we designed new advanced electroluminescent (EL) molecules composed of only conventional CHN atoms without any precious metals. With proper molecular design, the energy gap between the two excited states, i.e., singlet (S1) and triplet (T1) excited states, are minimized, promoting very efficient spin up-conversion from T1 to S1 states (reverse intersystem crossing (ISC)) while maintaining a rather high radiative decay rate of >106/s, leading to a very high fluorescence efficiency. Using these unique molecules, we realized a very high external EL efficiency that is comparable with those of high-efficiency phosphorescence-based OLEDs. Thus, these molecules harvest both singlet and triplet excitons for light emission under electrical excitation through fluorescence decay channels.

8829-5, Session 1

Novel host materials for blue phosphorescent OLEDs

Peter Strohriegl, Daniel Wagner, Pamela Schroegel, Sebastian Hoffmann, Anna Koehler, Univ. Bayreuth (Germany); Ute Heinemeyer, Ingo Muenster, BASF SE (Germany)

Phosphorescent OLEDs have attracted attention during the past years because of their ability to achieve nearly 100% internal quantum yield. Triplet emitters are doped in a host material to avoid concentration quenching and triplet-triplet annihilation. Matrix materials for blue phosphors are difficult to realize because a triplet energy of 2.8 eV or higher and efficient carrier transport have both to be realized.

We present two different classes of host materials. The first are

derivatives of the well known

CBP. By minimizing the conjugation through the central biphenyl unit in CBP by i) replacement of the biphenyl by a twisted 2,2' dimethylbiphenyl and ii) meta-substituted biphenyl units we were able to make efficient matrix materials for blue phosphors with triplet energies of more than 2.9 eV [1,2]. These materials were used as matrix for the carbene emitter Ir(dbfmi) with a pure blue emission at 450 nm.

The second class of matrix materials are donor-substituted triazines, in which the electron and hole transport are separated through a non-conjugated bridge to form a bipolar host material [3]. Density functional theory (DFT) calculations showed, that these materials are promising hosts for blue phosphors. The photophysical and electrochemical properties are reported. By a variation of the substitution pattern the thermal, morphological and electrochemical properties are tailored. With regard to the application as host material the energy transfer to phosphorescent blue emitters as well as blue phosphorescent OLEDs will be presented.

8829-6, Session 1

Novel oligonuclear copper complexes featuring exciting luminescent characteristics *(Invited Paper)*

Daniel M. Zink, D. Volz, Larissa Bergmann, Karlsruhe Institute of Technology (Germany) and cynora GmbH (Germany); Thomas Baumann, cynora GmbH (Germany); M. Nieger, Univ. of Helsinki (Finland); Hartmut Yersin, Univ. Regensburg (Germany); S. Bräse, Karlsruhe Institute of Technology (Germany)

In recent years, the research field of organic electronics has gained increasing interest due to its potential application fields such as organic light emitting diodes (OLEDs), organic photovoltaics (OPVs) and organic transistors. , , In the case of OLEDs for general lighting or displays, a substantial amount of research has been carried out on the development of new concepts and materials. Accordingly, tremendous improvements have been achieved by the use of luminescent triplet emitters, allowing for high efficiencies and color tunability. As a downside, however, these precious transition metals based on iridium, , , platinum, or ruthenium, are a costly commodity often due to their low availability. Therefore, more abundant and cost-efficient metals with d10-configuration such as Cu(I) or Ag(I) have received great attention as they offer a new path to efficient emitters by means of using both singlets and triplet excitons. Luminescent Cu(I) complexes, especially with their rich structural diversity and easy accessibility, allow for designing emitters with desired photophysical properties, such as the emission color while maintaining high efficiencies.

Various novel and highly luminescent mono- and oligonuclear copper complexes have been developed and synthesized by means of a modular ligand system of easily accessible chelating ligands, specifically those containing nitrogen and phosphorous. These novel complexes feature promising photoluminescence properties which can be easily tuned by changing the electronic characteristics of the appropriate ligands to cover the visible spectrum in the range of 480 to 690 nm. Additionally, high quantum yields, up to 95% in the solid state, have been reached.

8829-7, Session 1

Continuous synthesis of device-grade semiconducting polymers in droplet-based microreactors *(Invited Paper)*

James H. Bannock, Siva H. Krishnadasan, Adrian M. Nightingale, Chin Pang Yau, Kevin Khaw, Imperial College London (United Kingdom); Daniel Burkitt, Jonathan J. M. Halls, Solar Press (United Kingdom); Martin J. Heeney, John C. de Mello, Imperial College London (United Kingdom)

A method is reported for the controlled synthesis of device-grade semiconducting polymers, utilizing a droplet-based microfluidic reactor. Using poly(3-hexylthiophene) (P3HT) as a test material, the reactor is shown to provide a controlled and stable environment for polymer synthesis, enabling control of molecular weight via tuning of flow conditions, reagent composition or temperature. Molecular weights of up to 92 000 Da are readily attainable, without leakage or reactor fouling.

The method avoids the usual deterioration in materials quality that occurs when conventional batch syntheses are scaled from the sub-gram level to higher quantities, with a prototype five-channel reactor producing material of consistent molecular weight distribution and high structural order at a rate of ≈60 g/day. The droplet approach is especially well suited to the controlled synthesis of statistical and block co-polymers, providing greater control over stoichiometry than equivalent batch syntheses.

8829-8, Session 1

Efficient cyclometalated platinum complexes for displays and lighting applications *(Invited Paper)*

Jian Li, Arizona State Univ. (United States)

The white organic light emitting diodes (WOLEDs) with high power efficiency (>100 lm/W) are considered as strong candidates for next generation illumination devices. Especially, WOLEDs use environmentally benign organic materials and their fabrication cost can be significantly reduced with potential roll-to-roll processing technology. In this presentation, we will discuss some of our efforts towards the development of efficient WOLEDs, which include our progress on 1) excimer-based WOLEDs, 2) the development of deep blue halogen-free Pt-based phosphorescent emitters, 3) the efficient white OLEDs utilizing all Pt-based phosphorescent emitters, and 4) improve the light outcoupling efficiency by incorporating narrow band phosphorescent emitters in the microcavity device settings.

8829-9, Session 1

Conjugated polymer particles: towards self-assembling organic photonics *(Invited Paper)*

Alexander J. C. Kuehne, DWI an der RWTH Aachen e.V. (Germany)

Sub-micrometer structure formation is an intricate condition for high fidelity organic photonics. I will present various pathways towards batch preparation of monodisperse particles consisting entirely of conjugated polymer. These particles form colloidal crystals through energy-free self-assembly, resulting in large scale 3-dimensional photonic structures of high quality. (AJC Kuehne et al., Chem. Commun. 2011, 47, 12379; AJC Kuehne et al., Nature Commun. 2012, 3, 1088)

The monodisperse conjugated polymer particles are synthesized in a simple one-pot procedure, leaving the particles dispersed in a non-hazardous solvent . The samples can then be processed from dispersion, which allows customized processing by wet deposition techniques, such as ink-jet printing. After deposition, the solvent evaporates and the dispersed particles assemble into crystalline arrays due to capillary forces.

These opal photonic crystals exhibit a clear photonic-bandgap due to the periodicity of the particle array as well as luminescence from the individual conjugated polymer particles. Thus, the particles hold great promise for self-assembled filters, converters and resonator devices.

8829-10, Session 1

Electronic structure investigation of doping C60 with metal oxide *(Invited Paper)*

Chenggong Wang, Yongli Gao, Univ. of Rochester (United States)

Fullerene (C60) has been used extensively as an acceptor material in organic photovoltaic (OPV) cells. Other applications including n-channel organic thin film transistors (OTFT) and C60 based organic superconductors have been reported more than a decade ago. Ordinarily C60 behaves as a strongly n-type organic semiconductor with the lowest unoccupied molecular orbital (LUMO) close to the Fermi level. We have investigated p-doping of C60 with molybdenum oxide (MoOx) with ultra-violet photoemission spectroscopy (UPS), inverse photoemission spectroscopy (IPES) and atomic force microscopy (AFM). Both surface doping and bulk doping by MoOx are studied. It was found that the thermally evaporated MoOx inter-layer substantially increased the surface workfunction. This increased surface workfunction strongly attract electrons towards the MoOx layer at the C60/MoOx interface, resulting in strong inversion of C60. Energy levels of C60 relax gradually as the thickness of C60 increases. An exceptionally long (>400 Å) band bending is observed during this relaxation in C60. Such a long band bending has not been observed for other organic/MoOx interface. For the bulk doping, MoOx doping ratios from 1% to over 100% were investigated. The saturation occurs at ~20%, when the highest occupied molecular level (HOMO) of C60 starts to be pinned at the Fermi level. These studies demonstrate effective ways to manipulate the electronic structures of the fullerene.

8829-11, Session 2

Plasmonic photoinjection spectroscopy: unraveling charge carrier injection and transport directly in organic light emitting diodes *(Invited Paper)*

Noel C. Giebink, The Pennsylvania State Univ. (United States)

Current injection and extraction at a metal-organic semiconductor interface is central to the operation of all organic optoelectronic devices, strongly influencing the efficiency and performance of organic light emitting diodes (OLEDs), photovoltaics, and thin film transistors. Efforts to date have developed various working models aimed at describing injection in organic semiconductors, however, the goal of a comprehensive understanding has so far been complicated by the a lack of techniques capable of characterizing both the interface energetics and bulk electronic transport properties directly in an operating device.

Here, we exploit resonant coupling to the surface plasmon polariton (SPP) mode(s) of a metal contact to extend the method of internal photoemission and use it to investigate the injection process in various small molecule organic semiconductor devices. By measuring the injected current on and off resonance as a function of wavelength and external bias for sub-gap, near-infrared excitation, we determine the electron and hole injection barriers directly in OLED devices. As compared to conventional internal photoemission under free-space illumination, resonant coupling to an SPP mode affords three important advantages in application to organic semiconductors: an order of magnitude improvement in sensitivity, unambiguous differentiation between photoinjected current and spurious trap-state photoconductivity, and the capability to measure bulk time-of-flight mobility directly in sub-100 nm thick devices. This talk will focus on the development and application of this method to the commonly used OLED materials tris(8-hydroxyquinoline) aluminum (Alq3) and N,N'-diphenyl-N,N'-bis(1-naphthyl) -1,1'biphenyl-4,4" diamine (NPD) in conjunction with Ag, Au, and Al contacts.

8829-12, Session 2

Fundamental properties of vacuum-deposited amorphous organic semiconductor films: density, molecular orientation, and refractive index *(Invited Paper)*

Daisuke Yokoyama, Yamagata Univ. (Japan)

In OLEDs, amorphous organic semiconductor films are mainly used because they need to be driven under a high electric field uniformly applied to the thin devices. However, the fundamentals of electrical and optical properties of amorphous organic semiconductor films have not yet been elucidated sufficiently due to the complexity of higher-order structures of molecules in the amorphous films.

Although it is not easy to clarify the microscopic higher-order structures with randomness, we can obtain some macroscopic properties of the films from the results of experiments, some of which give us useful suggestive information on the "average" higher-order structures in the films. In this presentation, such informative macroscopic properties will be shown with systematic experimental results to discuss the fundamentals of structures and properties of vacuum-deposited amorphous organic semiconductor films.

The first property that we will focus on is the density of the films, which affects both of the electrical and optical properties of the films. We found that the density of vacuum-deposited amorphous organic films highly depends on materials [1]. This result shows us a critical difference of the properties between amorphous and crystalline films. Next, the second one is the optical anisotropy in the films, which is obtained by ellipsometry. From this property, we can discuss the molecular orientation. In addition to the orientation of molecular axis that have been reported previously [2], a detailed analysis of functional group orientation will be shown. Then, the third one is the refractive index. We have recently found that the refractive indices of amorphous organic semiconductor films can be widely controlled [3]. This refractive index control will be discussed with the variety of densities. We believe that the comprehensive analysis of these three properties leads to further understanding of the electrical and optical properties of the films and devices from a fundamental viewpoint.

8829-13, Session 2

Degradation mechanisms of light emitting diodes revealed by time-resolved photoluminescence measurements *(Invited Paper)*

Hideyuki Murata, Atula D. Sandanayaka, Japan Advanced Institute of Science and Technology (Japan)

The intrinsic degradation in Alq3-based OLEDs is found to be caused by the photophysical degradation processes of NPD and Alq3 molecules in the vicinity of the NPD/Alq3 interface. We demonstrate that two degradation pathways with different time constants take place during a decrease in electroluminescence under constant current operation. From time-resolved photoluminescence measurements, we identify the first stage of the degradation in the luminescence decay curve as the decomposition of NPD molecules triggered by an electron injection followed by the creation of excited states of NPD. The second stage of the degradation with a longer time constant was due to the formation of a luminescent quencher in the emission zone, where the decomposition of Alq3 occurs by the reaction of Alq3 cation and water molecules.

8829-14, Session 2

Exciplex forming co-host as a platform for OLEDs with ultimate efficiency *(Invited Paper)*

Jang-Joo Kim, Young-Seo Park, Sunghun Lee, Seoul National Univ. (Korea, Republic of)

Phosphorescent organic light-emitting diodes (OLEDs) with ultimate efficiency in terms of the external quantum efficiency (EQE), driving voltage, and efficiency rol l-off are reported using an exciplex-forming co-host. This exciplex forming co-host system enables efficient singlet and triplet energy transfers from the host exciplex to the phosphorescent dopant because the singlet and triplet energies of the exciplex are almost identical. In addition, it allows low probability of direct trapping of charges at the dopant molecules and no charge injection barrier from the charge transporting layers to the emitting layer. By combining all these factors, the OLEDs achieved a low turn-on voltage of 2.4 V, a very high EQE of 29.1% and a very high power efficiency of 124 lm/W. In addition, the OLEDs achieve an extremely low efficiency roll-off. The EQE of the optimized OLED is maintained at more than 27.8% up to 10,000 cd/m2.

8829-15, Session 2

Emitter orientation as a tool to enhance OLED efficiency *(Invited Paper)*

Wolfgang Brütting, Tobias D. Schmidt, Bert J. Scholz, Christian Mayr, Lars Jäger, Univ. Augsburg (Germany)

Organic light-emitting diodes (OLEDs) are promising large-area light sources on their way to commercialization. However, there is still room for improvement in terms of light outcoupling efficiency and long-term stability under electrical operation.

The external quantum efficiency (EQE) of OLEDs is significantly less than 100% since only a small fraction of the consumed electrical power is converted into visible light that is finally extracted to air. Most of the efficiency loss is caused by suboptimal radiative quantum efficiency (RQE) of the emitting guest-host system and by dissipating a huge part of the radiated energy to optical modes such as surface plasmons or waveguided modes, which cannot easily be extracted by common outcoupling schemes. In order to increase the EQE of OLEDs new approaches are needed [1].

Recent studies show that light outcoupling can be enhanced considerably by horizontally oriented emitters; a feature that is well known for fluorescent emitters [2,3] and has lately been demonstrated in phosphorescent state-of-the-art OLEDs [4,5]. We identify non-isotropic emitter orientation by a thorough efficiency analysis of OLED stacks with systematically varied thickness [6]. We show that in order to achieve a consistent analysis, it is indispensable to account for possible deviations from randomness. Ignoring these orientation effects leads to a significant misinterpretation of the RQE and other factors, which determine the EQE of a device. Furthermore, state-of-the art emitter-matrix combinations will be used to demonstrate the potential for improving the efficiency of OLEDs in this way.

8829-16, Session 2

Performance improvement of fluorescent blue organic emitting diode by insertion buffer layer between hole-transporting layer and emitting layer

Bumsung Lee, DS Hi-Metal Co., Ltd. (Korea, Republic of)

The efficiency improvement of fluorescent blue organic light-emitting diodes with buffer layer, were investigated by inserting buffer layer which has lower HOMO energy and lower hole mobility than HTL material, between interface of HTL and EML. The inserted buffer layer (HOMO, -5.70 eV) could control the effective hole injection by decreasing energy barrier between HTL (-5.58 eV) and EML (5.96 eV) and also change the recombination zone, resulting to better electron-hole balance. To investigate working principle such as the electron-hole balance, several buffer materials which have different HOMO energy and hole mobility were used as a buffer layer and also the movement of recombination zone was measured by doping controlled device, in which blue and red dopant were used at different thickness zone to measure hole-electron recombination ratio. Based on the the result, It was found that the insertion of buffer layer which has lower HOMO energy and lower hole mobility can make effective recombination zone and this can lead to high performance.

8829-17, Session 2

Charge transport and injection into triarylamine copolymers from solution processed metal oxide contacts *(Invited Paper)*

Stephen M. Logan, Jenny E. Donaghey, Imperial College London (United Kingdom); Weimin Zhang, Imperial College London (United Kingdom) and Guangxi Univ. for Nationalities (China); Iain McCulloch, Alasdair J. Campbell, Imperial College London (United Kingdom)

Triarylamine copolymers are air stable, amorphous organic semiconductors with versatile applications as active layers in Organic Light Emitting Diode (OLED) and Thin-Film Transistor (TFT) devices. In particular, incorporation of a bridged fluorene unit to create poly(fluorene-co-triarylamine) (PF-TAA) has been shown to yield mobility values in TFTs as high as 10-2 cm2/Vs and contribute to recorded mobilities in excess of 5 cm2/Vs in small molecule-polymer blends. The application relevant performance of PF-TAA as a blue light-emitting polymer has led to its commercial availability for use as the active layer in solution processed OLEDs.

Given the importance of these materials we have employed chemical design strategies to create a novel silafluorene bridged triarylamine; poly(silafluorene-co-triarylamine) (PSiF-TAA). Using time-of-flight transient spectroscopy (TOF) we present findings of a systematic study of bulk hole mobility in these materials. PSiF-TAA (mobility = 3.1x10-3 cm2/Vs at field 0.7x105 V/cm) shows a five-fold improvement in bulk hole mobility over that of PF-TAA.

Leading on from our study of charge transport we investigate charge injection into the polymers from three recently reported solution-processable metal oxide hole-injecting contacts. Under ambient conditions, we solution process molybdenum trioxide (MoO3), vanadium pentoxide (V2O5) and chlorinated-indium tin oxide (Cl-ITO) injecting contacts and use current-density - voltage space charge limited current analysis (SCLC) to quantify the charge injection efficiency into PF-TAA and PSiF-TAA.

On analysis of TOF and SCLC data we undertake to elucidate mechanisms of charge transport and injection that contribute to performance in TFT and OLED devices.

8829-18, Session 2

Measuring and modeling exciton recombination in organic light-emitting devices *(Invited Paper)*

Nicholas C. Erickson, Russell J. Holmes, Univ. of Minnesota, Twin Cities (United States)

The realization of high efficiency in organic light-emitting devices (OLEDs) requires the effective formation and confinement of excitons. Often, this confinement occurs through the use of a multilayer device architecture that employs both charge and exciton blocking layers. Recently, there has been an increase in the use of emissive layer architectures that contain mixtures or gradients of hole- and electron-transporting materials that are uniformly doped with a phosphorescent guest. Such structures have been used to efficient device operation, and in the case of graded emissive layers (G-EML), efficient single-layer OLEDs. In this work we demonstrate an experimental approach to determine the spatial extent and location of exciton recombination in a wide variety of OLED structures. We find that structures based on mixed and graded emissive layers have significantly broader exciton recombination zones than conventional devices based on planar heterostructures. The location of exciton recombination in an OLED is an important design parameter that strongly determines device efficiency. In particular, the spatial extent of exciton recombination can impact exciton quenching, particularly under high excitation. In the case of the G-EML device architecture, an electronic model is developed to predict the location and extent of the exciton density profile by considering the drift, diffusion, and recombination of charge carriers within the device. It is found that the location and extent of the exciton recombination zone may be tailored using the G-EML architecture, allowing for the realization of simple, single-layer devices with high-brightness, high-efficiency operation.

8829-19, Session 2

High-efficiency P-OLEDs: analysis and progress *(Invited Paper)*

Matthew Roberts, Cambridge Display Technology Ltd. (United Kingdom)

The efficiency of organic LEDs continues to rise, and as the technology advances the efficiency limits continue to be pushed beyond traditional limits. For fluorescent blues (singlet recombination), external quantum efficiencies >10% are now achievable without outcoupling enhancements [1], with triplet-triplet annihilation clearly demonstrating a route to minimizing triplet losses. For phosphorescent materials (triplet recombination), external quantum efficiencies in the range 20-25% are now routine without outcoupling enhancements, and recent observations of anisotropy in phosphor dipole alignment gives a potential route to increasing this even further [2]. Robust models of material and device factors limiting P-OLED efficiency are crucial to achieving further advances. This paper is organized as follows; Section 2 outlines the key factors determining P-OLED efficiency, and methods for characterising these parameters. Section 3 gives a comparative analysis of a previous and improved generation of RGB materials sets, showing which material parameters have given rise to advances in efficiency. Section 4 highlights further enhancements in performance attainable for display applications using a model microcavity device structure. Conclusions and current materials performance are summarised in Section 5.

8829-20, Session 2

Charge-transporting materials using quasi-planar structure as a key scaffold *(Invited Paper)*

Atsushi Wakamiya, Hidetaka Nishimura, Tatsuya Fukushima, Yasujiro Murata, Hironori Kaji, Kyoto Univ. (Japan)

The development of excellent charge-transporting materials with high charge carrier mobility is a crucial issue to achieve high performance in organic-device applications including organic light-emitting diodes (OLEDs). As a new π-conjugated skeleton for charge-transporting materials, we focused on partially bridged triphenylamine structure, in which three phenyl groups are constrained in a quasi-planar fashion with two oxygen-bridges. As model compounds, we synthesized a series of oxygen-bridged triphenylamine dimers 1–4. X-ray crystal structural analysis revealed that all of the dimers 1–4 form one-dimensional on-top π-stacking with intermolecular distances of 3.72–3.79 Å. Time resolved microwave conductivity (TRMC) measurements on the crystals of 2 showed the charge carrier mobility in the on-top π-stacking direction (1.72 cm2/Vs) was higher than those in the other directions (0.45–0.51 cm2/Vs). Anisotropic charge carrier mobility was also observed in the vacuum deposited amorphous film of 2; the carrier mobility in the perpendicular direction to the substrate (2.85 cm2/Vs) was higher than that in parallel (0.93 cm2/Vs), suggesting horizontal molecular orientation of 2 on the substrate. Time-of-flight (TOF) measurements on the vacuum-deposited amorphous film of 1–3 also showed good hole-transporting properties (1: 0.8 ? 10–3 cm2/Vs, 2: 1.7 ? 10–3 cm2/Vs, 3: 2.5 ? 10–3 cm2/Vs), suggesting the potential use of these materials as hole-transporting materials in organic devices.

8829-21, Session 2

Inverted top-emitting organic light-emitting diodes with high current efficacy *(Invited Paper)*

Bernard Kippelen, Keith A. Knauer, Ehsan M. Najafabadi, Wojciech Haske, Michael P. Gaj, Kendall C. Davis, Canek Fuentes-Hernandez, Ulises Carrasco, Georgia Institute of Technology (United States)

Inverted top-emitting green, blue, and red electrophosphorescent OLEDs are demonstrated with low turn-on voltages, high current efficacies, and high maximum values of luminance. The devices contain an electron-injecting cathode consisting of aluminum coated with lithium fluoride. Optimized green devices with a phosphorescent emitter of tris(2-phenylpyridine)iridium(III) (Ir(ppy)3) are demonstrated on flexible glass, polyethersulfone substrates, and large-area polyethylene terephthalate substrates. When an N,N'-Di-[(1-naphthyl)-N,N'-diphenyl]-(1,1'-biphenyl)-4,4'-diamine (?-NPD) optical outcoupling layer is deposited on the anode the device has a turn-on voltage of 3.4 V and current efficacies of 108.0 cd/A at a luminance of 114.0 cd/m2 and 95.6 cd/A a luminance of 1463.4 cd/m2. Optimized blue devices with an emitter of iridium(III)bi[(4,6-di-fluorophenyl)-pyridinato-N,C2']picolinate (FIrpic) have a turn-on voltage of 3.3 V and achieve current efficacies of 39.9 cd/A at 137.6 cd/m2 and 32.9 cd/A at a luminance of 1012.2 cd/m2. Red devices with an emitter of tris[2-phenyl-4-methylquinoline]iridium(III) Ir(Mpqh)3 have a turn-on voltage of 3.6 V and current efficacies of 12.0 cd/A at 149.1 cd/m2 and 8.9 cd/A at 1,100.1 cd/m2.

8829-22, Session 2

Analysis of hole mobility of fluorene derivative films based on the Disorder Model and relationship between disorder free mobility and reorganization energy in the Marcus theory

Masanao Era, Saga Univ. (Japan); Kento Mori, Ryoka Systems Inc. (Japan); Norio Tomotsu, Idemitsu Kosan Co., Ltd. (Japan)

Development of organic semiconductor with high carrier mobility is indispensable to attain high performance organic electronic devices. For example, organic light-emitting diode is driven in space charge limited (SCLC) region. In this region, electronic current is according to the following equation, JSCLC is proportional to carrier mobility. This relationship implies that employment of high carrier mobility organic semiconductor lowers the driven voltage and enhances the light emission power efficiency.

In this work, we examined temperature and electric field dependencies of two fluorine derivatives which we reported previously that they have high hole mobility, and typical hole-transporting material, 4,4'-bis[N-(p-tolyl)-N-phenyl-amino] biphenyl (TPD) and 4,4'-Bis(carbazol-9-yl)biphenyl (CBP). The experimental data was analyzed according to the Gaussian Disorder Model. Then, we evaluated their non-disorder mobility, energetic disorder distribution, and specific disorder distribution . In addition, their reorganization energy was evaluated by a quantum mechanical calculation with ADF (Amsterdam Density Functional package, Scientific Computing & Modeling Co.) based on the Marcus theory.

The experimental and calculation results demonstrated that the non-disordered mobility has good proportionality relation with reorganization energy. Because the non-disordered mobility mean as a rough standard of carrier-transporting, this result suggest that evaluation of reorganization energy is a promising approach to design molecular structure of carrier transporting materials with high carrier mobility.

8829-23, Session 2

Investigation of the opto-electronic processes in a near-infrared OLED based on a squaraine dye-doped polymeric matrix

Benedikt Stender, Sebastian F. Völker, Christoph Lambert, Julius-Maximilians-Univ. Würzburg (Germany); Jens U. Pflaum, Julius-Maximilians-Univ. Würzburg (Germany) and Bavarian Ctr. for Applied Energy Research E.V. (Germany)

The field of organic light-emitting diodes (OLEDs) has been investigated intensively during the past two decades. In particular, solution processed polymer devices have gained increasing interest due to their tunable emission range in combination with low-cost, large-area fabrication. Whereas OLEDs emitting in the visible have launched the market, electroluminescent devices emitting in the near-infrared (NIR) are still at an immature state despite their potential for application in optical communication and their ability of room temperature operation . A major drawback of bare organic NIR-emitters is their tendency of degradation caused by the extended ?-conjugated electron system. To cope with this challenge a novel organic host-guest system consisting of the squaraine dye monomer M embedded in a SY-PPV polymer matrix has been investigated. Comparative studies of the steady-state photo- and electroluminescence provide access to the opto-electronic processes on molecular length scales. Optical excitation reveals an efficient energy transfer from the visible to the NIR emission range at 750 nm for doping concentrations of less than 2.0 wt.%. The associated Förster radius of 4.0 nm agrees very well with experimental data and confirms the model characters of the squaraine doped SY-PPV host. In case of electrically driven NIR-emission a power efficiency of 1.6 lm/W together with a turn-on voltage of 2.0 V has been achieved already at a doping level of only 0.05 wt.%. Therefore, NIR emission in this system is controlled by charge carrier dynamics rather than by exciton transfer and highlights its potential for opto-electronic applications.

8829-24, Session 3

Influence of charge transfer-induced molecular orientation on charge injection and transport of organic devices *(Invited Paper)*

Toshinori Matsushima, Hideyuki Murata, Japan Advanced Institute of Science and Technology (Japan)

Dramatic improvement of performance of OLEDs has been obtained upon inserting a transition metal oxide film between an electrode and an organic film or doping of an organic film by transition metal oxide. Several years ago we found that insertion of a very thin layer of 0.75 nm MoO_3 between ITO and NPD led to formation of an Ohmic contact at an ITO/NPD interface. This optimized MoO_3 thickness of 0.75 nm was much smaller than that ever reported. The Ohmic contact formed by the 0.75 nm MoO_3 layer allowed a driving voltage and long-term operational stability of OLEDs to be markedly improved. Also we succeeded in observing a clear SCLC of NPD and estimating hole mobility of NPD from the SCLC analysis. The estimated hole mobility somehow increased as NPD thickness was increased. In this opportunity we will discuss mechanisms of the Ohmic contact formation and the increased hole mobility together with our previous results mentioned before. From our recent results we find that the Ohmic contact formation is due to charge generation from the MoO_3/ NPD interface as well as a horizontal orientation of NPD molecules near a MoO_3 surface. Moreover the increased hole mobility is attributed to a gradient structure of NPD film density formed normal to a substrate plane.

8829-25, Session 3

Organic biluminescence: highly efficient, simultaneous emission from singlet and triplet states of purely organic materials *(Invited Paper)*

Sebastian Reineke, Massachusetts Institute of Technology (Germany)

Organic semiconductors possess two fundamental excited states, namely the singlet (S1) and triplet (T1) states, which are differentiated by their total spin, i.e. either 0 or 1, respectively. Efficient photoluminescence (fluorescence) can occur from the singlet state where the relaxation conserves spin. Luminescence from the triplet state (phosphorescence) is, if observed at all, very weak because it involves a spin flip, which is quantum mechanically forbidden. Still, triplet states play a determining role in the vast of organic-based optoelectronic applications including lasers, photovoltaic cells, and light-emitting diodes. At room temperature, phosphorescence from purely organic molecules is considered a lab curiosity and has only been observed in crystals with strict chemical requirements and under special conditions in soft matter. In this talk, I will discuss highly efficient, simultaneous fluorescence and phosphorescence from a single, purely organic molecule. The share of both intensities is determined by the intersystem crossing between S1 and T1. Phosphorescence is easily observed at room temperature for various, archetypical materials, which is a result of a greatly reduced non-radiative rate for the triplet. As one exemplar application, I will demonstrate that the triplet state of a purely organic molecule can participate in Förster resonant energy transfer (FRET) to a singlet state of an acceptor molecule – turning the donor into a source for dual FRET. The unique potential of organic molecules to function as a dual state emitter opens new fields of applications including the use as ultra-broadband emitters, optical sensors and attenuators, and effective intermediates for energy transfer.

8829-26, Session 3

Novel technologies for commercialized 55-inch WRGB OLED TV *(Invited Paper)*

Yoon-Heung Tak, Chang-Wook Han, Hyo-Seok Kim, Bong-Chul Kim, Jong-Woo Kim, Tae-Seung Kim, Bum-Sik Kim, Chang-Ho Oh, Su-Yeol Cha, Byung-Chul Ahn, LG Display (Korea, Republic of)

World's first commercialized 55-inch WRGB OLED TV has been developed and launched recently. Large-sized OLED displays require novel technologies to realize mass production. We will introduce commercialized 55-inch WRGB OLED TV and its novel technologies including oxide TFT, WOLED, solid phase encapsulation, and compensation technologies. Commercialized 55-inch WRGB OLED TV was fabricated by employing oxide TFT, color refiner, WOLED, and SPE. Oxide TFT and color refiner were fabricated on Gen. 8 glass substrate. WOLED was fabricated by the in-line evaporation process at the ? Gen. 8 production line. After all processes, solid phase encapsulation was covered on WOLED. Commercialized 55-inch OLED TV employs WRGB sub-pixel technology, while conventional OLED TVs have only 3 RGB sub-pixels. Additional white sub-pixels to RGB sub-pixels reduce power consumption. White OLED of WRGB sub-pixel technology emits white light and this light passes through RGB color refiner to produce red, green, and blue emission. Two stacked tandem WOLED structure is evaporated a fluorescent blue stack, a charge generation layer, and a phosphorescent YG stack in series. Solid phase encapsulation is adopted a barrier layer deposited by plasma chemistry composed of Si-based materials on OLED devices. The barrier layer prevents OLED devices from degradation by humidity and mechanical damages. We will introduce an external compensation technology to solve the issues of internal compensation pixel circuit.

8829-27, Session 3

Reliable 6 PEP LTPS device for AMOLED's *(Invited Paper)*

Cheng-Wei Chou, Pei-Yun Wang, Chin-Wei Hu, York Chang, Ching-Sang Chuang, Yu-Hsin Lin, AU Optronics Corp. (Taiwan)

Active matrix organic light-emitting diode (AMOLED) display have attracted great attention as the next-generation display because of its outstanding advantages such as superior color performance, low power consumption and high contrast. To fabricate an AMOLED display product, a stable thin film transistor technology is required. Among the transistor materials, low temperature poly silicon (LTPS) is the most stable material for AMOLED display application. However, high manufacturing cost from LTPS TFT's complicated process steps is the main issue which limited its development in AMOLED displays. To overcome the disadvantages of LTPS TFT, reducing the amounts of the photo processes are the most critical action to achieve the cost competitiveness in AMOLED display markets.

More than 8-photo-Lithography processes were generally used to fabricate the LTPS based AMOLED display. A novel LTPS based 6 masks TFT structure for bottom emission AMOLED display is demonstrated in this paper. This structure is the first report as far as we know. 6-masks TFT structure can fabricated with the traditional TFT-LCD array instruments and recipes without tuning other new process steps. High field effect mobility (PMOS > 80 cm2/Vs) and high reliability (PBTS ?Vth< 0.02V @ 50oC VG=15V 10Ks) was accomplished without the high temperature and rapid thermal annealing (RTA) activation process. Furthermore, the LTPS based 6 photo processes 14" HD bottom emission AMOLED displays were achieved using the Gen. 3.5 mass production factory. These results demonstrate that the LTPS based 6 photo processes TFT can be executed in large size AMOLED display for mass production.

8829-28, Session 3

Enhancing the efficiency of organic light-emitting diodes through interzone and intrazone energy transfer *(Invited Paper)*

Yi-Lu Chang, Univ. of Toronto (Canada)

Considerable progress has been made on organic light emitting diodes (OLEDs) over the past decade. This has made the commercialization of active-matrix OLED displays for mobile phones and even large-area flat panels possible recently. However, in terms of solid-state lighting, further reduction in electrical energy consumption is highly desired to make the technology viable to the lighting industry and compete with its inorganic LED counterpart. To improve the energy efficiency, significant work has been focused on the use of a variety of device architectures including insertion of an exciton confining or carrier blocking layer, doping the transport layers, as well as employing multiple emissive zone structures (same dopant in multiple hosts) in a single device. While effective, these designs are quite inconvenient for large-scale commercial applications. In this work, we have developed two simple ways to enhance the efficiency of OLEDs through intrazone and interzone energy transfer. High external quantum efficiencies (EQEs) of ~19.3% and ~21.0% were achieved at 1,000 cd/m2 for red OLEDs using these two approaches, respectively, which are among the best performances reported to date for red OLEDs. Detailed comparisons between the two simple yet effective methods will be presented.

8829-29, Session 3

Probing film structure of organic light-emitting diodes with neutron reflectometry *(Invited Paper)*

Paul L. Burn, Ian R. Gentle, Arthur R. G. Smith, Paul Shaw, Jake McEwan, The Univ. of Queensland (Australia); Michael James, Australian Synchrotron (Australia)

Advances in light-emitting materials design and manufacturing have brought the first organic light-emitting diodes (OLEDs) to market. For all the devices the structure of the layers plays an important role in controlling their opto-electronic and device properties. Neutron techniques such as neutron reflectometry (NR) and small angle neutron scattering are important methods for studying the physical structures of (macro)molecules and their interactions in solution and/or the solid state. We have been using an in situ photoluminescence-NR measurement for elucidating the relationship between physical structure and emissive properties. In this presentation we discuss structures comprised of phosphorescent iridium(III) complexes. OLEDs containing iridium(III) complexes are highly efficient but achieving this efficiency usually involves diluting the emissive complex in a host material such as 4,4'-bis(N-carbazolyl)biphenyl and having multilayer structures. We will report our study on the effect of thermal annealing on multilayer OLED structures.

8829-30, Session 4

Solution processable small molecular host materials for blue and white phosphorescence OLEDs *(Invited Paper)*

Chin-Ti Chen, Academia Sinica (Taiwan); Yi-Ting Lee, Academia Sinica (Taiwan) and National Taiwan Univ. (Taiwan); Yung-Ting Chang, Academia Sinica (Taiwan); Chao-Tsen Chen, National Taiwan University (Taiwan)

A new series of CzPX small-molecule host materials for blue phosphorescence OLEDs have been characterized. These CzPX

materials are truly amorphous and their triplet state energy are high in the range of 2.58~2.73 eV, estimated from the time-gated low temperature photoluminescence spectra of the neat film. Corresponding solution processed active single layer in blue phosphorescence OLEDs has been achieved. These devices have shown peak current efficiency at 7~11 cd/A, surpassing ~6 cd/A acquired for SimCP2-molecular host-based device with same fabrication condition. The results of hybrid white OLEDs based on CzPx small-molecular host will be presented as well.

8829-31, Session 4

Highly efficient and multilayered phosphorescence OLEDs fabricated by solution-process *(Invited Paper)*

Yong-Jin Pu, Yamagata Univ. (Japan)

Multilayered organic light emitting devices (OLEDs) are difficult to be fabricated by solution-process because of similar solubility of materials in each layer. When sping coating of an electron-transporting material onto an emitting layer, a host material and an emitting dopant have to be insoluble to the coating solvent of the upper layer. We synthesized phenylcarbazole-type host materials with high molecular weight, showing controlled solubility to organic solvents for the coating. Coating solvents of the electron-transporting layer were also optimized not to dissolve the host and emitting dopant. We fabricated all-solution-processed green phosphorescence OLEDs, in which only electrodes were formed in vacuum, consisting of the four layers: hole-injection layer, hole-transporting layer, emitting layer, and electron transporting layer. High efficiencies of 53 lm/W, 76 cd/A, and 21%EQE at 100 cd/m2 were achieved without outcoupling. This is one of best efficiencies ever reported in solution-processed green OLEDs.

8829-32, Session 4

Recent progress in the development of solution processable materials for solid-state lighting *(Invited Paper)*

Olivier P. Gaudin, Jonathan F. Maunoury, Enrico Orselli, Dominique Bascour, Jean-Pierre Catinat, Solvay S.A. (Belgium); Neetu Chopra, Jing Wang, Christophe Grenier, Venkataramanan Seshadri, Christopher T. Brown, Mathew K. Mathai, Plextronics, Inc. (United States)

Lighting accounts for approximately 20% of the worldwide electrical power consumption, so that there is an increasing need for developing high efficiency lighting products. Organic light emitting diodes (OLEDs) have the potential to provide both efficient and low cost light sources which could be used to replace conventional lighting technologies. In addition, OLEDS can be produced in the form of diffuse, large area and flexible lighting tiles, thus enabling entirely new lamp designs.

Alongside vacuum processing, which typically yields highly efficient and long lifetime devices, deposition of the OLED layers can also be achieved using solution processing. The latter offers the advantage of being compatible with low cost, high throughput, printing techniques, such as roll-to-roll (R2R) processing on flexible substrates. However, solution processed OLEDs tend to lag behind their vacuum counterparts in term of efficiency and lifetime.

Solvay and its partner Plextronics have developped a set of solution processable organic materials which can be used for the fabrication of partially solution processed white OLEDs having both high efficiency and long lifetime. This presentation will outline Solvay's approach to the development of white OLEDs for lighting, where several layers are solution processed. As the Solvay materials can be both vacuum and solution processed, a direct comparison of the device performance as a function of the material deposition technique used can be achieved.

8829-33, Session 4

Solution processed, blue phosphorescent small molecule organic light emitting diodes comprising metal oxide buffer layers *(Invited Paper)*

Stefan Hoefle, Uli Lemmer, Alexander Colsmann, Karlsruher Institut für Technologie (Germany)

Today, organic light emitting diodes (OLEDs) and displays have achieved commercial relevance due to their unique contrast and low power consumption. While most state-of-the-art OLEDs for OEM applications are deposited in vacuum, science and industry work hard on solution processable and hence potentially low-cost fabrication alternatives. The main objectives are to overcome solvent limitations during the deposition of multi-layer devices and to enhance the lifetime of the devices. One material class that was proven to be very beneficial for (vacuum deposited) OLEDs are transition metal oxides. In this work we use a variety of metal oxide precursors in order to fabricate charge carrier transport layers from MoO3 or WO3 for OLEDs from solution. The respective layers are transparent to visible light and become insoluble to most solvents after deposition enabling the subsequent deposition of almost any emitters. In particular we have focused on processes that can be carried out at moderate temperatures to be suitable for roll-to-roll fabrication on flexible plastic substrates. While most precursors require oxygen to be converted into a metal oxide, we investigated processes that can be carried out under nitrogen atmosphere and hence can be beneficial for the device lifetime. By using metal oxides with very high work function, we were able to fabricate efficient phosphorescent blue emitting OLEDs from solution as holes could easily be injected into the low HOMO of the emitter matrix.

8829-34, Session 4

Bright blue all solution processed multi-layer polymer light emitting diodes realized by thermal layer stabilization and orthogonal solvent processing

Emil J. W. List, Technische Univ. Graz (Austria) and NanoTecCenter Weiz Forschungsgesellschaft mbH (Austria)

To extend solution processed polymer light emitting device (PLED) technology from lab- to full production scale significant improvements in the material performance have to be devised. In addition it is necessary to adapt material and device concepts to solution based roll-to-roll fabrication processes. Only if similar performance values as achieved for organic light emitting devices (OLEDs) fabricated based on vacuum vapor deposition techniques can be realized, the benefit of cost effective and high throughput fabrication based on solution processing can reach its full potential for large area (flexible) devices, signage and lighting applications. Yet, to achieve the necessary requirements of high brightness values in the device, alongside with high efficiency and stable operation, OLEDs require balanced charge carrier injection and charge carrier transport as typically realized only in multilayer device structures. In this contribution we report on fully solution processed doulbe and triple-layer PLED assemblies that combine a hard bake process – to insolubilize the bottom hole transporting layer (HTL) - and the deposition of polymers from orthogonal solvents for both the emissive layer (EML) and optionally the deposition of additional the electron transport layer (ETL). The successful implementation of two different solution based multilayer approaches – based on orthogonal solvents and thermal stabilization of a polymeric layer - for several sequential spin-coating and annealing steps without harming the preceding layer is investigated and proven by atomic force microscopy (AFM) investigations. In addition ultraviolet photoemission spectroscopy (UPS) measurements evidence that the combination of materials and their assembly in PLEDs, as presented in this work, exhibit a favourable energy level alignment, i.e., efficient electron blocking at the HTL/EML-interface and hole blocking at the EML/ETL-interface. This allows for good charge carrier confinement within the EML resulting in an enhancement of the maximum luminance and electroluminescence efficiency for multilayer PLEDs in comparison to single layer devices. As it will be shown such solution processed PLED-stack exhibit highly efficient high brightness state of the art deep blue electroluminescence emission clearly demonstrating the potential of the presented concept.

8829-35, Session 5

The development of HIL and HTL inks for OLED application *(Invited Paper)*

Jing Wang, Christopher T. Brown, Christophe Grenier, Mathew K. Mathai, Venkataramanan Seshadri, Neetu Chopra, Darin W. Laird, Christine McGuiness, Jian Wang, Sergey B. Li, Plextronics, Inc. (United States)

OLED technology has advanced rapidly in recent years, especially with respect to organic materials, color patterning, electronic driving methods, and encapsulation. While OLED has become a mass-market technology in small/medium displays the expected investments in new fabs indicate the growth will continue with increasing competition and will likely include larger size applications. Today, nearly all AMOLED displays are made using thermal evaporation which often yields a low material utilization, and is limited to smaller substrate sizes. Cost-Effective production of OLED displays requires a transition from all vapor manufacturing to one with solution printing processes.

Over the last few years Plextronics Inc. has been developing solution processing material and ink systems with a focus on materials and inks for hole injection (HIL, both aqueous and non-aqueous) and hole transport layers (HTL). We will report on recent developments that enable solution processed OLEDs with state-of-the-art device performance.

8829-36, Session 5

Recent advances in ITO-free SMOLEDs and polymer guest: small-molecule host devices *(Invited Paper)*

Joseph Shinar, Ruth Shinar, Min Cai, Rui Liu, Emily Hellerich, Zhuo Ye, Kai-Ming Ho, Rana Biswas, Jeremy Intemann, Malika Jeffries-El, Iowa State Univ. (United States)

Extremely efficient ITO-free SMOLEDs and polymer guest:small-molecule host devices will be reviewed. The former are due, in large part, to a microcavity effect. And although numerous extensive studies of guest-host OLEDs with a polymer or small molecule host and small molecule guests have been reported, such extensive studies on devices with a small molecule host and a polymer guest are lacking. Results on such guest-host devices with a CBP host and polymer (including newly synthesized) guests, will be described, including stability of such devices that has not been reported.

8829-37, Session 5

High efficiency in solution processed blue and white phosphorescent organic light-emitting diodes *(Invited Paper)*

Jun Yeob Lee, Ho Jong Kang, Oh Young Kim, Chil Won Lee, Yong Joo Cho, Kyoung Soo Yook, Dankook Univ. (Korea, Republic of)

High efficiency solution processed blue and white phosphorescent organic light-emitting diodes were fabricated by developing novel device architecture and soluble materials. Alcohol soluble host and dopant materials were synthesized to prepare multilayer device structure by solution process and high efficiency could be achieved in blue and white phosphorescent organic light-emitting diodes. In addition, several asymmetric host materials were synthesized for smooth amorphous film formation and high efficiency above 20% could be realized in blue phosphorescent organic light-emitting diodes.

8829-38, Session 5

Distinctive characteristics of solution processed OLEDs: physical studies *(Invited Paper)*

Denis Kondakov, Weiying Gao, Adam Fennimore, Shiva Prakash, DuPont (United States); Marc Sims, Ines Wyrsta, Ian D. Parker, DuPont Displays (United States)

Arguably, solution-processing of the emissive layer (EML) is the most desirable capability of OLED fabrication process because it replaces expensive FMM (fine metal mask) patterning step for RGB displays. Aside from the manufacturing advantages, there are multiple consequences to solution processing the EML.

Intermixing between HTL and EML is an important factor that requires a proper control through materials and process design. It may or may not be detrimental to device performance, depending on the particular OLED. For example, it is well known that in some evaporated devices an intentional admixing of the HTL component throughout the EML yields a specific advantage such as increased device lifetime or efficiency. In solution-processed devices, mixing is defined by a presence of a region where EML and HTL molecules coexist. Location and composition of such a region is determined by particular details of solution processing and has important performance implications. We applied techniques such as impedance spectroscopy, photoemission spectroscopy (UPS and XPS), and emission zone profiling with combined solution/vapor EMLs and HTL-EML exciplex formation as a marker to determine extent and properties of mixed layer.

Another consequence of solution processing is a different molecular ordering compared to that in evaporated layers. In a number of cases we have examined, the act of solution processing results in an isotropic molecular orientation in the film, whereas evaporated films are often dominated by a strong anisotropic orientation, with an increased number of parallel (or in-plane) transition dipoles and, consequently, higher light outcoupling and electroluminescence efficiency.

Although not an inherent to solution processing, solvent entrapment is a common consequence and may affect the performance of OLEDs. Using headspace gas chromatography/mass spectroscopy to quantify the amount of solvent entrapped, we have observed its effect on the device lifetime.

8829-39, Session 5

Metal oxide for solution-processed small molecule phosphorescent light emitting diodes

Franky So, Shuyi Liu, Rui Liu, Univ. of Florida (United States)

Solution-processed small molecule phosphorescent organic light emitting diodes (OLEDs) attract much research attention recently due to the combination of the low-cost fabrication method and decent luminance efficiencies. However, further development of such devices requires a better exciton confinement in multilayer structure, which was limited by the solvent orthogonality. Additionally, the poor stability of conventional organic HTL/HIL hindered the progress of phosphorescent OLEDs. In this study, we applied the solution-processed metal oxide as a novel HTL/HIL to replace conventional organic counterparts. In particular, the p-type nickel oxide (NiOx) and n-type electron accepting vanadium oxide (V2O5) are fully studied as HTL and HIL respectively. After spin-coating followed by appropriate treatment, a highly transparent film of either NiOx or V2O5

is formed. The oxide composition, morphology and injection/transport property of these materials were characterized by various methods. The NiOx HTL/V2O5 HIL yields an efficient device with similar or better hole transport /hole injection properties and improved stability compared to the typical organic counterparts. Our study paves the way for making efficient multilayer solution processed phosphorescent OLEDs.

8829-40, Session 6

Color tuning in organic light emitting field-effect transistors *(Invited Paper)*

Heinz von Seggern, Technische Univ. Darmstadt (Germany)

The unique property of ambipolar organic light emitting field-effect transistors (OLETs) is the ability to position the light emission zone within the transistor channel through the applied biases to the transistor terminals. In this talk the basics of the ambipolar OLET will be discussed and two examples for colour conversion will be demonstrated. Both approaches take advantage of the ability of a controlled displacement of the recombination zone through the organic semiconductors. In the first approach two different acenes with different emission colours are employed in a parallel stack in a top-contact bottom-gate FET configuration. It will be demonstrated that due to thermionic emission of electrons at the source, light of one colour can be generated near the source contact even in hole accumulation. Due to the electrically controllable positioning the charge carrier recombination zone can be directed from the top acene layer to in the bottom acene layer. Thereby the emitted light can be continuously shifted by about 50 nm from green to red. A second approach takes advantage of the horizontal displacement of the recombination zone within the channel of the transistor. On top of the semi-transparent gate electrode of a F8BT transistor a colour conversion layer is deposited in a wedge-like shape partially covering the channel. In the ambipolar regime the charge carrier recombination takes place in the F8BT layer, and dependent on the position of the recombination zone either the emitted light of the F8BT layer or the partially absorbed and converted light from the colour conversion layer can be detected. The electroluminescence maximum of the emitted light can be shifted by about 30 nm. The physics and potential applications of such colour tuneable OLETs will be discussed.

8829-41, Session 6

Low threshold polymer lasers: cavity design and fabrication *(Invited Paper)*

Ifor D. W. Samuel, Yue Wang, Emiliano R. Martins, Georgios Tsiminis, Graham A. Turnbull, Univ. of St. Andrews (United Kingdom)

The threshold is a key performance parameter of conjugated polymer lasers. Low threshold enables convenient pump sources to be used, such as nitride LEDs. We show that nanoimprint lithography can be used to make distributed feedback polymer lasers with very low thresholds, below 100 W/cm2. This process takes advantage of the favourable processing properties of polymer lasers, and has enabled us to make the first LED-pumped nanoimprinted polymer lasers. We also show how threshold can be reduced further by improved cavity design to control the relative amounts of feedback and output coupling.

8829-42, Session 6

Highly stretchable polymer light emitting devices *(Invited Paper)*

Qibing Pei, Univ. of California, Los Angeles (United States)

A fully stretchable light emitting device entails all materials employed in the device to be stretchable. Polymer composites comprised of silver nanowires or carbon nanotubes inlaid in the surface layer of a transparent polymer sheet have been developed as elastomeric transparent electrode. The surface smoothness, sheet resistance, and visual transparency of the composite electrode are comparable to ITO/glass. Depending on the polymer matrix selected, the composite electrode can be made flexible like PET or stretchable like a rubber. Polymer LEDs fabricated using the composite electrode as anode exhibit EL efficiencies higher than control devices fabricated on ITO/glass. Devices fabricated by laminating an EL polymer layer between two elastomeric composite electrodes can be elongated by greater than 40%.

8829-43, Session 6

Polymer nanofibers as novel light-emitting sources and lasing material *(Invited Paper)*

Andrea Camposeo, Luana Persano, Istituto Nazionale per la Fisica della Materia (Italy) and Istituto Italiano di Tecnologia (Italy); Dario Pisignano, Univ. del Salento (Italy) and Istituto Nazionale per la Fisica della Materia (Italy) and Istituto Italiano di Tecnologia (Italy)

Polymer micro- and nano-fibers, made of organic light-emitting materials with optical gain, show interesting lasing properties. Fibers with diameters from few tens of nm to few microns can be fabricated by electrospinning, a method based on electrostatic fields applied to a polymer solution. The morphology and emission properties of these fibers, composed of optically inert polymers embedding laser dyes, are characterized by scanning electron and fluorescence microscopy, and lasing is observed under optical pumping for fluences of the order of 10^2 J cm^-2. The reduced size of these novel laser systems, combined with the possibility of achieving wavelength tunability through transistor or other electrode-based architectures embedding non-linear molecular layers, open interesting perspectives for realizing miniaturized laser sources to integrate on-chip optical sensors and photonic circuits.

8829-44, Session 6

Recent progress on the vacuum deposition of OLEDs with feature sizes ≤ 20 ?m using a contact shadow mask patterned in-situ by laser ablation

Yoshitaka Kajiyama, Kevin A. J. Joseph, Univ. of Waterloo (Canada); Koichi Kajiyama, Syuji Kudo, V-Technology Co., Ltd. (Japan); Hany Aziz, Univ. of Waterloo (Canada)

We report progress on the development of a new technique that has the potential to enable the vacuum deposition of OLEDs with feature sizes ≤ 20um, and hence high resolution OLED displays. An OLED device with 16um by 130um sub-pixel size has been successfully demonstrated utilizing the novel idea of the in-situ shadow mask patterning method showing the capability to achieve high resolution OLED patterning. In the approach proposed here, two sheets of polyimide film are mounted on an electrode, and the top sheet of the two stacked sheets is patterned in-situ by laser ablation to create apertures. The protective under sheet is then removed, and OLED materials are deposited through the patterned slits. Since mask alignment is not required in this approach, the technique circumvents the resolution limitations imposed by the difficulty of aligning shadow masks in the conventional techniques, and allows achieving high resolution pixel patterning. Furthermore, shadow effects, another factor that limits resolution in conventional techniques, can be reduced due to the thin plastic shadow mask (~7.5um) that is directly held on the substrate by electrostatic force. In principle, by applying this technique to the standard three color side-by-side sub-pixel matrix scheme, a resolution and aperture ratio of 338ppi and 60%, respectively, can be expected, which is estimated based on the fact that the width of the deposited material is 25um for the 16um wide electrode.

8829-45, Session 7

Candle light-style OLED: a plausibly human-friendly safe night light *(Invited Paper)*

Jwo-Huei Jou, Jing-Ru Tseng, Chun-Yu Hsieh, Shiang-Hau Peng, National Tsing Hua Univ. (Taiwan); Ching-Chiun Wang, Chien-Chih Chen, Ching-Tung Fu, Szu-Hao Chen, Yi-Shan Wang, Industrial Technology Research Institute (Taiwan)

In response to the need for a human-friendly lighting source for use at night, we demonstrate a mimic candle light organic light emitting diode (OLED) with a very high color rendering index, and an efficacy at least 300 times that of candles. The device shows an 80% lumen spectrum resemblance with the candle, which is obtained by using 4 candle light complementary emitters dispersed in two different emissive layers separated by a nano-scale carrier modulation layer. Notably, a sensationally warm candle light-style emission can hence be driven by electricity in lieu of the hydrocarbon-burning and greenhouse gas releasing candles that invented 5,000 years ago.

8829-46, Session 7

Carrier-gas enhanced vapor phase deposition for organic thin films: addressing mass manufacturing requirements for OLEDs and overcoming existing challenges with OVPD *(Invited Paper)*

Juergen Kreis, Markus Schwambera, Dietmar Keiper, Markus Gersdorff, Michael Long, Michael Heuken, AIXTRON SE (Germany)

The vast majority of installed OLED manufacturing lines do utilize medium format mother glasses of Gen3.5 – Gen4.5 size (equals 650x750mm? to 730x920mm?), which are clearly too small to manufacture 56” panels and larger: a single 56” panel at 16:9 aspect ratio corresponds to approximately 1240x700mm?.

With these dimensions, cost-efficient manufacturing of OLED TV panels requires production technologies, which can handle mother glasses of Gen8 size and larger.

Using Gen8 substrates, corresponding to 2.200x2.500mm?, allow cutting 6x 55” panels or 4x 60” panels out of one mother glass sheet.

With such large area manufacturing, total cost of ownership considerations do see higher attention as for such sizes and production volumes, cost-efficiency are becoming of paramount importance.

By today, virtually all OLEDs utilizing small molecule organic stacks are deposited by vacuum thermal evaporation (VTE).

As long as scaling was not the main objective for this approach, VTE has proven to be a reliable method to make functional devices.

However, with increasing importance of total cost of ownership as well as raising technical challenges for scaling to larger areas, further propelled by the imminent need to significantly ramp-up on volumes, intrinsic limitations of VTE are understood as a challenge.

The concept of Organic Vapor Phase Deposition (OVPD®), originally developed by Stephen Forrest (*) to overcome perceived limitations of the VTE-based deposition, utilizes an inert carrier-gas for the transport of evaporated material from source to substrate and for controlling rates and composition with the partial gas flow instead of the evaporation temperature. The precise control of organic thin film processing by Organic Vapor Phase Deposition (OVPD®) is presented and analyzed on device level. With its decoupled process parameters, e.g. deposition rate, substrate temperature and deposition pressure, OVPD® offers accurate and individual control of deposition layer properties like mixing several materials (co-deposition) and the realization of various morphologies.

AIXTRON has taken the basic principle of OVPD® and, incorporating its in-house expertise of Close Coupled Showerheads (CCS®) as well as its proprietary Short Thermal Exposure Source (STExS™) technologies, offers solutions addressing the need of highly efficient production solutions for the deposition of organic thin films.

8829-47, Session 7

Hybrid white organic light-emitting diodes with high color-rendering index and stable color *(Invited Paper)*

Ma Dongge, Fangchao Zhao, Changchun Institute of Applied Chemistry (China); Hongmei Zhang, Nanjing Univ. of Posts and Telecommunications (China)

High efficiency hybrid white organic white light-emitting diodes (WOLEDs) for high color-rendering index (CRI) and stable color have been fabricated by the design of device structures. Here we fabricated two kinds of hybrid WOLEDs with red phosphorescent emissive layer/green phosphorescent emissive layer/spacer/blue fluorescent emissive layer (device 1) and red phosphorescent emissive layer/spacer/blue-green emissive layer (device 2), respectively. The key point in device 1 is using mixed 4,4?,4??-Tri(9-carbazoyl) triphenylamine (TCTA) and bis[2-(2-hydroxyphenyl)-pyridine] beryllium (Bepp2) as the host of phosphorescent EMLs as well as the spacer, which broadens the exciton distribution and improve the effective control of charge carriers in emissive layers. As a result, the hybrid WOLED exhibits a high power efficiency of 27.1 lm/W at brightness of 1000 cd/m2 and also a stable spectral emission with a high color rendering index (CRI) of 89 in a whole range of luminance. For device 2, the simultaneous emission of a blue light from the fluorescent host (Bepp2) and a green light from the phosphor (Ir(ppy)2(acac)) was realized by controlling the doping concentration of the green phosphor in the fluorescent host. It can be seen that the resulting hybrid WOLEDs achieved a CRI of 90 and kept rather stable spectral emission with Commission Internationale de L’Eclairage (CIE) coordinates of (0.42, 0.44) independent of driving voltages. This device2 also emits a high power efficiency of 23.0 lm/W at 1000 cd/m2.

8829-48, Session 7

Bending limits of flexible top-emitting OLEDs for lighting

Philipp Schwamb, Thilo C. G. Reusch, OSRAM Opto Semiconductors GmbH (Germany); Christoph J. Brabec, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany) and Bavarian Ctr. for Applied Energy Research E.V. (Germany)

OLED technology has the potential to allow the fabrication of flexible light sources. Flexible OLED lighting devices have great appeal due to new design options, being unbreakable and their low weight. Metal foils are impermeable and good thermal conductors and thus promising candidates for flexible substrates. The required top-emitting architecture uses transparent thin metal electrodes. While these electrodes result in difficult optical design replacing the commonly used brittle ITO electrodes is expected to result in improved bending limits. The bending limits of such electrodes and full OLED lighting devices on metal and plastic foils were studied.

For this study samples were bent in controlled manner to varying degrees. Thereafter the samples are tested using various methods to identify operation and or encapsulation failures or electro-optical anomalies. We investigated influences from substrate material and thickness, hard coating thickness and bending type being convex or concave.

The substrate thickness is found to dominate bending limits for samples without hard coating as expected by neutral layer modeling. Hard coating shows strong improvements for all substrates increasing with thickness. Bending radii <15mm without damage to device or encapsulation are achieved. We report and discuss the main failure mechanisms as well as options for fast testing and screening of bending limits.

8829-49, Session 7

High-performance all-phosphorescent three-color white OLEDs based on a new blue phosphorescent emitter

Soichi Watanabe, Stefan Metz, Peter Murer, Heinz Wolleb, Gerhard G. Wagenblast, Christian Lennartz, Ute Heinemeyer, Ingo Münster, BASF SE (Germany)

The use of all-phosphorescent OLED lighting devices with intrinsically high quantum yields is mandatory to satisfy energy efficiency demands. However, due to the limitation of emission color and lifetime of blue phosphorescent emitters, color quality and lifetime of devices are still limited. To overcome these limitations, a new class of stable pure blue phosphorescent emitters was developed. Photophysical measurements confirm a very efficient light emission, and integration of the blue emitter together with red and green emitters into white OLED devices led to significant increase in lifetime due to electrical stabilization. Devices reported in this contribution show high correlated color temperature (CCT) of 3500-4000K, high color rendering index (CRI) 76-82, and LT50% of over 9.000 hours at 1000 cd/m2 without use of any out-coupling structure.

8829-83, Session 7

OLEDs heading towards ultra-high efficiency *(Invited Paper)*

Malte C. Gather, Technische Univ. Dresden (Germany)

We will report on recent progress in our research on high-performance organic light-emitting diodes. Particular focus is on the investigation and understanding of the micro-optic processes that influence the efficiency and emission characteristics of OLEDs. For instance, we will review our recent work on the molecular orientation of emitter molecules in OLEDs and discuss the potential of controlled emitter-molecule alignment as a way to improve device efficiency. We will also present work on a novel scattering approach that enables extraction of light that is guided inside the inner organic layers of OLEDs. It is shown that our approach is universally applicable to different device configurations, including white-emitting OLEDs.

8829-50, Session 8

Strategy for enhancing light in/out-coupling of flexible organic optoelectronic devices *(Invited Paper)*

Jong-Lam Lee, Pohang Univ. of Science and Technology (Korea, Republic of)

Flexible electronics are pliable, thin, light-weight, impact resistant, and adaptable in design, so they have many possible applications in mobile information displays, solar cell, and general lighting. Therefore, to enable the flexible electronics, flexible substrates (plastic, steel) and fabrication methods have been studied in numerous reports. However, the required flexible nature of the substrate causes fundamental challenges. Polymeric substrates have process temperature limitations (< 350 ?) and high coefficient of thermal expansion (CTE) generating crack in devices during heating processes. A metal substrate has many advantages such as high flexibility, heat dissipation, dimensional stability and melting temperature, but the high surface roughness of the metal substrate (Ra > 100 nm) is a problem.

8829-51, Session 8

Optical design for efficient light emission in OLEDs and anisotropic layers *(Invited Paper)*

Lieven Penninck, Kristiaan Neyts, Univ. Gent (Belgium)

As organic light emitting diodes are now on the brink of large scale commercialization, detailed and reliable modeling of all emission properties of the OLED becomes essential. High efficiency, color point and angular variations should all be taken into account.

Four contributing factors to light emission in OLEDs can be identified: charge balance, singlet/triplet ratio, radiative efficiency and outcoupling efficiency. A charge balance and singlet/triplet ratio of near 100% are achieved in state of the art devices. But significant improvements are still possible in the outcoupling of light. Both radiative efficiency and outcoupling are influenced by the optical design of the organic layer stack.

Light emission is modeled as the radiation of a dipole antenna. The spectrum and angle distribution of the emission is modified by reflections from the OLED interfaces. The rigorous coupled wave analysis is used to simulate both external and internal periodic outcoupling structures. Measurements of the photo- or electroluminescent decay rate of different emitters can be used to probe the radiative efficiency and dipole orientation of the emitting molecules. We analyze and compare the importance and interaction between internal and external outcoupling structures, cathode reflectivity and oriented dipole emission.

The plane wave approach is expanded to account for anisotropic materials like liquid crystals or polymers. This approach is used to simulate emission form cholesteric liquid crystals which feature high reflectivity and low absorption due to their periodic nature. The gain threshold for lasing in cholesteric liquid crystals can be estimated by simulation and is verified experimentally.

8829-52, Session 8

Improved light outcoupling and mode analysis of top-emitting OLEDs on periodically corrugated substrates

Tobias Schwab, Cornelius Fuchs, Reinhard Scholz, Technische Univ. Dresden (Germany); Xuanhua Li, Feng-Xian Xie, Wallace C. H. Choy, The Univ. of Hong Kong (Hong Kong, China); Karl Leo, Malte C. Gather, Technische Univ. Dresden (Germany)

We demonstrate that the outcoupling of light from optimized planar top-emitting OLEDs can be further improved by exploiting Bragg scattering from periodic structures. Corrugated photoresist structures on planar glass substrates are obtained by a simple and versatile imprinting technique using a PDMS stamp carrying a sub-micron length scale grating. After UV-curing of the photoresist, the surface corrugation amounts to 39nm in depth with a period of 692nm. These samples are overgrown with a thick Al/Ag bottom contact, followed by a 345nm p-i-n OLED stack, a 20nm Ag top contact and a 70nm organic capping layer.

An optimized planar reference device with this architecture achieves an external quantum efficiency (EQE) of 11%. For devices containing the corrugated photoresist layer, the light outcoupling efficiency is increased while the electrical properties of the devices are conserved, resulting in an EQE of 12.5%.

This improvement is explained as follows: The highly reflective top and bottom contacts in our top-emitting OLEDs introduce strong microcavity effects affecting both, directly outcoupled light (i.e., the mode that is emitted into the surrounding air independent of the grating structure) and waveguided modes. Bragg scattering of waveguided modes into the forward direction can result in constructive or destructive interference with the directly outcoupled mode. In our samples, this interference results in a strong enhancement of the emission into air and in additional emission of the scattered modes in the orange-red spectral region with respect to the reference devices. Together, these effects lead to a 42% increase of the luminous efficacy.

8829-53, Session 8

Spontaneously formed nanostructure as a light extraction layer for organic light-emitting diodes *(Invited Paper)*

Jonghee Lee, Jaehyun Moon, Seung Koo Park, Chul Woong Joo, Jin-Wook Shin, Keunsoo Lee, Doo-Hee Cho, Nam Sung Cho, Joohyun Hwang, Hye Yong Chu, Jeong-Ik Lee, Electronics and Telecommunications Research Institute (Korea, Republic of)

Organic light-emitting diodes (OLEDs) have attracted considerable interest as a potential cost-efficient alternative lighting sources for both flat panel display and lighting applications and can help to solve the global energy crisis. However, there are still challenges on OLEDs, which are the out-coupling issues. The generated light in emissive layer of OLEDs is confined inside OLEDs because of refractive index mismatch between air (nair=1)/ glass substrate (nlow=1.5)/ ITO anode (nITO=2.0)/ organic (norg=1.7-1.9). Therefore, the development of efficient light extraction structures is of great necessity and significance to realize the practical applications in large area and cost-effective lighting sources.

In this paper, we report on a solution-processed wrinkled structure based film that acts a light extraction layer for OLEDs. The film can be prepared by a UV curing process of a liquid pre-polymer solution which has crosslinking moieties. After simple spin coating, the prepolymer bind to form spontaneously a wrinkled structure during the UV curing process as shown in Figure. Additionally, this film has very high haze factor over 95 and furthermore, photo-patternability thanks to the UV curable moiety.

To examine the light extraction ability, we fabricate OLEDs with the wrinkled structure as an external or an internal light extraction layer and demonstrate over 40 % efficiency enhancement because of an excellent light scattering effect.

We believe that this simple, inexpensive, and reliable system can be a key technology and will greatly contribute the development of OLEDs for both lighting and display applications.

8829-54, Session 8

A new approach to UV-blocking and passivation method for organic electronics

Illhwan Lee, Sungjun Kim, Bonhyeong Koo, Jong-Lam Lee, Pohang Univ. of Science and Technology (Korea, Republic of)

Over the last few years, there has been much work on fabricating organic electronic devices such as organic light emitting diodes (OLEDs) and organic photovoltaics (OPVs). However, organic electronics have some limitations due to stability of organic material. In general, the exposure of organic electronic device to oxygen, moisture and Ultraviolet (UV) light leads to degradation of electrical properties. There are a number of approaches reported in the literature for protecting the organic electronic devices, which can be categorized into two groups: passivation and UV blocking.

In this work, we report that fabrication of efficient passivation and UV blocking layer by refractive index graded Distributed Bragg Reflector (DBR). DBR has high reflectivity in certain wavelength. We designed the DBR structure which can reflect at UV wavelength region (300~400 nm wavelength). The DBR is composed of silicon nitride which is well known material for passivation. Also, we can control the refractive index according to composition of Si and N ratio during silicon nitride deposition. That means the DBR structure is only composed of silicon nitride. So, we can deposit the DBR without stopping the deposition process. It is easy and fast to fabricate the UV-reflecting passivation layer.

8829-55, Session 8

Improving light extraction from large area flexible organic lighting panels

Jack W. Levell, Raghu Kishoro Pendyala, Peter A. Rensing, Alessia Senes, Stephan Harkema, Holst Ctr. (Netherlands); Olivier P. Gaudin, Solvay S.A. (Belgium); Duncan MacKerron, DuPont Teijin Films U.K. Ltd. (United Kingdom); Joanne S. Wilson, Holst Ctr. (Netherlands)

A general challenge in Organic Light Emitting Diodes (OLEDs) is to extract the light efficiently from the devices from waveguided modes within the structure. This can be accomplished by applying an additional scattering layer to the substrate which results in outcoupling increases between 25% to >100% in external quantum efficiency. In this work we aim to address this large variation in outcoupling efficiency with some general design rules and show routes to even higher performance.

Vapour deposited Organic light emitting diodes (OLEDs) have shown high efficiencies and are now commercially successful in mobile display applications. Unfortunately at the moment these devices are costly and are limited to rigid and fragile glass substrates. The high efficiency and novel form factor of OLEDs also show promise for lighting applications. In addition they offer high colour rending index and glare free and ascetically pleasing warm light without the need for bulky luminaries. However, these devices show additional promise if used with flexible shatterproof substrates while facilitating low cost manufacture. Holst Centre and partners are developing flexible substrates and roll to roll compatible processing techniques to enable this next step in OLED development both for lighting and display applications.

In this work also show that refining the light extraction using specially designed flexible PEN substrate foils with DuPont Teijin Film we have enhanced performance in partially solution processed 69 cm2 OLEDs with scattering from 30 lm/W to 42 lm/W at 1,000 cd/m2 luminance with Solvay and Plextronics.

8829-56, Session 8

Enhanced light out-coupling from surface plasmonic loss minimized transparent organic light-emitting diodes

Jungbum Kim, Jeong-Hwan Lee, Chang-Ki Moon, Sei-Yong Kim, Jang-Joo Kim, Seoul National Univ. (Korea, Republic of)

Light extraction of organic light emitting diodes (OLEDs) has been an important issue in order to increase the external quantum efficiency (EQE) of the devices for displays and solid-state lighting, because 70%~80% of the emitted light is confined in the substrate (substrate mode), in the organic layer and in the transparent electrode (waveguide mode), or lost by absorption and surface plasmon polaritons of the metal electrode (absorption and SPP mode). Various methods have been proposed to extract the substrate mode and/or the waveguide modes. However, the absorption and SPP losses by the metal electrode(s) in bottom and top emission OLEDs cannot be avoided in most cases, therefore we need to minimize them in OLEDs to increase the EQE.

Several approaches have been suggested to reduce the surface plasmon loss, such as by controlling the molecular orientation of the emitter, increasing the distance between the emitting layer and the metal electrode, or fabricating a metal electrode free OLED. A metal free OLED with good transparency combined with a method to extract the light efficiently from the device could be a solution for the purpose of reducing the surface plasmon loss.

In this presentation, we will demonstrate through simulation that the surface plasmon and intrinsic absorption loss in OLEDs can be significantly reduced by using a metal free transparent OLED based on TCO electrodes, in contrast to other OLEDs with metal electrodes, maximizing the total amount of extractable light. By integrating microstructures on both sides of a transparent OLED to extract the confined light, we have experimentally realized an OLED with an EQE

value of 47.3%, enhanced from 18.2% without the microstructures. The efficiency was enhanced further to 62.9% by integrating a micro-cone array on one side and a half-sphere lens on the other side. The experimental results are well described by a combined simulation of the classical dipole model and the 3 dimensional ray tracing method. Moreover, the transparent OLED with the microstructures showed no color shift with viewing angle. A simple process which combined the high efficiency and no color shift suggests the great potential of our device for application in solid state lighting.

8829-57, Session PWed

Direct measurement of the composition profile in graded emissive layer organic light-emitting devices and its relation to device performance

Nicholas C. Erickson, Univ. of Minnesota (United States); Sankar Raman, Scott Bryan, Physical Electronics USA (United States); Russell J. Holmes, Univ. of Minnesota, Twin Cities (United States)

In this work, the composition profile of graded emissive layer (G-EML) organic light-emitting devices (OLEDs) is examined through the use of X-ray photoelectron spectroscopy (XPS) with a gas-cluster ion-beam (GCIB) milling tool. The use of Argon in the GCIB allows for careful control of the sputtering rate of the organic layers and avoids altering or contaminating the chemical environment of the exposed organic surfaces. Together, the GCIB and XPS allow precise identification of the chemical state, and quantity, of molecular species as a function of depth through the organic active layers. This technique is applied to devices containing a continuously-varying host composition from predominately hole-transporting material (HTM) at the anode to predominately electron transporting material (ETM) at the cathode. Devices having overall composition profiles of 2:1, 1:1, and 1:2 HTM:ETM show distinct operation and performance differences. These differences are attributed to a variation in the composition of the HTM and ETM materials throughout the device, confirming that the as-deposited composition profiles are distinct, are present post-processing, and are responsible for the changes in operation observed. G-EML based OLEDs have shown promise in achieving highly efficient operation while being fabricated in a single deposition step, potentially allowing for the realization of simple, efficient OLEDs.

Efficient near-infrared emission at 1.3 micron range of narrow-band phthalocyanines thin-films

Xiaoke Hou, Harbin Institute of Technology (China); Xiguang Du, Northeast Normal Univ. (China); Chunyu Ma, Northeast Normal University (China); Shengli Zhang, NeoPhotonics Co. (China); Lei Wang, NeoPhotonics (China); Yong Yao, Harbin Institute of Technology (China)

Organic near-infrared (NIR) emitting materials are extremely rare and receive increasing attention. The optical properties of organic compounds are determined by their energy band gap. Considering several design factors for tuning the energy band gap, we have designed and synthesized a new aza metal-free phthalocyanine containing four 1,10-phenanthroline subunits. The maximum absorption wavelength reaches beyond 1 micron for the aggregated solid samples. The solution deposited thin-film shows fluorescence emission lies in the blue region with a maximum at 460 nm and also emission lies in the NIR region with a maximum at 1292nm. Such a NIR emission at 1.3 micron range, i.e., zero dispersion wavelengths of fiber, is extremely rare for organic compound. The great red shift in optical activity, in our view, lie in at least two aspects: the molecular structure as well as the aggregation formed by molecular interactions. The extension of the conjugation leads to a reduction of the gap between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO). Adding of the peripheral electrophilic subunits also reduce the LUMO energy level. On the other hand, the aggregated state effect not only broadens the emission spectrum, but also causes the great red shift of the fluorescence emission. The energy band gap is determined to be 1.1eV by the cyclic voltammetry measurement which further explains the NIR optical activity. This paper provides a new thought and experimental data for developing organic NIR materials.

Optimization of stacked inverted top-emitting green electrophosphorescent organic light-emitting diodes

Keith A. Knauer, Ehsan M. Najafabadi, Wojciech Haske, Michael P. Gaj, Kendall C. Davis, Canek Fuentes-Hernandez, Ulisis Carrasco, Bernard Kippelen, Georgia Institute of Technology (United States)

Different green electrophosphorescent two-unit stacked organic light-emitting diodes (OLEDs) with inverted top-emitting structures are demonstrated. These devices combine the advantages of inverted top-emitting OLEDs with the benefits gained from having a stacked architecture. The electrical and optical characteristics of the two-unit stacked OLED are evaluated by comparing their performance to that of the constituent single-unit OLEDs. The connecting-unit between the two light-emitting units consists of Al/LiF/1,4,5,8,9,11-hexaazatriphenylene hexacarbonitrile (HAT-CN). The performance of the stacked OLED is shown to be highly sensitive to the thicknesses of the thin layers of Al and LiF, as well as the choice of the hole transport-material in the hole-transport layer adjacent to the connecting-unit. Device performance increases when the Al interlayer thickness is increased from 1.0 nm to 2.5 nm. This could be due to the increased conductivity of the connecting unit with thicker Al, improving electron injection into the neighboring light-emitting unit. Decreasing the LiF thickness from 2.5 nm to 1.0 nm also results in a significant enhancement in device performance. The poorer performance of the stacked OLED with 2.5 nm of LiF could be due to the connecting-unit becoming too insulating at this greater LiF thickness. Finally, when the hole transport material adjacent to the connecting-unit is changed from N,N'-Di-[(1-naphthyl)-N,N'-diphenyl]-(1,1'-biphenyl)-4,4'-diamine (?-NPD) to 1,1-bis-(4-bis(4-methyl-phenyl)-amino-phenyl)-cyclohexane (TAPC), the device performance is significantly improved. With a TAPC hole-transport layer, the two-unit stacked OLED has a current efficacy of about twice that of a single-unit OLED. A final optimized device with an (?-NPD) optical outcoupling layer achieves a current efficacy exceeding 200 cd/A at luminance values up to 1,000 cd/m2.

8829-60, Session PWed

Highly efficient red-emitting OLEDs based on a novel phosphorescent iridium(III) complex

Bona Yang, Hye Jin Lee, Sung Nam Lee, Dongmyung Shin, Hongik Univ. (Korea, Republic of)

A new phosphorescent Iridium complex, Ir(TMP-TT)2(acac) was synthesized for organic light-emitting diodes (OLEDs). This material was designed by result of Gaussian modeling program. The ligand, TMP-TT, have sites of both the electron donor and acceptor in structure. So, It showed Intramolecular Charge Transfer(ICT) property. The TMP-TT was synthesized by Suzuki coupling reaction, and Ir(TMP-TT)2(acac) was synthesized by Nonoyama reaction. The UV-Visible absorption peak of TMP-DT was measured to be at 363 nm and its photoluminescence (PL) emission spectrum showed blue light-emission peaked at 425 nm in chloroform solvent. The devices fabricated by Ir(TMP-TT)2(acac) as emitting layer dopant. The device structures were ITO / NPB / CBP: Ir(TMP-TT)2(acac) / Bphen / Liq / Al.

New platinum complexes for hybrid white organic light-emitting diodes

Anurach Poloek, Chin-Ti Chen, Academia Sinica (Taiwan); Chao-Tsen Chen, National Taiwan Univ. (Taiwan)

Two groups of platinum(II) complexes containing hydroxynapthyridine derivatives or octaphenyltatraazaporphyrin ligands were newly synthesized, and their photophysical properties were examined. Single crystal X-ray diffraction of some of the platinum(II) complexes were determined to elucidate their variation of solid state phosphorescence and electroluminescence. Organic hole transporting as well as blue light-emitting NPB (1-naphthylphenylbiphenyl diamine) or 4P-NPD (1-naphthylphenylquaterphenyl diamine) was employed in the platinum complex-based hybrid white organic light emitting diodes (WOLEDs) with a simplified device configuration of ITO/4P-NPD/CBP:platinum complex/TPBI/LiF/Al or ITO/4P-NPD/4P-NPD: platinum complex /TPBI/LiF/Al.

8829-62, Session PWed

Al2O3/TiO2 multilayer thin film encapsulation for top emitting OLED using ALD process

Lae Ho Kim, Seonuk Park, Chan Eon Park, Pohang Univ. of Science and Technology (Korea, Republic of)

Organic light-emitting diodes (OLED) have great potential for use in next-generation flat-panel display due to their many advantages, such as their fast response, light weight, wider viewing angles and for use with flexible displays. It is still remain to solve the problem of low light-out coupling efficiency and short lifespan. One of the method to overcome low light extraction efficiency is that control the microcavity structre in OLEDs. We were fabricated top emitting OLED and then deposited stacks of Al2O3 and TiO2 layer for encapsulation using atomic layer deposition (ALD) process. The properties including electrical characteristics (I-V-L), EL spectra, and water vapor transmission rate were investigated.

8829-63, Session PWed

Triplet-triplet annihilation in phosphorescent organic light emitting diodes

Yifan Zhang, Stephen R. Forrest, Univ. of Michigan (United States)

Triplet-triplet annihilation (TTA) has been identified as a significant source for efficiency roll-off at high brightness (> 1000 cd/m2) in phosphorescent organic light emitting diodes (PHOLEDs). TTA can be described as the collision between two triplets resulting in de-excitation of one of them. To fully understand TTA, we developed a dynamical model that includes both triplet diffusion and triplet-triplet energy transfer. From the transient photoluminescence of a variety of widely used iridium and platinum complex doped films, we extract the TTA rates. By comparing these rates to model predictions, we find the triplet diffusion dominates TTA. Further, the TTA rate dependence on phosphor doping concentration suggests triplet diffusion follows a Dexter type exchange interaction. Interestingly, iridium complexes have approximately two orders of magnitude higher radiative decay and TTA rate than platinum complexes. To maintain the PHOLED efficiency at high brightness, the TTA rate must be minimized, while maximizing the radiative decay rate. These two rates are independent in the case of Dexter transfer. Thus, we find the difference in TTA rates between the Ir and Pt complexes can be explained by the coincidence in energy between the excited and ground states of the respective molecular species. Thus, minimizing the emission and absorption spectral overlap is a useful means for selecting phosphors for high efficiency PHOLEDs operating at high brightness.

8829-64, Session PWed

Synthesis of fluorene-based polyelectrolytes tethering different counterions for single-component white light-emitting electrochemical cells

Sheng-Hsiung Yang, Chia-Sheng Tsai, Bo-Cun Liu, Hai-Ching Su, National Chiao Tung Univ. (Taiwan)

We demonstrate the synthesis and characterization of fluorine-based polyelectrolytes tethering Br, BF4, or PF6 counterions. 2,1,3-Benzoselenadiazole moieties were incorporated into polymer main chains to produce single-component white light-emitting polymers. The thermal stability of Br-containing ionic polyfluorenes was decreased because of the Hofmann elimination occurred at higher temperature. By replacing Br with BF4 or PF6 counterions, the thermal stability of polymers was significantly improved. UV-vis absorption and photoluminescence spectra revealed that Br-containing ionic PF generates blue shift in methanol, while BF4 and PF6-containing ionic PFs show blue shift in acetonitrile. Electrochemical analysis revealed that oxidation potentials of BF4 and PF6-containing ionic PFs were decreased, resulting in increase in HOMO and LUMO levels. The white light-emitting electrochemical cells (WLECs) with the configuration of ITO/PEDOT/polymer/Ag showed a maximum luminescence efficiency of 1.56 lm/W at a low operation bias of 3 V. The single-component LEC device exhibited pure white light emission with CIE'1931 coordinates approaching (0.33, 0.33) and high color rendering index (CRI > 85), referring to its potential use in solid-state-lighting application.

8829-65, Session PWed

The far-field optical distribution profiles and properties of a planar white organic light-emitting diode

Henglong Yang, Yu-Chen Lien, Lih-Jeih Chen, National Taipei Univ. of Technology (Taiwan)

The far-field optical distribution profiles and characteristics of a planar white organic light-emitting diode (WOLED) with 10x10mm2 emitting area were experimentally investigated by using a 2-axis automatic optical measuring system in which the optical power distribution can be measured in hemi-spherical space. The far-field optical distribution profiles and characteristics of a lighting source are crucial for practically designing specific lighting application. WOLED has become a potential planar lighting source due to its single device structure consisted of multiple organic layers sandwiched by cathode and anode electrodes on glass substrate. This relatively large planar device can be regarded as one of the most unique features compared to a point-source white LED (WLED). The far-field optical distribution characteristics of a WOLED planar lighting source is also expected to be unique and different compared to that of a point source. Our preliminary experimental result measured from a point-source WLED indicates that its far-field optical distribution profile is close to the ideal point-source. Our experimental result measured from a WOLED with 10x10mm2 emitting area reveals its far-field optical distribution characteristic is slightly different from a point source.

8829-66, Session PWed

Improvement of operation voltage and efficiency in inverted blue phosphorescent organic light-emitting devices

Chih-Hao Chang, Hao Siang Huang, Yu-De Su, Chuan-Hao Chiu, I-Chun Lien, Yi-Hu Liang, Yu-Shuo Chang, Yuan Ze Univ. (Taiwan); Hsin-Hua Chang, Vanung Univ. (Taiwan)

An increasing number of smart phones, digital cameras, and tablet PCs use active-matrix OLED (AMOLED) for displays, taking advantage of the performance improvements over passive-matrix OLEDs. Inverted OLEDs (IOLEDs) have drawn considerable attention for use in AMOLED displays because of their easy integration with n-channel metal-oxide based thin film transistors (TFTs). In general, an IOLED consists of a top anode and a bottom cathode that connects to the drain end of the TFTs. To meet the stringent requirement of the TFTs, it is highly desirable to decrease the operation voltage of the IOLED. In this study, we focus on the developing blue phosphorescent, bottom-emission IOLEDs with low operating voltages through the use of adequate-charge injection materials. The most crucial issue for IOLEDs is the poor electron injection caused by the bottom cathode. According to previous reports, the turn-on voltages of FIrpic-based IOLEDs are within a range from 4 to 8 V. This study successfully demonstrates a turn-on voltage as low as 3.5 V for bottom-emission IOLEDs. The electron injection layers were constructed by combining an ultrathin aluminum layer with an alkali metal oxide layer. The peak efficiencies of the IOLEDs reached 15.8%, 32.5 cd/A and 27.7 lm/W. Furthermore, the light extraction technique could be used to improve device performance. Thus, an embedded nanocomposite film is integrated into the IOLEDs to further improve the operating voltage and efficiency.

Recent progress on solution processable small molecules for organic light-emitting diodes in ITRI

Teng-Chih Chao, Han-Cheng Yeh, Jung-Yu Liao, Jin-Sheng Lin, Mei-Rurng Tseng, Industrial Technology Research Institute (Taiwan)

A series of novel phosphorescent dopants containing thieno[3,2-c] pyridine-based ligand were synthesized and characterized. By introducing electron withdrawing/donating substituents, the emission wavelength of these Ir complexes can be tuned from blue to red region. The conventioal vacuum-deposted devices exhibited high efficiencies. The yellow devices showed extremely high efficiency of 98 lm/W@1000 cd/m2. The green devices with efficacies of 56 cd/A and 39 lm/W were reported with the brightness of 1447 nits. When double emitting layers were adopted, the efficacy was improved to 63 cd/A and 44 lm/W@1257 nits. Recently, solution-processed small-molecule OLEDs have drawn many intentions and shown continuously improving efficiency. We successfully fabricated RGBY OLEDs by solution/evaporation hybrid process. The performance of green solution processed OLEDs without HTL showed relatively high efficiency of 36 cd/A and 28 lm/W@1240 cd/m2.

8829-68, Session PWed

Improved light extraction of white LED using the CdSe/ZnS QDs embedded in blue polymer matrix by efficient energy transfer

Sung-Woo Lim, Byoung-Ho Kang, Sang-Won Lee, Su-Hwan Kim, Jae-Sung Lee, Eun-Yoon Jang, Shin-Won Kang, Kyungpook National Univ. (Korea, Republic of)

We propose white-light emitting diode (WLED) that is made up of colloidal QDs embedded in polymer matrix as a hybrid single emissive layer. The red/green colored QDs were mixed with blue emissive PFO to form hybrid emissive layer and it generated proper white emitting with basic structure of OLED. The WLED consist of ITO, PEDOT:PSS, poly-TPD blended with PVK for reducing the hole injection barrier, emissive layer, Alq3, and LiF:Al. As a result, our WLED showed brightness of 1,163 cd/m2 and 1.01 cd/A of efficiency at (0.33, 0.36) CIE coordinate. Inspection of these results, we optimized WLED structure for charge balance in emissive layer and enhanced color purity for the white emission.

White light emission from alternating current organic light-emitting devices using high frequency color-mixing

Markus Fröbel, Technische Univ. Dresden (Germany); Ajay Perumal, Imperial College London (United Kingdom); Karl Leo, Malte C. Gather, Technische Univ. Dresden (Germany)

We report on a novel device concept for organic light-emitting devices (OLEDs) which requires no charge injection from external electrodes and instead uses a capacitively-coupled alternating current (AC) driving signal to operate the device. Here, we show for the first time the generation of white light from these AC-OLEDs. In our approach, both half-cycles of a sinusoidal driving signal are used to independently address a phosphorescent green as well as a triplet-harvesting blue/red unit. Both emission units are spatially separated and connected by sharing a common n-doped electron transport layer. Upon application of a sinusoidal driving voltage, the device alternately emits green and purple light. For high frequencies, the human eye cannot resolve this modulation and the emitted light is perceived as white. This approach yields devices with warm-white color coordinates (0.43, 0.44) and a CRI of 77 at high brightness values of up to 1000 cd/m?. Modifying the AC driving scheme in terms of pulse-height and/or pulse-width of both positive and negative half-cycle can be used to address both emission units separately, providing control over the composition/color-point of the emitted light.

We show evidence proving that the devices operate on a capacitive-coupling based driving scheme and that the emission is solely due to charge carriers provided by the doped transport layers. High dielectric constant insulating layers between electrodes and organic layers efficiently suppress charge carrier injection and improve the Zener tunneling mechanism that is required to replenish the depleted transport layers after each emission cycle.

Organic/electrode interfacial photo-degradation in organic optoelectronic devices

Qi Wang, Mina Abdelmalek, Hany Aziz, Univ. of Waterloo (Canada)

Electrical contacts are integral components of nearly all organic optoelectronic devices such as organic light emitting devices (OLEDs) and organic photodetectors (OPDs), creating organic/electrode interfaces. Indium tin oxide (ITO) and metals are frequently used as electrode materials in these devices. Due to their critical role in device performance, organic/electrode contacts have been the focus of numerous investigations, aiming at studying the chemical and electronic properties of these interfaces. Surprisingly, and despite the high illumination intensities that these interfaces are subjected to in optoelectronic devices, the effect of irradiation on these interfaces and their photo-stability have not been studied until very recently.

We recently discovered that both ITO/organic and organic/metal interfaces are susceptible to irradiation. This photodegradation leads to deterioration in both charge injection and extraction. In this work we present results from investigations on various organic/electrode contacts, and employ fluorescence lifetime measurements to verify that the photo-induced changes occur mainly at organic/electrode interfaces rather than in bulk organic layers. Such organic/electrode interfacial photo-degradation is found to play an important role in the degradation of OLEDs and OPDs, where the interfacial photo-degradation is caused by either device own electroluminescence or external irradiation.

Furthermore, approaches for reducing organic/electrode interfacial photo-degradation are studied. For the ITO/organic interface, the use of MoO3 interfacial layer and CF4/O2 plasma treatment is found to significantly improve the interfacial photo-stability. For the organic/metal interface, on the other hand, the use of interfacial layers such as Cs2CO3, LiF and Li-acetylacetonate of an optimum thickness is found to be effective.

Effect of Thermal Annealing on Electroluminescent Properties of Undoped and Doped Polyfluorene OLEDs

Karoliina Jokinen, Alexander V. Bykov, Rafal Sliz, Kari Remes, Tapio Fabritius, Risto Myllylä, Univ. of Oulu (Finland)

The effect of thermal annealing on electroluminescence properties of polyfluorene-based organic light emitting diodes (OLEDs) was studied. Two types of light emitting layers were investigated: undoped layers made of poly(9,9-di-n-octylfluorenyl-2,7-diyl) (PFO) and doped layers consisting of 95 wt-% of PFO and 5 wt-% of poly[(9,9-di-n-octylfluorenyl-2,7-diyl)-alt-(benzo[2,1,3]thiadiazol-4,8-diyl)] (F8BT). Light emitting layers were spin coated from o-xylene solutions on top of glass substrates preliminary covered with ITO and PEDOT:PSS films. Prior to vacuum deposition of LiF/Al top contacts, the thermal annealing treatment was performed in the oven at 190 ºC or 290 ºC. All the fabrication steps and characterization procedures were executed in the nitrogen-filled glove boxes, excluding spin coating of water-based PEDOT-PSS.

The experiments indicated that the annealing treatment results in significant changes of luminescence and current efficiency in both types of the considered OLEDs, however, the annealing temperature affects them differently. For the undoped OLEDs the current efficiency was highest for the devices annealed at 190 ºC. For the doped OLEDs the highest current efficiency was observed in non-annealed devices. Remarkably, green emission originating from F8BT was observed for the doped OLEDs in the case of non-annealed and annealed (290 ºC) devices. Whereas, the spectrum of the similar devices annealed at 190 ºC had an additional strong blue component corresponding to PFO emission. This fact can be explained by a phase separation between the dopant and host polymers appearing at 190 ºC and leading to incomplete Förster energy transfer from the host to dopant polymer.

Efficient blue emitters based on linear carbazole-fluorene triads

Saulius Jursenas, Karolis Kazlauskas, Paulius Baronas, Vilnius Univ. (Lithuania); Simonas Krotkus, Vilnius Univ. (Lithuania) and Technische Univ. Dresden (Germany); Ausra Tomkeviciene, Vilnius Univ. (Lithuania); Juozas V. Grazulevicius, Kaunas Univ. of Technology (Lithuania)

Realization of efficient blue emitters, particularly, electrically-pumped organic semiconductor laser still remains a challenge. Recently, linear multi-fragment molecular structures based on carbazole or fluorene functional units and featuring extended pi-conjugation attracted attention as promising blue-emitters with emitting dipoles oriented in the plane of the active layer [1,2].

In this work, emission efficiency, excited state lifetime, fluorescence concentration quenching and amplified spontaneous emission of a series of linear carbazole-fluorene triads, designed for lasing applications, were investigated. The triads expressed high fluorescence quantum efficiency in both dilute solutions (~90 %) and neat solid films (up to 60 %), short excited state lifetimes (0.7-1.2 ns), what resulted in high radiative decay rates beneficial for achieving low threshold of amplified spontaneous emission (ASE). Additionally, the linear triads exhibited negligible concentration quenching up to 10 wt % when dispersed in rigid polymer matrix while maintaining high fluorescence quantum efficiency (70-80%). These features enabled to achieve ASE for the compounds dispersed in the polymer matrix in a wide concentration range (0.5 – 10 wt %) with the threshold of as low as 10 kW/cm^2. Based on the density functional theory calculation results and the experimental data the influence of intramolecular twisting, type and the linking topology of the fragments on the emission properties and ASE threshold are discussed.

OLED emission zone measurement with high accuracy

Rossa MacCiarnain, Dirk Michaelis, Christoph A. Wächter, Norbert Danz, Fraunhofer-Institut für Angewandte Optik und Feinmechanik (Germany)

The spatial distribution of the light generation rate in Organic LEDs (OLED), often referred to as the ‘emission zone’, is subject to continuous investigation for many reasons. First, its simulation [1] is desired in order to achieve design based engineering of OLED stacks. Second, its knowledge is required to estimate the internal electro-optical conversion efficiency from far-field measurements. Furthermore, complicated processes such as device ageing might affect the emission zone as well, thus suggesting an approach to gain insight into the underlying phenomena.

The experimental analysis of the emission zone in electrically operated OLEDs usually rely on reverse simulation of radiation pattern measurements [2,3,4], and superior resolution has been claimed for extended polymer emitters [2]. Although this approach seems to be straight-forward, the radiation pattern usually consists of a convolution of multiple emitter properties, and adapted OLED stacks and analytical procedures need to be utilized [5].

In the case of highly efficient state of the art devices, the thickness of emitting layers is in the order of 10 nm. We discuss the problem of emission zone measurement mathematically for such systems, utilizing singular value decomposition (SVD) of the linear problem. This yields insight into the potentially achievable spatial resolution, and allows one to verify experimental approaches (e.g. to use half-ball lenses to access internal substrate patterns). Experimental results illustrate the theoretical results and prove the validity of the approach.

Semitransparent Ag/HAT-CN anode structure in high-performance inverted top-emitting organic light-emitting diodes

Ehsan M. Najafabadi, Keith A. Knauer, Wojciech Haske, Bernard Kippelen, Georgia Institute of Technology (United States)

Inverted top-emitting green electrophosphorescent organic light-emitting diodes (OLEDs) with a Ag/1,4,5,8,9,11-hexaazatriphenylene hexacarbonitrile (HAT-CN) semitransparent anode structure are demonstrated. The devices are fabricated upon polyethylene dioxythiophene-polystyrene sulfonate (PEDOT:PSS)-coated glass substrates. The cathode consists of Al and an electron-injection layer of lithium fluoride (LiF). The OLEDs contain an electron-transport layer of 1,3,5-tri(p-pyrid-3-yl-phenyl)benzene (TpPyPB) and an emissive layer comprising tris(2-phenylpyridine)iridium(III) (Ir(ppy)3) doped in a 4,4’-bis(N-carbazolyl)-1,1’-biphenyl (CBP) host (doped at 6% by volume). Two different device structures are compared, differing only in the choice of material for their hole-transport layers (HTLs). The HTL is composed of either CBP or 1,1-bis-(4-bis(4-tolyl)-aminophenyl)cyclohexene (TAPC). The devices with an HTL of TAPC show superior performance to those with an HTL of CBP. To clarify the alignment of the energy levels of these materials, the material interfaces must further investigated by inverse photo electron spectroscopy and ultraviolet photoelectron spectroscopy. Additionally, devices were fabricated with different thicknesses of HAT-CN and an HTL of TAPC. Devices with 1 nm, 5 nm, and 15 nm of HAT-CN show very similar performance indicating insensitivity to the HAT-CN thickness and demonstrate that as little as 1 nm of HAT-CN is sufficient

for efficient interfacial charge transfer. Devices with 0 nm showed no light emission. Optimized devices with an N,N'-Di-[(1-naphthyl)-N,N'-diphenyl]-(1,1'-biphenyl)-4,4'-diamine (?-NPD) optical outcoupling layer on the semitransparent anode have a low turn-on voltage of 3.0 V and a current efficacy of 118.9 cd/A at a luminance of 115.8 cd/m2. This current efficacy stays above 100 cd/A for luminance values up to 6,000 cd/m2.

Doping-concentration-dependent hole mobility in p-doped amorphous organic semiconductors

Seung-Jun Yoo, Jeong-Hwan Lee, Seoul National Univ. (Korea, Republic of); Jae-Hyun Lee, Hanbat National Univ. (Korea, Republic of); Jang-Joo Kim, Seoul National Univ. (Korea, Republic of)

Despite decades of research on electrical doping and its utilization in organic electronics, our fundamental understanding of the doping effect in organic semiconductors is still far from complete, compared to the case of inorganic semiconductors. One example is the effect of doping on charge-carrier mobility, where different systems display different behaviors. The hole mobility was increased with increasing doping concentration in F4-TCNQ doped m-MTDATA, MoO3-doped NPB, F4-TCNQ-doped MEH-PPV, and F4-TCNQ-doped ZnPc. Hole mobilities were measured using field-effect transistors (FETs) or space-charge-limited current (SCLC). On the other hand, other studies report that the hole mobility is reduced by increasing the doping concentration in F4-TCNQ-doped P3HT, and F4-TCNQ-doped ?-NPD. We believe one of the main reasons for these different behaviors is related to the dependence of the carrier mobility on the carrier density in the amorphous organic semiconductors. When the mobility is measured using FETs and SCLC measurements where the injected carrier density is greater than the free-carrier density generated by doping, the total carrier density in the organic semiconductors is dominated by the carriers injected via the electrodes.

In this presentation, we report the effect of electrical doping on the hole carrier mobility in a p?doped organic semiconductor in the ohmic current region where the density of carriers generated by doping is much higher than that of injected carriers to exclude the effect of the injected charge-carrier density and the electric field. The hole mobility decreases as the doping concentration increases, indicating that the negatively charged dopants form Coulomb traps that disturb hole transport in the p?doped organic system. The activation energy of the mobility increases as the doping concentration increases, consistent with a broadening of the Gaussian density-of-states distribution.

High-throughput quantum chemistry and virtual screening for OLED material components

Mathew D. Halls, David J. Giesen, Thomas F. Hughes, Schrödinger, LLC (United States); Alexander Goldberg, Yixiang Cao, Schrödinger, LLC. (United States)

Computational structure enumeration, analysis using an automated simulation workflow and filtering of large chemical structure libraries to identify lead systems has become a central paradigm in drug discovery research. Transferring this paradigm to challenges in materials science is now possible due to advances in the speed of computational resources and the efficiency and stability of chemical simulation packages. State-of-the-art software tools that have been developed for drug discovery can be applied to efficiently explore the chemical design space to identify solutions for problems such as organic light-emitting diode (OLED) material components. In this presentation, virtual screening for OLED ETL and HTL layer materials based on intrinsic quantum mechanical properties is illustrated. Also, a new approach to more reliably identify candidate systems is introduced that is based on the chemical reaction energetics of decomposition pathways for OLED materials.

Low roll-off and high efficiency orange OLEDs using green and red dopants in an exciplex forming co-host

Sunghun Lee, Kwon-Hyeon Kim, Seung-Jun Yoo, Young-Seo Park, Jang-Joo Kim, Seoul National Univ. (Korea, Republic of)

Orange emitting organic light emitting diodes (OLEDs) are important in order to achieve highly efficient hybrid tandem white OLEDs, in which a blue fluorescent (FL) and an orange phosphorescent emitting system are connected by using a charge generation unit. These hybrid tandem white OLEDs take advantage of a stable blue fluorescent unit with a long device lifetime and a high efficiency orange phosphorescent unit, and are the most widely used structure for displays and solid state lighting.

There are two possible ways to construct an orange phosphorescent OLED. One way is to utilize a single orange emitting phosphorescent material. The other way is to utilize both green and red emitting phosphorescent materials. The first method has the advantages of easy fabrication and color stability with increasing luminance over the second method. However, it is difficult to synthesize an orange emitting phosphorescent dye covering both the green and red regions of the spectrum, resulting in a low color rendering index (CRI) and a low color gamut (CG) when combined with a blue emission in white OLEDs.

The combination of green and red emissions leads to an orange emission with a broad spectrum. Moreover emitting color can be tuned from green to red by adjusting their doping ratio. This quasi orange emitter results in white OLEDs with high CRI values compared to white OLEDs with just one type of orange emitting molecule when combined with a blue emitting layer.

Large numbers of tandem white OLEDs incorporating orange OLEDs have been reported using green and red phosphorescent dyes. Unfortunately, however, there are only a limited number of papers on the orange OLEDs themselves and their EQE values were less than 17.6% to our best knowledge.

In this presentation, we demonstrate high efficiency orange emitting OLEDs with low driving voltage and low roll-off of efficiency using an exciplex forming co-host by (1) co-doping of green and red emitting phosphorescence dyes in the host and (2) red and green phosphorescent dyes doped in the host as separate red and green emitting layers. The former orange OLEDs achieved a low turn-on voltage of 2.4 V, which is equivalent to the triplet energy gap of the phosphorescent-green emitting dopant, and a high external quantum efficiency (EQE) of 25.0%. Moreover, the OLEDs showed low roll-off of efficiency with an EQE of over 21% at 10,000 cdm-2. The device displayed a very good orange color (CIE of (0.501, 0.478) at 1,000 cdm-2) with very little color shift with increasing luminance. The transient electroluminescence of the OLEDs indicated that both energy transfer and direct charge trapping took place in the devices. The latter OLED shows the maximum external quantum efficiency (EQE) of 22.8%, low efficiency roll-off with the EQE of 19.6% at 10,000 cd/m2, and good orange color with the CIE coordinate of (0.442, 0.529) and no color change from 1,000 to 10,000 cd/m2. The exciplex forming co-host system distributes the recombination zone all over the EMLs and reduces the triplet exciton quenching processes.

ITO-free top emitting high efficiency organic light emitting diodes

Soniya D. Yambem, Mujeeb Ullah, Kristen Tandy, Paul L. Burn, Ebinazar B. Namdas, The Univ. of Queensland (Australia)

The field of organic electronics and specifically organic light emitting diodes (OLEDs) have significantly advanced in the last decade driven by the promise of light weight, flexible, extremely thin, high colour contrast, and high efficiency displays and lighting. However, increasing the out-coupling efficiency of emitted light is still a challenge. Conventionally, OLEDs have a bottom emitting structure with Indium Tin oxide (ITO) as the transparent anode, and in such a structure ~ 80 % of the generated light is lost in waveguided modes, and hence only ~ 20 % is out-coupled. Therefore, increasing the out-coupling of emitted light is an important goal for OLEDs. Here we present an ITO-free high efficiency fluorescent emitter-based OLED using a top emitting structure. A multilayer electrode comprising of MoOx(5nm)/Ag (10 nm)/MoOx (40 nm) MAMs) was used as an anode while fluorescent polymer Super Yellow (SY) was used as the emissive layer. The device has a structure: substrate/Al/Cs2CO3/SY/MAMs. For comparison, bottom emitting 'standard' ITO devices with structure: substrate/ITO/PEDOT:PSS/SY/Ba/Al were also fabricated. Current efficiency and external quantum efficiency of top emitting MAMs devices were found to be double that of the standard ITO devices, reaching a maximum of 21.2 cd/A and 6.69 %, respectively. These efficiencies are better than those reported MAMs-based OLEDs with phosphorescent materials in which the MAMs were used on the cathodic side of the device. The enhancement in efficiency is directly attributable to the increased out-coupling of light in the top-emitting configuration where light loss in substrate mode is suppressed. Out-coupling efficiency of the top emitting MAMs devices was estimated to be ~ 40%.
