Transparent conducting electrodes (TCEs) are of technological importance because of their application in optoelectronic and photonic devices. These devices require high transmittance and low resistance. ITO is most frequently used as a TCE in optoelectronic applications because of low resistivity and high transmittance. However, due to the limited supply of indium, dielectric/metal/dielectric (D/M/D) multilayers have been extensively studied to replace ITO. Thin Ag is commonly used as the middle layer for D/M/D multilayers because of its low resistance and high transmittance. In this work, we investigated the effect of ZnO layer thickness on the optical and electrical properties of ZnO/Ag/ZnO multilayer films deposited on glass substrates. It was shown that the transmission window became wider and shifted toward lower energies with increasing ZnO thickness. The ZnO/Ag/ZnO (40 nm/18.8 nm/40 nm) multilayer sample showed a transmittance of ~96% at 550 nm. As the ZnO thickness increased from 8 to 80 nm the carrier concentration gradually decreased from 1.74 x 1022 to 4.33 x 1021 cm–3, while the charge mobility varied from 23.8 to 24.8 cm2/Vs. With increasing ZnO thickness, the samples exhibited similar sheet resistances of 3.6 – 3.9 ohm/sq, but the resistivity increased by a factor of 4.58. The samples showed smooth surfaces with a root mean square roughness in the range of 0.47 – 0.94 nm. Haacke's figure of merit (FOM) was calculated for all the samples; the ZnO (40 nm)/Ag (18.8 nm)/ZnO (40 nm) multilayer produced the highest FOM of 148.9 x 10–3 ohm–1.

Singlet harvesting technology for OLED applications

Daniel M. Zink, Charlotte Fléchon, Thomas Baumann, cynora GmbH (Germany)

Luminescent materials for optoelectronic applications based on the Singlet Harvesting technology are more and more becoming a serious competitor for current state-of-the-art Iridium-based emitter systems. These new materials evoke high industrial interest because of their straightforward chemical accessibility, their high efficiency and versatility. In addition, Singlet Harvesting materials can be color-tuned from red to deep-blue, modified for solution-processing as well as evaporation and are therefore suitable for a wide range of OLED application and production processes.

Singlet Harvesting is based on thermally-activated delayed fluorescence and means that both triplet and singlet excitons can be used, which leads to internal efficiencies up to 100%. Different classes of materials can be used: copper complexes as well as pure organic materials are currently in the focus of science and industry. The use of such emitter systems results in device efficiencies comparable with the state-of-the-art iridium-based OLEDs, by achieving external quantum efficiencies well above 20%.

Due to smart molecular engineering, several new and highly potent emitter systems for displays, lighting and smart packaging applications have been developed by CYNORA and are presented in this paper. The high versatility of these molecules leads to very efficient OLED devices and demonstrates how Singlet Harvesting materials are competitive in today's market.

Synthesis and characterization of red phosphorescent iridium(III) complexes based on electron-acceptor modulation of main ligand for high efficiency organic light-emitting diodes

Sang Yong Park, Hongik Univ. (Korea, Republic of)

A new series of red phosphorescent iridium(?) complexes, (PT-TFP)2Ir(tmd), (PT-P)2Ir(tmd), and (PT-MP)2Ir(tmd) were synthesized for highly efficient red emitter of the organic light-emitting diodes (OLEDs). The main ligands consisted of electron-donor (phenanthren) and electron-acceptor (trifluoromethyl pyridine, pyridine, and methyl pyridine) were synthesized by Suzuki coupling reaction. The iridium(?) complexes based on main ligands and 2,2,6,6-tetramethyl-3,5-heptanedione(tmd) ancillary ligand were synthesized by Nonoyama reaction. Their luminescence properties were investigated by UV-visible spectroscopy and photoluminescence (PL) spectroscopy. The OLEDs devices were manufactured by vacuum deposition and their configuration was indium tin oxide (ITO)/PEDOT:PSS (40 nm)/HTL (17 nm)/RH-35:red dopant (5%, 10%, 40 nm)/HCL (5 nm)/ SNABH 205: 6s-12 (5%, 15 nm)/TPBi (20 nm)/LiF (1 nm)/Al(100 nm). These OLEDs devices were characterized by investigation of current density-voltage-luminance (J-V-L), current efficiency, power efficiency, external quantum efficiency (EQE), EL spectrum. The Iridium(?) complexes will be used as a solution process dopant for the hybrid OLED devices.

Development of the efficient deep-blue organic emitters exhibiting thermally activated delayed fluorescence: Design, experimental, and theoretical studies

Nadzeya A. Kukhta, Juozas V. Grazulevicius, Kaunas Univ. of Technology (Lithuania)

The development of the highly efficient and stable deep-blue phosphorescent materials has proved to be a big challenge in the last decades [1]. An efficient triplet harvesting method that uses thermally activated up-conversion of triplet into singlet states, giving thermally activated delayed fluorescence (TADF), has been reported [2]. In order to design a promising deep-blue TADF emitter a thermally accessible gap between the lowest singlet and triplet excited states [3], high and stable triplet charge transfer state and spatially separated HOMO and LUMO orbitals are required.

In current work we present design and synthesis of new bipolar carbazole derivatives with 1,3,5-triphenylbenzene backbone. The influence of the substituent orientation on the photophysical characteristics of the compounds was investigated. The enhancement of the photoluminescence quantum yield (from 0.80 to 0.99 in oxygen-free conditions) was observed. DFT calculations revealed small energy difference ?EST (0.04-0.27 eV) and spatially separated HOMO and LUMO orbitals with a slight overlap.

Dependent of light outcoupling in organic light-emitting devices on ITO thickness and roughness

Yingjie Zhang, Hany Aziz, Univ. of Waterloo (Canada)

The efficiency of organic light-emitting devices (OLEDs) is shown to significantly depend on both the thickness and roughness of the indium tin oxide (ITO) anode. The effects of changing the ITO thickness from 45 nm to 130 nm are found to be able to vary the current efficiency by 40%. The underlying mechanism is studied and revealed to be related to microcavity effects. The transmittance of the ITO substrate changes significantly with the ITO thickness, resulting in variations in microcavity, and thus light outcoupling efficiency. On the other hand, the effects of increasing the ITO roughness (rms) from 3.3 nm to 8.5 nm are found to increase light scattering at the ITO/organic interface, thus improving extraction of light trapped in the organic/ITO wave-guided mode. In addition to the enhancement in current efficiency, the device fabricated on rough ITO shows similar driving voltage to that made on smooth ITO, indicating that change balance is not altered by ITO roughness. Contrary to common belief in the community, the lifetime of the OLED is not affected when using rough ITO. Finally, by optimizing the ITO thickness and roughness, an OLED that exhibits very high current efficiency at a remarkably high brightness, demonstrating 56 cd/A at 105 cd/m2 without any external light outcoupling techniques, is obtained. The results demonstrate the significant efficiency benefits of using ITO with optimal thicknesses and higher roughness in OLEDs.

High performance inverted top-emitting organic light-emitting diodes with enhanced intrinsic quantum yield

Yu-Kun Wu, Runda Guo, Hongbo Wang, Zhensong Zhang, Yi Zhao, Jilin Univ. (China)

Top-emitting organic light-emitting diodes (TEOLEDs) have attracted considerable interest in recent years, owning to their intrinsic merit that they are more suitable for high resolution active matrix full color displays. It is advantageous to invert the TEOLEDs for integrating with the n-channel amorphous silicon thin film transistors (a-Si TFTs) which cannot produce adequate p-channel TFTs.

In this work, inverted top-emitting organic light-emitting diodes (ITOLEDs) with aluminum as cathode and semitransparent silver as anode are investigated. Iridium complex of bis(4,6-(difluorophenyl)pyridinato-N,C2)picolinate iridium(III) (FIrpic), fac-tris(2-phenylpyridine)iridium(III) (Ir(ppy)3), bis(2-methyldibenzo[f,h]quinoxaline)(acetylacetonate) iridium(III) (Ir(MDQ)2acac) are used as blue, green and red phosphor emitters, respectively. The basic ITOLED structure is: Si/SiO2/Al/electron injection layer (EIL)/electron transport layer (ETL)/ /emission layer (EML)/ electron blocking layer (EBL)/hole transport layer (HTL)/hole injection layer (HIL) /Ag (20 nm), and the control bottom-emitting organic light-emitting diodes (BEOLEDs) with the basic structure of glass substrate/indium tin oxide (ITO)/HIL/HTL/EBL/EML/ETL/EIL/Al (100 nm).

We pleasantly find that the red ITOLED exhibits a higher external quantum efficiencies (EQEs) nearly twice as that of the bottom-emitting counterpart, 18.1% vs. 8.7% at ~2mA/cm2, while EQEs of green ITOLEDs and BEOLEDs at ~1.5mA/cm2 are 15.2% vs. 13.5% and that of blue devices at ~1mA/cm2 are 12.9% vs. 11.3% respectively. We explain that the role of the strong microcavity effect improved the spontaneous emission of emitters in all ITOLEDs, what's more, only the intrinsic quantum yield (IQY) of the red emitters is improved due to its comparable radiative and nonradiative decay rates.

An electro-optical characteristics test equipment for OLED lighting panels with homogeneity and non-uniformity test function

Hector H. Y. Lin, Gilbert C. W. Chen, Jamie J. M. Liu, Paul B. Y. Wu, MPI Corp. (Taiwan); Chih-Ming Lai, Wen-Yung Yeh, Chi-Yi Leu, Chao-Feng Sung, Mei-Ju Lee, Industrial Technology Research Institute (Taiwan)

To meet the testing requirement of OLED lighting panels listed on the datasheet, a test equipment capable of searching panel driving current under constant luminance (for example 1000cd/m2) has been developed. The OLED test equipment has two station. Non-uniformity, homogeneity, output luminance and operation current of OLED lighting panel is tested by first station using an imaging photometer. Luminous flux, power efficiency and chromaticity parameters is then tested by the second station in integrating sphere by spectrometer with driving current obtained from constant luminance measurement.

A comparison of homogeneity and non-uniformity from test results of 8cm?8cm light emitting area hybrid tandem white OLED lighting panels is investigated. OLED lighting panels fabricated by ITRI OLED lighting baseline has power efficiency 40 lm/W, CCT about 4,000 K, CRI>85. Panel homogeneity H(?) is calculated based on finding the largest luminance gradient with ?=0.5 suggested by CIE TC-2 68 committe. For most of OLED lighting manufactures, the luminance non-uniformity within 15% is suggested. However, there is no data about their panel homogeneity. Our test result shows that H(?=0.5) is about 0.65~0.70 when luminance non-uniformity is 15%. Interestingly, these panels can just be classified as homogeneous. In general, human eyes cannot detect luminance variation when non-uniformity smaller than 5%, and the related H(?=0.5) is about 0.88. Moreover, non-uniformity of OLED lighting panels should at least lower than 8% to be classified as very homogeneous H(?=0.5) > 0.8. OLED lighting panels will be classified as inhomogeneous H(?=0.5) < 0.6 when non-uniformity higher than 18%.

OLED microdisplay in 0.35 um complementary metal-oxide semiconductor technologies for wearable electronic display applications

Chih Hsiang Chang, Po-Tsun Liu, National Chiao Tung Univ. (Taiwan)

The demand of head-mounted and wearable display is predicted in the next decades covering application areas such as sport, security and entertainment. Microdisplay technologies for near–to-eye applications mostly use a complementary metal-oxide semiconductor (CMOS) processing chip as backplane for pixel addressing, with extensive post-processing on top of the CMOS chip to deposit organic LED or liquid crystal display. In this paper TEOLED (Top-emitting Organic Light-Emitting Diode) for the microdisplay based on the CMOS integrated circuit substrate will be adopted. The microdisplays are implemented in a standard 0.35 um CMOS processing. The presented microdisplays offer a cost effective alternative to conventional LC and OLED based displays.

Precise color-tuning using solution processed LECs in a hybrid device architecture

Serpil Tekoglu, Karlsruher Institut für Technologie (Germany) and InnovationLab GmbH (Germany); Martin Petzoldt, Ruprecht-Karls-Univ. Heidelberg (Germany) and InnovationLab GmbH (Germany); Sebastian Stolz, Karlsruher Institut für Technologie (Germany) and InnovationLab GmbH (Germany); Uli Lemmer, Karlsruher Institut für Technologie (Germany); Manuel Hamburger, Ruprecht-Karls-Univ. Heidelberg (Germany) and InnovationLab GmbH (Germany); Gerardo Hernandez-Sosa, Karlsruher Institut für Technologie (Germany) and InnovationLab GmbH (Germany)

Organic light-emitting devices are promising elements for display and artificial lighting technologies. In the fabrication of full color displays, one of the challenges is complex device fabrication to get full-color emission containing red, green, blue emissions in small areas. Furthermore, three color displays can be used to get white light emission via complicated methods. In this perspective, color-tuning have always drawn significant attention of the researchers in the field either to achieve white light, multi- or full-color devices. A simple light-emitting device which can emit a wide range of colors is always desirable to simplify the fabrication techniques.

In our work, color-tunable organic light emitting devices (OLEDs) were fabricated using a hybrid device architecture combining polymer organic light emitting diode (PLED) and light emitting electrochemical cells (LEC) characteristics in one structure. A novel water-soluble quaternized polyfluorene (PFO) was utilized as polyelectrolyte in a single component LEC layer on top of a conventional PLED stack. Depending on the thickness of the PFO layer, we obtained a fine tuning in the emission color of OLEDs. The luminance-current density-voltage, the lifetime and the electroluminescence characteristic of the organic light emitting devices were defined. The solution processed bilayer hybrid device showed a maximum luminance of ~ 500 cd/m2 with CIE chromaticity coordinates x=0.29, y=0.43. We highlight this new method as a strategy for white or multi-color organic light emitting devices.

Computer simulation of OLED devices: From chemical structures to drift-diffusion equations

Pascal Kordt, Max-Planck-Institut für Polymerforschung (Germany); Sven Stodtmann, Mustapha Al Helwi, Alexander Badinski, BASF SE (Germany); Denis Andrienko, Max-Planck-Institut für Polymerforschung (Germany)

Drift-diffusion equations coupled to the Gaussian disorder lattice models [1] have been successfully used to study OLED devices, e.g. space-charge formation, charge density-mobility relations, and current-voltage characteristics [2]. In order to provide parameter-free description of amorphous organic semiconductors, here we couple drift-diffusion equations to a multiscale approach which combines density functional theory, molecular dynamics, stochastic modeling, and kinetic Monte Carlo simulations [3]. We thus establish a link between underlying chemical structures and current-voltage characteristics of OLED devices. Our approach is verified against experimentally measured current-voltage characteristics of an amorphous layer of DPBIC, a hole-conductor used in blue phosphorescent OLEDs.

To enhancement illuminance efficiency of OLED by thin film included microparticle

Chuang-Hung Chiu, Chunghwa Picture Tubes, Ltd. (Taiwan); Chao-Heng Chien, Jen-Chi Lee, Wei-Cheng Chien, Tatung Univ. (Taiwan)

The main purpose of this study is to enhance OLED illuminance. The PDMS is used to be as the enhanced illuminance film material and has a refractive index of 1.48 to be similar as the OLED glass substrate of 1.5. Two metal oxidation microparticles are doped into PDMS film, the refractive index are 1.7 and 2.4 for each other. All of particles size are 2?m and concentration of 2%.

The illuminometer (DX-200) is applied to measure the illuminance of the OLED light. The OLED is located at the center of sphere which has the radius of 30cm, and the illuminance is measured on the different location around the surface of the sphere.

The peak value of illuminance either in the X-axis or Y-axis is the light emitting angle at 90 degrees.

The original OLED forward illuminance is 4.2 lux. The enhanced illuminance film attached to the OLED, the illuminanc is 6.2 lux. OLED half-power angle is 65 degree. The enhanced illuminance film attached to the OLED, the Lambertian emission patterns is 55 degree. In this study, the optical film attached to the OLED, the Lambertian emission patterns of 10 degrees will reduce, but it can enhance the illuminance of more than 45%. Therefore to be understood that the film has a concentrator effect.

Summary:

An enhanced optical film to increase the illuminance of OLED was successful to be presented. The PDMS was chosen as the substrate material for the optical film, and including the two kinds of the micro particles. The optical film is applied on the LOED light lamp to enhance the illuminance up to 45%.

Photophysical studies of the thermally-activated delayed fluorescence of a highly luminescent mononuclear copper(I) compound

Larissa Bergmann, cynora GmbH (Germany); Gordon J. Hedley, Univ. of St. Andrews (United Kingdom); Thomas Baumann, cynora GmbH (Germany); Ifor D. W. Samuel, Univ. of St. Andrews (United Kingdom)

Efficient emitting materials for organic light-emitting diodes are a continued focus of academic and industrial research. A broad variety of luminescent copper(I) complexes for OLED applications was developed in recent years, as high material and processing costs of nowadays used iridium and platinum materials led to the search for easier accessible and solution-printable OLED materials. Although copper(I) exhibits only a small spin-

orbit coupling constant when compared to iridium(III), its complexes can harvest both triplet and singlet excitons for the emission of light and achieve internal quantum efficiencies of 100% by utilizing the smaller spin-orbit coupling for thermally activated delayed fluorescence (TADF). Furthermore, the concept of TADF enables short emission decay times for emitting materials with small spin-orbit coupling.

In contrast to photophysical studies on organic TADF compounds, which gain increasing interest in the last few years, there are only few publications about the electronic processes occurring after excitation in luminescent copper(I) compounds which are characterized by thermally-activated delayed fluorescence behavior. We studied the thermally-activated delayed fluorescence behavior of a mononuclear neutral copper(I) complex by time-resolved spectroscopy. The intersystem crossing (ISC) rate from excited singlet to triplet states was determined in the solid state for the first time, and thus, better understanding of the excited state processes and mechanisms that ensure TADF has been explored.

Study on cadmium sulphide nanoparticles on blue and green light emitting polymers

Pradeep Chandran, Cochin Univ. of Science and Technology (India); Mathew Sebastian, Cochin Univ. of Science & Technology (India); Manoj A. G. Namboothiry, Indian Institute of Science Education and Research (India); C. P. G. Vallabhan, Cochin Univ. of Science & Technology (India); P. Radhakrishnan, International School of Photonics (India); V. P. N. Nampoori, Cochin Univ. of Science & Technology (India)

Cadmium Sulphide nanoparticles have been the focus of recent scientific research due to their electroluminescent and conductive properties. As a transition metal chalcogenide (II-VI) semiconductor, this material has been largely investigated in optical filters, photo detectors, solar cells, light emitting devices, thin film field effect transistors, photocatalysis etc. The material properties essentially depend on the optical bandgap, morphological and structural features, and hence require extensive and elaborative research to understand the underlying mechanism in light emitting devices. With the difficulty of making thin films from nanoparticles, these material could easily be embedded in polymers to make hybrid (organic-inorganic) light emitting diodes. Such diodes combine the advantageous of processing flexibility of polymers and the semiconducting properties of the nanoparticles.

In this paper we investigate the electroluminescence emission performance from light emitting polymers doped in cadmium sulphide nanoparticles. The nanoparticles were synthesized by precipitation technique and obtained nanoparticles of size 10 nm. The blue emitting PFO [Poly(9,9-di-n-octylfluorenyl-2,7-diyl)] and green emitting F8BT [Poly(9,9-dioctylfluorene-alt-benzothiadiazole)] were doped with CdS nanoparticles and used as active emissive layer in polymer light emitting diodes. We see a decrease in the turn on voltage in both polymers and increase in the brightness in green emitting polymer. We present and discuss the possible mechanism for the improved performance due to the incorporation of CdS nanoparticles in light emitting polymers.

Measurement of charge balance and its effect on electrophosphorecent organic light emitting device lifetime

Caleb Coburn, Stephen R. Forrest, Univ. of Michigan (United States)

The long term operational lifetime of phosphorescent organic light-emitting diodes (PHOLED), particularly in the blue spectral region, remains a barrier to their widespread adoption in displays and solid state lighting. PHOLED degradation can be attributed to multiple pathways, including the loss of charge balance, molecular degradation due to high energy bi-molecular recombination reactions, and delamination. We present studies on the contribution of charge balance to degradation of high efficiency PHOLEDs. For this, we introduce a technique that allows for a quantitative measurement of charge imbalance over time. We use this technique to probe charge and exciton leakage from the emissive layer of blue emitting PHOLEDs as a function of current density. The measured charge balance together with luminance loss, voltage rise, and time-resolved external quantum efficiency characteristics are used to model mechanisms leading to the degradation of PHOLEDs. For example, we calculate the relative importance of each degradation mode, namely charge balance, non-radiative recombination, and quenching on deep trap sites formed by molecular degradation in the emissive layer. Finally, the efficacy of electron/exciton blocking layers over the device lifetime is examined.

A systematic comparison of the effect of joule heating vs thermal annealing on the morphology of typical hole transport layers in organic light emitting devices

Tyler Davidson-Hall, Hany Aziz, Univ. of Waterloo (Canada)

It is well-known that hole transport layers (HTLs) in organic light emitting devices (OLEDs) are more sensitive to morphological changes than other organic layers due to lower glass transition temperatures. A high operational temperature can alter the HTL morphology, severely impacting OLED performance and stability. Although joule heating is a known factor affecting OLED stability during operation, its effect in experimental studies is typically simulated through thermal annealing of the devices rather than applying current. In this work, a systematic comparison of the effects of joule heating vs thermal annealing on the morphological stability of a N,N'-di(1-naphthyl)-N,N'-diphenylbenzidine (NPB) HTL and the impact this has on OLED performance is investigated. While thermal annealing of an OLED is a good first-order approximation of joule heating, the temperature distribution profile of the OLED is different under the two stress conditions and thus can impact the morphology of the HTL differently. However, joule heating introduces a confounding factor whereby the OLEDs experience intrinsic degradation by the flow of current, aside from thermal stress. Our recent investigations show that electrical stress can bring about morphological changes induced by polaron-exciton interations independent of those induced by thermal effects. Therefore, in this work, polaron-exciton interactions are decoupled from the findings by studying joule heating in unipolar devices that comprise solely of a NPB organic layer. Device IVL, lifetime and morphology as a function of temperature for both joule heating and thermal annealing are presented as a means to evaluate stability and performance.

Vacuum nano-hole array embedded organic light emitting diodes with high efficiency

Sohee Jeon, Korea Institute of Machinery & Materials (Korea, Republic of)

OLEDs intrinsically provide higher energy efficiency than other light sources, and this efficiency has been increased significantly through the use of phosphorescent emitters and charge transport materials. As the OLED had an ultrahigh external quantum efficiency (EQE) of 29.1%, the internal quantum efficiency had almost reached the theoretical limit. However, 70% of the internal light was still wasted by the substrate, the organic layers, and the transparent electrode even in the case of the highest EQE of 29.1% which equates with an internal efficiency of 100%.

Here, high-efficiency organic light emitting diodes (OLEDs) with an EQE of greater than 50% and low roll-off were produced by inserting a vacuum

nanohole array (VNHA) into phosphorescent OLEDs (PhOLEDs). The VNHA substrate was fabricated using a novel process called robust reverse-transfer (R2T). The R2T process was utilized to generate the nanohole array, which was then inserted to the PhOLED in a vacuum to maximize the refractive index (RI) contrast of the PhC slab for a given background material of high RI. The VNHA substrate obtained by the proposed R2T process has a smooth surface that is comparable to the surface roughness of polished silicon wafers, and thereby leads to a negligible electrical loss, which indicates that the experimental results can be compared with those from optical modeling. The resultant extraction enhancement was quantified in terms of EQE by comparing experimentally measured results with those produced from optical modeling analysis, assuming almost perfect electric characteristics of the device. The measured performance of the VNHA OLEDs was compared with optical modeling analysis results, and the VNHA was verified to extracts the entire waveguide loss into the air. The EQE obtained in this study is the highest value obtained for bottom-emitting OLEDs to date.

Correlation of carrier mobility with energetic disorder of host molecules in p-doped amorphous organic semiconductors

Seung-Jun Yoo, Seoul National Univ. (Korea, Republic of); Jeong-Hwan Lee, Seoul National Univ. (Korea, Republic of) and IMEC (Belgium); Jae-Min Kim, Jang-Joo Kim, Seoul National Univ. (Korea, Republic of)

Electrical doping in organic semiconductors (OSs) has been actively investigated to enhance the conductivity of bulk organic films. Despite of wide use of dopants in OSs, the charge generation efficiency (CGE) is obviously smaller than 100%. The low CGE is dominated by the dissociation process, since the transferred carriers mostly bound to the mutual ionized dopant by a strong Coulombic binding energy due to the low dielectric permittivity of about 3 in OSs. Therefore, the Coulomb trap induced by the ionized dopant will give a significant effect on the charge transport in OSs. In order to understand the effect of Coulomb trap on the charge transport in doped OSs, it is necessary to systematically analyze the correlation of carrier mobility with energetic disorder of hosts.

In this work, the effect of Coulomb traps on hole mobility was investigated using various p?doped OSs possessing different CGE and energetic disorder of hosts. The hole mobility was analyzed in the Ohmic current region to minimize the effect of the injected carrier density on the carrier mobility. Even though the hole mobility of pristine OSs has a big difference by a few orders of magnitude, that of p?doped OSs is almost same, indicating that the majority of doping-induced holes are localized in Coulomb traps caused by negatively ionized p?dopants. However, the doping-concentration-dependent hole mobility has a specific tendency, depending on the magnitude of the energetic disorder of the hosts. These phenomena are interpreted by calculating the effective density-of-states distribution of p?doped OSs and by measuring the activation energy of conductivity.

9566-74, Session PMon

Controlling orientation of emitting dipoles of iridium complexes for highly efficient phosphorescent organic light-emitting diodes

Kwon-Hyeon Kim, Seoul National Univ. (Korea, Republic of); Jae-yeol Ma, Gyeongsang National Univ. (Korea, Republic of); Chang-Ki Moon, Seoul National Univ. (Korea, Republic of); Yun-Hi Kim, Gyeongsang National Univ. (Korea, Republic of); Jang-Joo Kim, Seoul National Univ. (Korea, Republic of)

It has been recently discovered that orientation of phosphorescent emission dipoles is a crucial factor influencing the efficiency of phosphorescent organic light-emitting diodes (PhOLEDs) because higher efficiency than 30% can be obtained from OLEDs if emission dipoles are oriented along horizontal direction (parallel to the substrates). We recently reported that the preferred emitting dipole orientation of iridium complexes originates from preferred direction of the triplet transition dipole moment of the molecules along a specific direction and strong supramolecular arrangement between iridium complexes and host molecules in an EML. And, we demonstrated high efficiency OLEDs with external quantum efficiency of 32% for green ad 36% using red using iridium based phosphorescent dyes with preferred horizontal orientation of emission dipoles. However, the relationship between structure of phosphorescent dyes and orientation of emission dipoles, and the factors influencing the orientation of emission dipoles of phosphorescent iridium complexes in doped films are little studied yet to our best knowledge. Besides, it has yet to be identified how to increase the ratio of horizontal dipoles of phosphorescent dyes and resultantly the EQE of OLEDs. Here, we report that the orientation of emission dipoles of heteroleptic iridium complexes doped in an emission layer is linearly proportional to the angle of the transition dipole moments against the C2 axis of the dyes using a newly synthesized series of materials. We also demonstrated unprecedented high efficiency of green OLEDs using a new emitter.

9566-75, Session PMon

Introducing a thermally activated delayed fluorescence emitter for a highly efficient blue fluorescent organic light emitting diode

Jin-Won Sun, Kwon-Hyun Kim, Seoul National Univ. (Korea, Republic of); Yun-Hi Kim, Gyeongsang National Univ. (Korea, Republic of); Jang-Joo Kim, Seoul National Univ. (Korea, Republic of)

Enhancing electroluminescence (EL) efficiency might be a never ending pursuit from displays to lightings where organic light emitting diodes (OLEDs) are being used as sources. For past years, phosphorescent OLEDs (PhOLEDs) based on heavy metal complexes have been considered as an only solution to realize high efficiencies by harvesting both singlet and triplet excitons as light. However, recent progress utilizing delayed fluorescence challenges the conventional idea of achieving high EL efficiencies. Fluorescent material showing thermally activated delayed fluorescence (TADF) phenomenon enables additional harvest of triplet excitons as well as singlet excitons via reverse intersystem crossing (RISC) from triplet (T1) to singlet (S1) state due to thermal activation and small energy gap between the two excited states.

In order to enhance EL efficiency for blue fluorescent OLEDs, a blue TADF emitter has been newly synthesized for this work. Spatial spearation of the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) of the emitter led to small exchange energy that enhances RISC.

The balanced device structure implementing a mixed co-host system and the blue TADF emitter exhibited unprecedented external quantum efficiency (EQE) for blue fluorescent OLEDs.

9566-76, Session PMon

Efficiency loss in solution processed organic light emitting diodes

Szuheng Ho, Ying Chen, Franky So, Univ. of Florida (United States)

Efficiency loss in solution processed organic light emitting diodes (OLEDs) compared to vacuum deposited counterpart is studied in a highly efficient phosphorescent OLED system. The molecular packing is examined with ellipsometry measurements. The refractive index is extracted from the data.

It reveals that compared to thermally evaporated film, solution processed counterpart is less dense. Besides, the packing of solution processed film can be closer to that in the evaporated one if higher solute concentration and higher spin speed are used in spin-casting process. The influence of molecular packing on carrier transport was also verified by the current density-voltage characteristics of single carrier devices. A relative vacuum level shift and expansion of band tail states in solution processed devices were observed. This might lead to worse charge confinement and impair device performance. The substitution of electron transport layer (ETL) with deeper highest occupied molecular orbital (HOMO) level can ameliorate this situation. A solution processed OLED with extremely high efficiency (external quantum efficiency of 28.9%) is achieved by employing ETL with deep HOMO level, which significantly suppresses the efficiency loss due to transport variation and interfacial energy level shift.

9566-77, Session PMon

Organic light emitting diodes with enhanced out-coupling efficiency and operational stability due to spontaneously formed corrugated structure within active layers

Cheng Peng, Xiangyu Fu, Shuyi Liu, Ying Chen, Franky So, Univ. of Florida (United States)

Spontaneously formed corrugated structure is realized in an all-organic system. The morphology of the corrugated structure is characterized with atomic force microscopy (AFM) technique. The results show that the corrugation can be well controlled by material choice, layer thickness and treatment conditions. Furthermore, this corrugated structure can be realized directly inside organic light emitting devices (OLEDs) with similar treatments and it can serve both as the functional layers of the OLED and the out-coupling enhancing layer. We applied this technique to OLED active layers and fabricated corrugated devices. Compared with the control device, which is a planar OLED with the same composition and thickness of each layer, the corrugated OLED shows a more than 35% enhancement in current efficiency. In addition, the corrugated OLED also has a greatly improved operational stability. The lifetime LT90 at 1000cd/m2 is improved as much as 40 times in the corrugated OLED. The enhancement in efficiency is the result of improved out-coupling of electroluminescence (EL), since the corrugated structure leads to reduced EL loss in surface plasma mode. The simplicity of the treatments and the significant enhancements in both device efficiency and operational lifetime demonstrate the potential of this technique in pursuing low-cost and high-performance OLEDs.

Passivation of metal oxides surfaces for high performance organic and hybrid optoelectronic devices

Franky So, Shuyi Liu, Szuheng Ho, Ying Chen, Univ. of Florida (United States)

The exciton quenching properties of solution-processed nickel oxide (NiOx) and vanadium oxide (VOx) are studied by measuring the photoluminescence (PL) of a thin emitting layer (EML) deposited on top of the metal oxides. Strong exciton quenching is evidenced at the metal oxide/EML interface, which is proved to be detrimental to the performance of optoelectronic devices. With a thin polymer passivation polymer adsorbed on top of metal oxides, the PL quenching is found to be effectively suppressed. A short UV-O3 treatment on top of the polymer passivated metal oxides turns out to be a key procedure to trigger the chemical binding between the passivation polymer and the metal oxide surface species, resulting in substantially improved hole injection and extraction for organic light emitting diodes (OLEDs) and solar cell devices, respectively. With the passivation layer followed by UV-O3 treatment, the OLEDs incorporating NiOx as a hole transport layer (HTL) shows a record current efficiency of 91 Cd A-1 with significantly suppressed efficiency roll-off, the OLEDs incorporating VOx as a hole injection layer (HIL) also shows higher current efficiencies at higher luminescence. Both perovskite solar cells and polymer solar cells incorporating passivated NiOx HTL also shows an enhancement of 60% due to passivation.

Delayed fluorescence on triazine phenothiazine derivative

Ikbal Marghad, Ecole Polytechnique (France)

Since the report of the OLED's third generation based on the hyper-fluorescent materials thermally activated delayed fluorescence (TADF) [1], a large number of TADF materials have been synthesized such as the Phenothiazine-Triphenytriazine (PTZ-TRZ) [2]. We propose a novel TADF material which is a (PTZ-TRZ) derivative. The latter is the 2,4 bis 3-thienyl 1, 3, 5-triazine 6-phenyl phenothiazine featuring donor–acceptor parts .The donor part is the phenyl phenothiazine and the acceptor one is the 2,4 bis-3 thienyl 1, 3, 5 triazine. The distribution of the HOMO and LUMO suggests a well separation of the donor and acceptor parts which are localized on the HOMO and LUMO energetic levels respectively. The properties of this material have been studied and exhbits TADF proprieties. Moreover, the substitution of 2,4 bis-phenyl on the donor part of the (PTZ-TRZ) by the 2,4 bis 3-thienyl indicate new proprieties.

Optical effect of graphene electrodes on organic light-emitting diodes

Hyunsu Cho, Jin-Wook Shin, Nam Sung Cho, Jaehyun Moon, Jun-Han Han, Electronics and Telecommunications Research Institute (Korea, Republic of); Young-Duck Kwon, Seungmin Cho, SAMSUNG Techwin Co., Ltd. (Korea, Republic of); Jeong-Ik Jeong-Ik, Electronics and Telecommunications Research Institute (Korea, Republic of)

Graphene films have been probed as a transparent electrode because it suggests a solution to overcome the drawback of ITO electrode, mechanical brittleness making it difficult to apply in flexible or stretchable electronics. In organic light-emitting diode (OLED) applications, graphene electrode has been achieved noteworthy efficiencies not only in monochromatic but also in white colors. The physical thickness of single layer graphene is about 0.34nm. The refractive index (n) of it ranges as 2.3 ~ 3.0 and the extinction coefficient (k) is bigger than 1 in the visible range. Regarding this aspect, the optical importance of graphene film as a transparent electrode in OLEDs needs to be confirmed.

In this study, we performed both optical simulations and experiments to investigate an optical effect of graphene electrodes on efficiencies and spectral emission properties of OLEDs. Simulation results suggest that graphene electrode attenuates the oscillatory behavior in efficiency of OLEDs for different organic layer thicknesses. In experiments, the current efficiency of OLEDs with graphene anode is only varied from 39 cd/A to 46 cd/A, though that of ITO anode is varied from 36 cd/A to 54 cd/A in the same variation in organic layer thickness. In addition, emission spectra distribution of graphene anode OLEDs showed weak dependency on the organic layer thickness as well as the viewing angles.

Efficient OLEDs based on embedded silver grid electrodes for flexible lighting applications

Jaeho Lee, KAIST (Korea, Republic of); Jee-Hoon Seo, HANA Microelectronics, Inc. (Korea, Republic of); Sungyeon Kim, Jin Chung, Eunhye Kim, Sunghee Park, Eungjun Kim, Seung S. Lee, Seunghyup Yoo, KAIST (Korea, Republic of)

Organic light-emitting diodes (OLEDs) are being regarded as a next-generation lighting source due to their form-factor and cost advantages as well as their large-area compatibility. To fully utilize their potential benefits, it is critical to secure scalable and affordable transparent electrode (TE) technologies that are compatible with flexible devices and exhibit high performance (e.g. low sheet resistance and high transmittance). However, indium tin oxide (ITO), which is a TE typically used in OLEDs, is known to have a poor mechanical flexibility, being subject to bending-induced fracture and increase in Rs. Relatively high cost and high process temperature can also be limiting factors in realizing low-cost and/or flexible OLEDs.

In this study, we present large-area and/or flexible OLEDs built with a hybrid TE based on Ag grids engraved onto a plastic substrate and high-conductivity-grade PEDOT:PSS layers (Clevious PH1000 with DMSO 5 wt%) covering the grids. The proposed hybrid TEs exhibit a sheet resistance of 9.7 ohm/sq. and transmittance of 87.1% (at 550 nm), yielding the effective DC to optical conductivity ratio of 302.1, which is comparable to that of ITO. OLEDs based on these hybrid TEs show a stable, leak-free operation and external quantum efficiency as high as 22.3%. Furthermore, these devices turn out to be highly flexible, exhibiting no degradation even after 1000-time bending at a radius curvature of 7.9 mm. In addition, we demonstrate a large-area OLED (50 mm ? 25 mm) that shows uniform surface emission characteristics and compare it with a PSPICE model that analyzes the area scaling behavior of local luminance distribution in consideration of TE sheet resistance and the equivalent diode characteristics of an OLED under study.

Photophysical Properties of Thermally Activated Delayed Fluorescence from OLED Materials

DaSom Kim, Hee Won Shin, Tae Kyu Ahn, Sungkyunkwan Univ. (Korea, Republic of)

Improving the efficiency and lifetime of blue organic light-emitting diodes (OLEDs) are vital toward a success of OLEDs as a replacement for LCD technology. So, considerable researches have been explored to develop OLEDs with high external quantum efficiency. External quantum efficiency values of 20% and 19% have been reported for red (625 nm) and green (530 nm) diodes. However, blue diodes (430 nm) have only been able to achieve maximum external quantum efficiencies in the range of 4% to 6%. In order to realize the high blue electroluminescence efficiency in OLEDs, we adopt e?cient thermally activated delayed fluorescence (TADF) which have long operational lifetime with excited-state intermolecular proton-transfer (ESIPT) process. We explored the ESIPT molecules with charge-transporting functional groups, hydroxyl-substituted tetraphenylimidazole (HPI) derivatives to have longer lifetime component up to microsecond order.

In this study, we measured the time-resolved photoluminescent (PL) decay and transient photovoltage curves of HPI derivatives with a nanosecond pulsed laser (Quanta-Ray INDI Nd:YAG Laser, Spectra-Physics). Therefore, we proved non-negligible contribution of the delayed fluorescence in the total emission. Our study provides the design information of the dynamical behaviors of photocarriers to develop high-efficiency blue electroluminescence OLEDs.

Hollow-core polymeric nanoparticles for the enhancement of OLED outcoupling efficiency

Jun-Hwan Park, Pusan National Univ. (Korea, Republic of)

Since the half of light was trapped in organic/ITO layer, the most efficient way to enhance the outcoupling efficiency was to insert an optical scattering structure close proximity to the ITO layer. Various optical elements such as a diffraction grating, scattering particles and scattering grid had been incorporated in the OLED device. In this work, hollow-core nanoparticles (HCNPs) dispersed polymer layer was inserted under the ITO layer to scatter the light more efficiently. Due to the high index contrast between the hollow nanoparticle and a host polymer, HCNPs increased the optical scattering efficiency. The efficiency also depends on the size and the volume fraction of the HCNPs in the polymer solution, together with the refractive index and the thickness of the polymer layer. For investigating the effect of these parameters, finite difference time domain (FDTD) numerical method was used. It was shown that HCNPs dispersed in a polymer layer could enhance the EQE by a factor of 2.5 with the optimum size range of 200 ~ 400 nm. The HCNPs was easily obtainable from a polystyrene/silica nano-composite. In order to synthesize the HCNPs, microfluidic synthesis method was introduced due to the advantage of smaller size dispersion and in-line production based on flow-through self-assembly process. It utilizes the interfacial reaction obtained from laminar flow and self-assembly of polymers in a microchannel. 400 nm-thick PVA film containing HCNPs with a size distributed in the range of 100 ~ 800 nm was obtained in our preliminary experiment.

Highly enhanced green phosphorescent organic light-emitting diodes with cesium fluoride doped electron injection layer

Jongseok Han, Yongwon Kwon, Changhee Lee, Seoul National Univ. (Korea, Republic of)

Organic light emitting diodes (OLEDs) have attracted a lot of interest because of their potential applications in solid state lightings and displays. In order to improve device performance, one of critical issues which should be studied carefully is efficient electron injection between metal cathode and organic layer. In recent years, electrical doping has been extensively utilized in improving electron injection and transport. It decreases the operating voltage and improves power efficiency by increasing conductivity. For instance, alkali metals, including cesium and lithium, etc., as a low-work function n-type dopants in electron injection layers (EILs) can facilitate electron injection effectively and reduce ohmic losses. However, some of these derivatives have disadvantages such as their high sensitivity to oxygen or moisture and complicated evaporation process. In this work, we systematically studied doping effect of cesium fluoride (CsF) on the device performance of green phosphorescent OLEDs because CsF can be used as a stable n-type dopant due to its low chemical reactivity and simple deposition process. We confirmed that CsF could be employed as an effective n-type dopant based on experimental studies of optical absorption spectroscopy in thin films of 3,3'-[5'-[3-(3-Pyridinyl)phenyl][1,1':3',1''-terphenyl]-3,3''-diyl]bispyridine (TmPyPB) doped with CsF at various concentrations and impedance spectroscopy in an electron only device (EOD) with CsF-doped TmPyPB. Owing to high electrical property of CsF-doped TmPyPB EIL, green phosphorescent OLEDs showed significantly lower voltage and considerably enhanced efficiency. The device with 30 vol% CsF-doped TmPyPB showed power efficiency of 28.1 lm/W at 1000 cd/m2, whereas the device with undoped EIL exhibited 13.8 lm/W.

Numerical characteristics of the intensity distribution for a white organic light-emitting diode

Henglong Yang, Wei-Cheng Li, National Taipei Univ. of Technology (Taiwan)

A feasible numerical model capable of characterizing the unique intensity distribution of a planar white organic light-emitting diodes (WOLED) as a lighting source was theoretically investigated by fitting our experimental data obtained by microscopic goniometer (MG) system associated with an energy analyzer to a statistical distribution function with three adjustable parameters. The WOLED is one of the upcoming lighting sources with planar device structure without additional optical components. The intensity characteristic of a lighting source is crucial for practical purpose. The procedure of an optical design usually requires proper numerical tools to satisfy specific application by adjusting parameters. Relatively uniform intensity distribution of a planar lighting source is needed for a specific lighting application such as back-lighting (BL) for liquid-crystal displays (LCD) in which Regular white LED's (WLED) and light-guide plate are assembled as a planar module after proper optical design. However, our intensity measurement of a WOLED revealed an unique distribution pattern in which the relative intensities near central area are higher than that near the edge of the emissive area. A practical numerical model is required to characterize this unique intensity distribution pattern exclusively for optical design tool. Our preliminary result of finding a feasible numerical model to characterize the intensity distribution of a WOLED was established by fitting experimental data to the Gaussian statistical distribution function with amplitude, average, and standard deviation as adjustable parameters. This parametric model may be used as a potential optical design tool for WOLED in the future.

Improved light out-coupling efficiency of organic light emitting diodes with a simple processed light-extraction layer

Jae-Hyun Lee, Chur-Hyun Shin, Min-Hoi Kim, Yoonseuk Choi, Hanbat National Univ. (Korea, Republic of)

Organic light emitting diodes (OLEDs) are now widely commercialized in the display market due to many advantages such as possibility of making thin or flexible devices. Nevertheless there are still several things to obtain the high quality flexible OLEDs, one of the most important issues is the light extraction efficiency of the device. Since flexible OLEDs are composed of many sub-organic layers with different refractive indices and plastic substrate, it is known that flexible OLEDs have the typical light loss such as the waveguide loss, plasmon absorption loss and internal total reflection, et al.

In this presentation, we demonstrate the one-step processed light scattering films with aluminum oxide nanoparticles and polystyrene matrix composite. Light scattering films was directly fabricated by the spin-coating process on the opposite side of green phosphorescent flexible OLED devices consisting of PEN/indium zinc oxide (IZO)/molybdenum oxide (MoO3, 10 nm)/N,N'-dicarbazolyl-4,4'-biphenyl (CBP, 40 nm)/6 wt% tris-(2-phenylpyridyl) iridium(III) (Ir(ppy)3) doped CBP (15 nm)/1,3,5-tris(N-phenylbenzimidazole-2-yl)benzene (TPBi, 55 nm)/aluminum (100 nm). Especially the low annealing temperature (65?) of the light scattering film was adaptable to the plastic substrate and OLED devices.

We found that the maximized light extraction efficiency can be obtained by optimizing the size and concentration of nanoparticles. This approach shows that it can simply increase the total emission of OLEDs up to 65% with simple fabrication process. We believe this technique could be highly applicable for large size OLED application such as the lighting system.

Delayed electroluminescence studies of emission mechanism in quantum dot light emitting devices with a phosphorescent sensitizer

Hossein Zamani Siboni, Hany Aziz, Univ. of Waterloo (Canada)

Quantum Dot light emitting devices (QDLEDs) have attracted significant attentions in recent years due to their ability of producing very pure emission colors. The uniquely narrow linewidth emission and size-controlled emission wavelength of nano-crystalline quantum dots make them a superior emitter material for display panels. However, in comparison to other electroluminescent technologies (i.e. inorganic and organic LEDs (OLED)), QDLEDs exhibit very low efficiency. The lower efficiency in QDLEDs is mainly caused by the misalignment of the QD energy levels with those of the adjacent charge transport layers, particularly the hole transport layer, since QDs generally have very deep conduction and valence bands. In this work we demonstrate efficient and bright hybrid organic QDLED with the use of a phosphorescent sensitizer. Results show that the thickness of the QD layer plays an important role in the efficiency enhancement by Forster resonance energy transfer (FRET) from the phosphorescent sensitizer. Using delayed EL measurements we find that the extent of efficiency enhancement by FRET is also dependent on the concentration of the phosphorescent sensitizer, where very high sensitizer concentrations reduce triplet-polaron quenching at the QD/sensitizer layer interface. In this case, efficiency enhancement in the QD layer is attributed to both an increased e-h recombination in the sensitizer layer and efficient FRET.

Shape-memory polymer resonators for novel continuously tunable organic distributed feedback lasers

Senta Schauer, Xin Liu, Matthias Worgull, Uli Lemmer, Hendrik Hölscher, Karlsruher Institut für Technologie (Germany)

We introduce shape-memory polymers (SMPs) as novel materials for the fabrication of tunable diffractive optical elements. Diffractive phase gratings are important tools for many applications in optics and photonics. For instance they serve as Bragg resonators in organic semiconductor distributed feedback (DFB) lasers. SMPs are a class of smart polymers which are able to remember a predefined shape and recover it even after strong deformations, if they are triggered by a proper stimulus like heat. The SMP we used is the thermally triggered thermoplastic polyurethane Tecoflex®. To replicate nanometer scale 2nd order Bragg gratings into the surface of SMP foils we utilized the hot embossing technique. After stretching, these gratings feature increased periods which shrink back to their original length as long as a thermal stimulus is applied. In order to demonstrate the practical applicability of these gratings as useful components for photonics, we successfully fabricated continuously tunable DFB lasers based on SMP resonators with the organic semiconductor Alq3:DCM serving as laser active material. The device consisting of a pre-stretched SMP substrate covered with organic material is optically pumped and then heated with a thermoelectric element to initialize the recovery process. To evaluate our novel device we quantified the lasing threshold to about 140μJcm^-2 and the lifetime to >10^7 pulses. By changing the resonator's period via the shape-memory effect we achieved a continuously tunable and adjustable shift in the emission wavelength of about 30nm. Furthermore, our tunable devices can be integrated in Lab-on-Chips to enable various applications for point-of-care analysis.

Towards fully solution processed OLEDs: Introducing a novel amino-functionalized polyfluorene as electron injection layer

Sebastian Stolz, Karlsruher Institut für Technologie (Germany) and InnovationLab GmbH (Germany); Martin Petzoldt, Ruprecht-Karls-Univ. Heidelberg (Germany) and InnovationLab GmbH (Germany); Uli Lemmer, Karlsruher Institut für Technologie (Germany); Manuel Hamburger, Ruprecht-Karls-Univ. Heidelberg (Germany) and InnovationLab GmbH (Germany); Gerardo Hernandez-Sosa, Karlsruher Institut für Technologie (Germany) and InnovationLab GmbH (Germany)

The fabrication of OLEDs by high throughput printing techniques requires the development of solution processable electron injection layers. In this context, two classes of organic materials, aliphatic amines such as polyethylenimine (PEI) and amino-functionalized polyfluorenes such as PFN, have raised interest. However, processing of PEI poses a big challenge as films need to be very thin (~5 nm) in order to reach a high device performance [1,2]. In contrast, processing of PFN is easier but OLEDs that use it as electron injection layer exhibit limited power efficiencies due to high operational voltages [3,4].

In this work, we present a novel polyfluorene hybrid material, consisting of multiple PEI-like tertiary amine side-chains connected to the polyfluorene backbone via an amide. As a result of its molecular structure, layer thicknesses of up to 15 nm can be used in OLEDs while low operational voltages are maintained.

We solution process OLEDs that use a PPV derivative as emitting layer and either PEI, PFN or the hybrid material in combination with silver as cathode layer. OLEDs that use our new material exhibit a current efficiency of ~ 7.5 cd/A compared to ~ 7 cd/A for both PFN and PEI. At the same time, operational voltages are lowered by more than 1 V compared to PFN.

These results can be correlated to KP measurements that show that the hybrid material reduces the work-function of silver substrates by ~ 1eV, exceeding the reduction observed for PFN and PEI by ~ 0.5 and 0.2 eV, respectively.

The effect of plasmonic nanostructure at the interface of optoelectronics

Seong Jun Kang, Kyung Hee Univ. (Korea, Republic of)

In this presentation, we would like to demonstrate the plasmon effect on quantum-dot light emitting diodes (QLEDs) and transparent phototransistors. Plasmon-enhanced QLEDs were fabricated by inserting gold (Au) nanorods at the interface of the QLEDs. The length of the nanorods was 60 nm, which corresponds to the plasmonic absorption of wavelengths in the range of 630 to 670 nm. CdSe/ZnS quantum-dots (QDs) were used as emission layers with additional hole injection, transport, and electron transport layers. The maximum emission was observed at 630 nm, which is in the range of the plasmon resonance of Au nanorods. The QLEDs with Au nanorods showed enhanced electroluminescent properties compared to the devices without the plasmonic nano-structure. A 172% increase in electroluminescent intensity was observed due to the plasmon coupling effect. Also, silver nanoparticles were prepared to study the plasmon effect on the phototransistors. The Ag NPs effectively absorbed light in the wavelength range of 500 and 600 nm, which corresponds to the plasmonic effect. Due to the plasmon resonance of Ag NPs, a significantly enhanced photocurrent was observed on the devices. The current increased by 348% with exposure to light when the Ag NPs were formed at the interface between the 10-nm-thick oxide semiconductor film and SiO2 substrate. The increased photocurrent revealed the presence of strong coupling between the localized plasmon and electrical carrier of the devices. The device characteristics and origin of the improvement will be presented in detail.

Solution-processed sodium hydroxide as electron injection layer in inverted bottom-emitting organic light-emitting diodes

Hongmei Zhang, Nanjing Univ. of Posts and Telecommunications (China)

The challenge of building IBOLEDs is to explore an effective approach to make the bottom electrode (ITO) easy for electron injection, i.e. reduce the electron injection barrier (EIB) from ITO (4.7 eV) to the lowest unoccupied molecular orbital (LUMO) level of organic electron transport layer (ETL). Modifying the organic/metal interface is an efficient method to reduce the EIB between organic active layer and metal cathode. Various modifications at the organic/metal interface have been reported, including the deposition of an ultrathin layer of alkali metals, alkaline-earth metals, metals and metallic compounds with low work function, as well as organic self-assembled monolayer.

Here, we present inverted bottom-emitting organic light-emitting diodes (IBOLEDs), consisting of tris-(8-hydroxyquinoline) aluminum (Alq3) as the emissive layer and an ultrathin layer of sodium hydroxide (NaOH) on top of indium tin oxide (ITO) as the electron injection layer. The devices with NaOH treated by water vapor and CO2 and annealing show higher current efficiency than those with NaOH untreated. The current efficiency (6 cd/A) of the optimal devices with treated NaOH layer is improved. The enhancement is attributed to the reduction in barrier height for electron injection due to the dipole formation caused by the conversion of NaOH to sodium carbonate.

9566-93, Session PMon

Organic/inorganic (F8T2/p-GaN) white-light emitting device

Yen-Ju Wu, Cheng-Yi Liu, National Central Univ. (Taiwan)

We report a stable white-light emitting device, which is an organic/inorganic (F8T2/p-GaN epi-layers) interface. F8T2 is poly (9,9-dioctylfluorene-co-bithiophene). Two possible mechanisms to produce white light are electroluminescence (EL) and photoluminescence (PL). We found that the primary mechanism for this white-light emission is EL. The white-light emission attributes to the combination of two major EL emission peaks, which are 464 nm and a broad EL emission peak ranging from 521 nm to 580 nm. The 464 nm EL emission peak is contributed from the GaN LED and broad EL emission peak comes from F8T2. The International Commission on Illumination (CIE) coordinate of the white-light emission from the present device is at (0.28, 0.30), which is very close to the standard white light (0.33, 0.33). The detail optical and electrical characterization of this white-light organic/inorganic (F8T2/p-GaN epi-layers) device would be present and discussed in this talk.

9566-95, Session PMon

Near-infrared microlasers based on whispering-gallery mode microresonators of self-assembled organic hemispheres

Hongbing Fu, Xuedong Wang, Institute of Chemistry (China)

Near-infrared (NIR) lasers are key components for applications, such as telecommunication, spectroscopy, display, and biomedical tissue imaging. Inorganic III-V semiconductor (GaAs) NIR lasers have achieved great successes,1 but require expensive and sophisticated device fabrication techniques. Organic semiconductors exhibit chemically tunable optoelectronic properties together with self-assembling features that are well suitable for low-temperature solution processing.3-5 Major blocks in realizing NIR organic lasing include low stimulated emission of narrow-bandgap molecules due to fast nonradiative decay, and exciton–exciton annihilation which is considered as a main loss channel of population inversion for organic lasers under high carrier densities.6 Here, we designed and synthesized the small organic molecule 3-[(4-(N,N-di(p-tolyl)amino) phenyl)-1-(2-hydroxynaphthyl)prop-2-en-1-one (DPHP) with amphiphilic nature, which elaborately self-assembles into micrometer-sized hemispheres than simultaneously serves as the NIR emission medium with a moderate quantum-efficiency of ~15.2%, and the high-Q (~1.4?103) whispering-gallery-mode microcavity. Moreover, the radiative rate of DPHP hemispheres is enhanced up to ~1.98 ns-1 on account of the exciton-vibrational coupling, and meanwhile the exciton–exciton annihilation process is eliminated. As a result, NIR lasing with a low threshold of ~610 nJ/cm2 is achieved in the single DPHP hemisphere at room temperature. Our demonstration is a major step towards incorporating the organic coherent light sources into the compact optoelectronic devices,7 which have been applied as a lab-on-a-chip for high-sensitivity explosive detection.

Long-lived highly efficient green and blue phosphorescent emitters and device architectures for OLED displays

Christian Eickhoff, Peter Murer, Thomas Gessner, Jan Birnstock, Michael Kröger, Zungsun Choi, Soichi Watanabe, Minlu Zhang, Falk May, Christian Lennartz, Ilona Stengel, Ingo Münster, Klaus Kahle, Gerhard G. Wagenblast, Hannah Mangold, BASF SE (Germany)

The development of phosphorescent emitters started in the late 1990s, aiming to combine outstanding efficiencies with high diode lifetimes. Since that time the green emitter Ir(ppy)3 has been the reference material for OLED research and development. In 2001, BASF started to develop a new class of OLED emitter materials based on iridium carbene complexes. These complexes have several properties that make them attractive when compared to phenyl pyridine complexes: outstanding stability due to the absence of weak coordinative N-metal bonds, straight forward synthetic approach and outstanding photophysical properties, even in the deep blue regime, where carbene emitters have proven to be the most stable emitter class. Lifetimes of deep blue phosphorescent diodes can be further boosted by a concept that we call hyperphosphorescence [1].

In this talk, device architectures, materials and performance data will be presented showing that carbene type emitters have the potential to also outperform established phosphorescent green emitters both in terms of lifetime and efficiency.

The specific class of green emitters under investigation shows much larger electron affinities (2.1 to 2.5 eV) and ionization potentials (5.6 to 5.8 eV) than the standard emitter Ir(ppy)3 (5.0/1.6 eV). That difference in energy levels requires an adopted OLED design, in particular with respect to emitter hosts and blocking layers. Consequently, in the diode setup presented here, the emitter species is electron transporting or electron trapping.

For said green carbene emitters, the typical peak wavelength is 525 nm yielding CIE color coordinates of (x=0.33, y=0.62). Device data of green OLEDs will be shown with EQEs exceeding 26%. Driving voltage at 1000 cd/m? is below 3V. In an optimized stack, a device lifetime of LT97 = 4100h (1000 cd/m?) have been reached, thus fulfilling AMOLED display requirements (fig. 1).

9566-301,

Current status of high efficiency OLEDs based on delayed fluorescence

Chihaya Adachi, Kyushu Univ. (Japan)

In recent years, we have reported a series of highly efficient thermally activated delayed fluorescence (TADF) molecules and their OLED performance. We clarified that a large delocalization of the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) in charge transfer compounds provides a small energy gap between singlet and triplet excited states (?EST < 0.2 eV). Simultaneously, even when there is a small overlap between the two wavefunctions, we can successfully keep rather high radiative decay rate (kr) by inducing a large oscillator strength (f). Thus, compatibility of both small ?EST and large kr is fundamental for high efficiency delayed fluorescence. Based on this design concept, we systematically synthesized a wide variety of TADF molecules and demonstrated high efficiency OLEDs with maximum external quantum efficiencies of ~20%. In this talk, we review material design, synthesis, photophysics and OLED performance and discuss the future prospects.

9566-37, Session 9

Light emitting transistors: A new route for display pixels *(Invited Paper)*

Ebinazar B. Namdas, The Univ. of Queensland (Australia)

Organic light emitting transistors (LEFETs) are an emerging class of light emitting devices that have been successfully demonstrated in single-layer [1] and mutli-layer device structures [2]. LEFETs can simultaneously execute light-emission and standard logic functions (ON/OFF) of a transistor in a single device architecture [1]. This dual functionality of LEFETs has a potential to offer a new route to simplify fabrication of display pixels. However, the key problem of existing LEFETs thus far has been their low external quantum efficiency (EQE) at high brightness, poor ON/OFF ratio, and mobility. More recently, hybrid light emitting transistors [3-4], consisting of solution processed n-type metal oxide (inorganic) as the charge transport layer and light emitting conjugated polymer (organic), have been used to achieve higher mobility, ON/OFF ratio and brightness. In this talk, I will discuss the various factors that currently influence device performance in LEFETs, and will provide insights into our recent progress in developing high-performance hybrid LEFETs.

OLEDs: Light-emitting thin film thermistors revealing advanced self-heating effects *(Invited Paper)*

Axel Fischer, Technische Univ. Dresden (Germany); Thomas Koprucki, Annegret Glitzky, Matthias Liero, Weierstrass-Institut für Angewandte Analysis und Stochastik (Germany); Klaus Gärtner, Univ. della Svizzera italiana (Switzerland); Jacqueline Hauptmann, Fraunhofer-Einrichtung für Organik, Materialien und Elektronische Bauelemente COMEDD (Germany); Sebastian Reineke,

Daniel Kasemann, Technische Univ. Dresden (Germany); Björn Lüssem, Kent State Univ. (United States); Karl Leo, Reinhard Scholz, Technische Univ. Dresden (Germany)

For lighting applications, OLEDs need much higher brightness than for displays, causing substantial self-heating accompanied by unpleasant brightness inhomogeneities. Although the relevance of electrothermal interplay has been recognized, the fundamental understanding is still missing. For example, there is no explanation why regions with the highest temperatures shift to the device borders albeit the heat conduction is worst at the center of the substrate. Furthermore, large area OLED panels can show a saturation of brightness around their mid position at elevated self-heating (Fischer et al., Adv. Funct. Mater. 2014, 24).

Recently, we have shown that the temperature-activated transport in C60 devices favors thermal runaway as a result of negative differential resistance (NDR) of 'S'-shape type. The effect can be explained by purely electrothermal effects arising from the positive feedback loop between the temperature dependent conductivity and the power dissipation. Such a behavior is well-known for thermistor devices with a negative temperature coefficient (NTC), but has not been shown for organic semiconductor devices.

Here, we show by experiment and simulation that due to electrothermal feedback in OLEDs, 'S'-shaped NDR occurs as well. For increasing voltage applied to the contacts, self-heating combined with the series resistance of the transparent electrode produces regions with decreasing voltage across the organic layers. Furthermore, due to the laterally extended geometry novel effects take place, like regions in which the current is switched back while the total current increases.

Our work shows that an accurate understanding of nonlinear electrothermal feedback is essential for proper device function at elevated temperatures.

9566-39, Session 9

Highly transparent electrodes for flexible electronics: Ultra-thin metal, 2D materials and their hybrid structures *(Invited Paper)*

Illhwan Lee, Pohang Univ. of Science and Technology (Korea, Republic of); Ki Chang Kwon, Chung-Ang Univ. (Korea, Republic of); Juyoung Ham, Seung O Gim, Pohang Univ. of Science and Technology (Korea, Republic of); Soo Young Kim, Chung-Ang Univ. (Korea, Republic of); Jong-Lam Lee, Pohang Univ. of Science and Technology (Korea, Republic of)

Transparent electrodes are crucial for opto-electronic devices such as organic light-emitting diodes, solar cells, and liquid-crystal displays. Conventionally, indium tin oxide (ITO) has been widely used as the electrodes, but the increasing cost of indium and its brittleness make it unsuitable for future opto-electronic devices. Therefore, it is desirable to develop alternative transparent electrodes. In recent years significant research efforts have been directed towards replacing the ITO.

In this work, we present a novel way to produce the transparent electrode would be to incorporate ultra-thin metal electrode. We show that merely a minute-plasma treatment on the glass before the deposition of Ag layer leads to significantly improved growth homogeneity. These ultra-thin Ag electrodes have very high optical transparency and sheet resistance that are comparable to or better that those of ITO electrode. In addition, their mechanical property is appropriate for flexible devices.

We also demonstrate the transparent electrode using graphene and 2D material. Graphene has shown considerable potential as a replacement for ITO because of its theoretically excellent optical, electrical, and mechanical properties. Despite graphene's ideal properties, pristine graphene films have relatively low work function, high sheet resistance and low chemical stability. We demonstrated a multilayered structure of a graphene electrode sandwiched between metal oxides, which has high stability and superior optical properties. The metal oxide over-coated graphene showed enhanced stability to air exposure and maintained the sheet resistance. Furthermore, we demonstrated hybrid structure which was highly air stable structure comparing to PEDOT:PSS using graphene and 2D material.

9566-54, Session 9

Efficient inverted organic light-emitting devices by amine-based solvent treatment *(Invited Paper)*

Myoung Hoon Song, Kyoung-Jin Choi, Ulsan National Institute of Science and Technology (Korea, Republic of)

The efficiency of inverted polymer light-emitting diodes (iPLEDs) were remarkably enhanced by introducing spontaneously formed ripple-shaped nanostructure of ZnO (ZnO-R) and amine-based polar solvent treatment using 2-methoxyethanol and ethanolamine (2-ME+EA) co-solvents on ZnO-R. The ripple-shape nanostructure of ZnO layer fabricated by solution process with optimal rate of annealing temperature improves the extraction of wave guide modes inside the device structure, and 2-ME+EA interlayer enhances the electron injection and hole blocking and reduces exciton quenching between polar solvent treated ZnO-R and emissive layer. As a result, our optimized iPLEDs show the luminous efficiency (LE) of 61.6 cd A-1, power efficiency (PE) of 19.4 lm W-1 and external quantum efficiency (EQE) of 17.8 %. This method provides a promising method, and opens new possibilities for not only organic light-emitting diodes (OLEDs) but also other organic optoelectronic devices such as organic photovoltaics, organic thin film transistors, and electrically driven organic diode laser.

9566-40, Session 10

Enhanced light extraction from organic light-emitting devices using a sub-anode grid

Yue Qu, Michael Slootsky, Stephen R. Forrest, Univ. of Michigan (United States)

We demonstrate a method for extracting waveguided light trapped in the organic and indium tin oxide layers of bottom emission organic light emitting devices (OLEDs) using a patterned planar grid layer (sub-anode grid) between the anode and the substrate. The scattering layer consists of two transparent materials with different refractive indices on a period sufficiently large to avoid diffraction and other unwanted wavelength-dependent effects. The position of the sub-anode grid outside of the OLED active region allows complete freedom in varying its dimensions and materials from which it is made without impacting the electrical characteristics of the device itself. Full wave electromagnetic simulation is used to study the efficiency dependence on refractive indices and geometric parameters of the grid. We show the fabrication process and characterization of OLEDs with two different grids: a buried sub-anode grid consisting of two dielectric materials, and an air sub-anode grid consisting of a dielectric material and gridline voids. Using a sub-anode grid, substrate plus air modes quantum efficiency of an OLED is enhanced from (33±2)% to (40±2)%, resulting in an increase in external quantum efficiency from (14±1)% to (18±1)%, with identical electrical characteristics to that of a conventional device. By varying the thickness of the electron transport layer (ETL) of sub-anode grid OLEDs, we find that all power launched into the waveguide modes is scattered into substrate. We also demonstrate a sub-anode grid combined with a thick ETL significantly reduces surface plasmon polaritons, and results in an increase in substrate plus air modes by a >50% compared with a conventional OLED. The wavelength, viewing angle and molecular orientational independence provided by this approach make this an attractive and general solution to the problem of extracting waveguided light and reducing plasmon losses in OLEDs.

9566-41, Session 10

Extracting and directing light out of organic light emitting diodes *(Invited Paper)*

Uli Lemmer, Amos Egel, Matthias Hecht, Jan B. Preinfalk, Guillaume Gomard, Karlsruher Institut für Technologie (Germany)

Light extraction from organic light emitting diodes (OLEDs) is attracting considerable interest as being crucial for enhancing the energy efficiency in lighting applications. Light extraction can be realized by lithographically defined internal diffraction gratings or stochastic scattering centers. The former approach needs in addition an external optical layer for scrambling the angularly dependent emission spectra in order to avoid color shifts [1]. Micro lens arrays cannot only be used for fulfilling this task but they can also be used for enhancing the luminosity into a specific direction. We demonstrate recent advances towards high efficiency OLEDs with high directionality. In addition to the relevant technologies we have also developed a comprehensive simulation software for the quantitative description of the light propagation inside the devices. Here, a particular challenging task is the description of multiple and coherent optical scattering. We have recently developed a software for the exact simulation based on a scattering matrix formalism [2].

Outcoupling enhancement of ITO-free white organic light-emitting diodes with an air void-mediated scattering layer *(Invited Paper)*

Tae-Wook Koh, Joshua Spechler, Craig B. Arnold, Barry P. Rand, Princeton Univ. (United States)

White organic light-emitting diodes (WOLEDs) are one of the most promising technologies to realize future solid-state lighting (SSL) that require high power efficiency, excellent color quality and novel form factors. One major bottleneck in realizing such WOLED lighting is the limited outcoupling efficiency, with most light generated in the device either being evanescently coupled to metal surface plasmon modes, or trapped within the substrate or organic/transparent electrode stacks.

Hence to solve this low outcoupling efficiency we suggest two innovative ideas including (1) scattering layers with air voids embedded in transparent plastic films to reduce substrate-trapped mode loss, and (2) Ag nanowire-based transparent conductive electrode embedded in a high refractive index planarization layer. Air voids in the plastic substrate take advantage of the refractive index contrast between air and the plastic host medium to effectively scatter the substrate-trapped light, while absorption in those voids is virtually zero. Also, refractive index matching from the internal organic active layers to the planarization layer that is incorporating networks of Ag nanowire electrodes helps to convert conventional waveguided mode in organic layers to the substrate-trapped mode, which maximizes the effect of the scattering layer. These approaches were then integrated to demonstrate ITO-free WOLEDs on flexible substrates, with processes and materials that are upscalable and compatible to low-cost mass production of WOLED lighting.

9566-43, Session 10

Simple fabrication of a three-dimensional porous polymer film as a diffuser for microcavity OLEDs *(Invited Paper)*

Min Chul Suh, Kyung Hee Univ. (Korea, Republic of)

We used a porous polymer film with ?40% optical haze as a diffuser. It was fabricated by a simple spin-coating process during continuous water mist supply by a humidifier. The pores were created by the elastic bouncing mechanism (rather than the thermocapillary convection mechanism) of the supplied water droplets. The shapes and sizes of the caves formed near the polymer surface are randomly distributed, with a relatively narrow pore size distribution (300–500 nm). Specifically, we focused on controlling the surface morphology to give a three-dimensional (3D) multi-stacked nanocave structure because we had already learnt that two-dimensional nanoporous structures showed serious loss of luminance in the forward direction. Using this approach, we found that the 3D nanoporous polymer film can effectively reduce the viewing angle dependency of strong microcavity OLEDs without any considerable decrease in the total intensity of the out-coupled light. We applied this porous polymer film to microcavity OLEDs to investigate the possibility of using it as a diffuser layer. The resulting porous polymer film effectively reduced the viewing angle dependency of the microcavity OLEDs, although a pixel blurring phenomenon occurred. Despite its negative effects, such as the drop in efficiency in the forward direction and the pixel blurring, the introduction of a porous polymer film as a scattering medium on the back side of the glass substrate eliminated the viewing angle dependency. Thus, this approach is a promising method to overcome the serious drawbacks of microcavity OLEDs.

9566-44, Session 10

Anisotropy in OLEDs *(Invited Paper)*

Michiel Callens, Kristiaan Neyts, Univ. Gent (Belgium); Daisuke Yokoyama, Yamagata Univ. (Japan)

Small-molecule OLEDs, deposited using thermal evaporation, allow for precise control over layer thicknesses. This enables good control over the optical behaviour of the stack which ultimately determines the outcoupling efficiency. In terms of optical outcoupling there are limits to the efficiency by which the generated electromagnetic radiation can be extracted from the stack. These limitations are linked to the refractive indices of the individual layers. Values for maximum outcoupling efficiency are sometimes calculated under the implicit assumptions that the OLED stack is planar, that all layers are isotropic with a certain refractive index and that emitters are not preferentially oriented. In reality it is known that these assumptions are not always valid, be it intentional or unintentional.

In our work we transcend these limiting assumptions and look at different forms of anisotropy in OLEDs. Anisotropy in OLEDs comes in three distinct flavours; 1. Spatial anisotropy, where one thinks of gratings, lenses or other internal or external scattering centres, 2. Anisotropic emitters, where the orientation significantly influences the direction in which radiation is emitted and 3. Anisotropic layers, where the anistropic nature of the layers breaks with the customary assumption of isotropic layers. We investigate the effect of these anisotropic features on outcoupling efficiency and ultimately, external quantum efficiency (EQE).

9566-45, Session 10

Extracting and shaping the light of OLED devices

Daniel Riedel, OSRAM Opto Semiconductors GmbH (Germany) and Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); Thomas Wehlus, OSRAM Opto Semiconductors GmbH (Germany); Christoph J. Brabec,

Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany)

Before the market entry of OLEDs in the field of general illumination can take place, limitations in lifetime, luminous efficacy and cost needs to be overcome. Additional requirements for OLEDs used in general illumination may be imposed by workplace regulations for glare reduction that e.g. limit the luminance for high viewing angles. These requirements are in contrast to the typically Lambertian emission characteristic of OLEDs having internal extraction layers, which results in the same luminance levels for all emission angles. As a consequence, without additional measures, glare reduction could limit the maximum possible luminance of Lambertian OLEDs to relatively low levels. On the other hand, high luminance levels are desirable to get high light output. We are presenting solutions to overcome this possible limitation.

Therefore this work is focused on internal light extraction layers and light shaping structures for OLEDs. Simulations of beam shaping structures and shapes as well as the verification of the simulations with experimental measurements of the most promising structures are presented. An evaluation of the loss channels has been carried out and the overall optical system efficiency was evaluated for all structures. The most promising beam shaping structures achieve system efficiencies up to 80%, close to the theoretical limit derived from étendue calculations.

Finally, a general illumination application scenario has been simulated. The number of OLEDs needed to illuminate an office room has been deduced from this scenario. By using light-shaping structures for OLEDs, the number of OLEDs needed to reach the mandatory illuminance level for a workplace environment can be reduced to one third compared to Lambertian OLEDs

Interface trap density effect on efficiency of Fullerene organic Schottky diode

Mebarka Daoudi, Univ. Tahri Mohammed Béchar (Algeria)

The growing demands for environmental protection and clean energy urge scientists to create new techniques and materials for a sustainable energy. The interest for Organic Electronics has dramatically increased over these past years, not only in academic research, but also in an industrial perspective. Key efforts to the success include the development of device prototype design and scale-up. The complications of these processes pose significant challenges. The main reasons for focused interest in this field is the opportunity to produce low cost devices on plastic substrates on large areas, opening, indeed, an entire new market segment. One of the fundamental points in determining the electrical performances in organic devices is that, even though they are usually thought as macroscopic devices, their behavior is strongly driven by interfacial phenomena taking place in the nano-scale.

In this work, we are going to study the electronic transport in organic thin films which is strongly affected by interfacial phenomena. For example, the scattering of conduction electrons at grain boundaries or at planar interfaces defined by the top and bottom surfaces of the film can contribute significantly to the efficiency of device [1,2]. So, in order to optimize the device performance it is very important to have knowledge about intrinsic properties, particularly the charge transport and charge injection properties. One of the basic methods to investigate the charge transport in interface metal/organic semiconductors is to determine the dark I-V characteristics, where the important effects which describe that transport mechanism are the space charge, trapping and schottky effects [3]. These are obtained from the dependence of observables on the temperature, electric field and trap density.

The interface trap density effect on dark I-V characteristics for fullerene (C60) schottky diode is investigated here for different electrodes (Al, Au, Ag).

Conformation modulated quinoxaline-based low band gap polymers with non-covalent Coulomb interaction for photovoltaic cells with efficiency of 8%

Yuxiang Li, Pusan National Univ. (Korea, Republic of); Seo-jin Ko, Jin Young Kim, Ulsan National Institute of Science and Technology (Korea, Republic of); Han Young Woo, Pusan National Univ. (Korea, Republic of)

A series of fluorinated quinoxaline-based ϖ-conjugated polymers with non-covalent conformational locks was designed and synthesized by considering the solubility, planarity, chain curvature and intramolecular steric hindrance for applications in polymer solar cells (PSCs). Insertion of different number of the axis symmetrical thiophene (as a donor moiety in a polymer backbone) allows fine-adjusting not only absorption range, the frontier energy levels, but also accompanied with the symmetrical changes. The molecular geometry, bulk film morphology and ordered film structure were investigated in detail by density function theory (DFT) calculations, atomic force microscopy (AFM) and grazing-incidence wide-angle X-ray scattering (GIWAX) analysis. Via rational design of semi-crystalline photovoltaic polymers considering chain planarity, non-covalent intra- and inter-molecular coulomb interactions and molecular geometry, the optimized photovoltaic cell based on PDFQx3T:PC70BM achieved power conversion efficiency (PCE) of 8% with an open-circuit voltage (Voc) of 0.74 V, a short-circuit current (Jsc) of 17.19 mA/cm2 and a fill factor (FF) of 63% at ~270 nm thick active layer. Most previous PSCs show the best PCE at the film thickness on the order of 100 nm. However it is not currently viable to fabricate defect-free and homogeneous films by industrial casting techniques. Our photovoltaic data at the thicker active layer suggest a great potential for industrial mass production of printed PSCs. The markedly high efficiency is most likely attributed to rationally modulated molecular geometry and highly ordered polymer structure in the active layer, in which the axis symmetry conformation of molecular, the short ϖ-ϖ stacking distance (3.6 Å) with favorable face-on orientation were achieved, also formed well interpenetrated networked morphology. We also found that quite high hole mobility with balanced h/e mobility ratio, proper miscibility and phase separation are the main reasons for high IPCE (83%) and FF (63%) at ~270 nm thick active layer. This study provides an insight into rational molecular design for efficient semi-crystalline photovoltaic structures with non-covalent conformation lock.

Verification of effect of electric field on electron transport in TiO2 electrode

Kai-Ling Chuang, Ming-Show Wong, Yi-Jia Chen, Chih-Hung Tsai, National Dong Hwa Univ. (Taiwan); Hong Syuan Ling, Chien Chin Wang, National Dong Hwa Univ. (Taiwan)

We demonstrated that the dense TiO2 planar negative electrode is an effective electron transport material in the perovskite solar cells. The highest Voc is 900 mV using negative electrode with a dense TiO2 layer of 400 nm plus a mesoporous TiO2 layer of 500 nm. For conventional dye-sensitized solar cells (DSSCs) the thickness of the mesoporous negative electrode is around 15 ?m. The ideal range of film thickness in DSSCs is usually 12~16 ?m, suggesting that the electron has comparable diffusion length in the mesoporous negative electrode such that the electron recombination is insignificant below 15 um. However, design of thicker mesoporous TiO2 negative electrode in perovskite solar cells is not usually encouraged as the solar cell efficiency decreases with electrode thickness greater than 500 nm. In this study, we would like to verify if the efficiency decrease of perovskite solar cells with electrode thickness is really due to the increase of thickness of TiO2 electrode itself or some consequences that come with the increase of thickness, such as increased roughness. We will report the solar cell efficiency dependence on the thickness of dense TiO2 layer in negative electrode so to verify if the electric field does play a role in electron transport in the TiO2 electrode. With this understanding, we will be able to design a novel structure of TiO2 electrode that is suitable for perovskite solar cells.

Structure-property correlations of merocyanines and their application in organic solar cells

Julian Krumrain, Univ. zu Köln (Germany); Alhama Arjona-Esteban, Julius-Maximilians-Univ. Würzburg (Germany); Selina Olthof, Dirk Hertel, Univ. zu Köln (Germany); Matthias Stolte, Frank Würthner, Julius-Maximilians-Univ. Würzburg (Germany); Klaus Meerholz, Univ. zu Köln (Germany)

Organic photovoltaics based on donor-acceptor heterojunctions using conjugated polymers or small molecules as donor component have recently achieved power conversion efficiencies of up to 9% in single junctions.

[1,2] Of particular interest is the establishment of small molecules as donor material in organic solar cells due to their simplified, large-scale synthesis and purification in comparison to conjugated polymers. However, predictable correlations between the molecular structure, molecular properties and the device performance rarely exist, but they are needed to further drive the progress in this area.

Here we demonstrate that single crystalline merocyanines show zero to three dimensional patterns which correlate with the device performance. We have characterized several merocyanines as thin films and single crystals with X-ray diffraction and ultraviolet photoemission spectroscopy. Additionally, we have studied the temperature and light dependence of the current-voltage response of planar as well as bulk heterojunction solar cells.

The power conversion efficiencies of the studied solar cells range from 1% to 5%, depending on the dimensionality of the aggregation pattern. By comparing the planar and bulk heterojunction solar cells, we demonstrate that the often reported temperature dependence of the ideality factor is caused by deep lying trap states. Our results on the temperature dependence of the open-circuit voltage complete and bring together previous studies, where either only bulk or planar heterojunctions were investigated.[3,4] Furthermore, we show that by doing precise analysis of temperature dependent current-voltage characteristics, it is possible to determine losses in the open-circuit voltage within a solar cell.

Femtosecond transient absorption spectroscopy of thienylenevinylene-phthalimide copolymer and of bulk heterojunction blend with PC71BM

In-Sik Kim, Seong-Hoon Kwon, Juhwan Kim, Dong-Yu Kim, Do-Kyeong Ko, Gwangju Institute of Science and Technology (Korea, Republic of)

For an enhancement of power conversion efficiency in organic solar cell, low band gap polymers are a prerequisite because the low band gap polymers can absorb a broad range of solar spectrum and induce much charge carriers. Arranging electron-rich and electron-deficient moieties alternately is one of the appropriate technics for tuning the band gap of polymers, since orbital mixing between two moieties promotes the formation of an intramolecular charge transfer state which is involved in an additional absorption band. Moreover, the band gap tuning by such structure can be useful to achieve deep-lying highest occupied molecular orbital (HOMO) level for high open circuit voltage as well.

We have developed donor-acceptor alternating copolymer which was based on alkyl-substituted thienylenevinylene and phthalimide units, and the copolymer:fullerene derivative performed intense visible absorption and the open circuit voltage of >0.8 V. In this study, we present the photo-induced carrier dynamics of the copolymer by using the femtosecond transient absorption (TA) measurement. By introducing the copolymer as a donor and [6,6]-phenyl-C71-butylic acid methyl ester (PC71BM) as an acceptor, effective charge separation in bulk heterojunction (BHJ) blend was measured from the TA. Also, the effect of processing additive for improved photovoltaic performance of this BHJ was revealed with this femtosecond TA measurement.

Criteria for stabilizing polymer and small molecule solar cells

Rongrong Cheacharoen, William R. Mateker, I. T. Sachs-Quintana, Thomas Heumüller, Michael D. McGehee, Stanford Univ. (United States)

We study the degradation of organic solar cells (OSCs) and find that stability can be improved on both short and long time scales by careful material selection and operating OSCs in an oxygen-free environment. In the first 60 hours of operation, more crystalline regioregular P3HT and ZZ115 solar cells lose 10% of starting efficiency, mostly due to loss in open circuit voltage (Voc) and fill factor (FF), while more amorphous PCDTBT and regiorandom P3HT lose 25%. We find that photo-induced Voc loss is caused by a change in the density of states, while recombination dynamics remain unchanged. This effect is minimized in crystalline materials. We further demonstrate no photoinduced burn-in in highly crystalline T1 small molecule solar cells. While T1 solar cells show photostability, their efficiency degrades at elevated temperatures, and work is ongoing to better understand thermal degradation in small molecule solar cells. We further compare crystalline and amorphous films in photobleaching experiments in air and find that increased crystallinity of materials show slower photochemical degradation. For example, crystalline rubrene photobleaches three order of magnitudes slower than amorphous films. We also investigate solar cells on long time scales. We have monitored PCDTBT for 7500 hours in an oxygen free environment and extrapolate lifetimes to more than 20 years. We are also investigating the stability of molecules and polymers with power conversion efficiency approaching 10%. As these materials are highly crystalline, we are hopeful to show promising stability.

9567-55, Session PMon

Effect of thermal annealing on charge transfer states and exciton dissociation in PCDTBT: PC70BM bulk heterojunction solar cells

Iordania Constantinou, Tzung-Han Lai, Erik D. Klump, Univ. of Florida (United States); Hsien-Yi Hsu, The Univ. of Texas System (United States); Kirk S. Schanze, Franky So, Univ. of Florida (United States)

The effect of thermal annealing on charge generation was investigated for PCDTBT:PC70BM devices. Photocurrent spectral response and transient photoluminescence measurements were used to confirm that device annealing leads to more effective carrier generation due to a higher degree of charge transfer (CT) exciton delocalization. The delocalization of CT excitons was also accompanied by an increase in the dielectric constant of the blend. Even though no obvious difference in the film morphology was observed, the solar cell performance changed significantly after thermal treatment mostly due to a decrease in the device fill factor (FF). It was shown that even though the photocurrent generated for the annealed PCDTBT:PC70BM device is higher due to delocalization, a larger amount of generated photo-carriers are lost to recombination and do not contribute to the output current. Energetic disorder measurements along with recombination measurements at short and open circuit revealed a negligible bimolecular recombination for both devices. Finally, the decrease in FF was found to be due to an increase in the concentration of deep level traps causing an increase in Shockley-Read-Hall recombination. Our findings suggest that thermal annealing can not only cause significant changes in the film morphology and packing but also in the photo-generation process in organic bulk heterojunction solar cells.

Probing the organic-inorganic interfaces of organic photovoltaic devices

Andrew J. Clulow, Hui Jin, Mike Hambsch, Jake A. McEwan, Paul L. Burn, Ian R. Gentle, Paul Meredith, The Univ. of Queensland (Australia)

Whilst a great deal of attention has been directed at optimising the properties of the active layers of organic photovoltaic (OPV) devices, interactions at the interface are of equal importance. The accumulation or depletion of active organic materials at the electrode interface during device manufacture and operation has the potential to greatly influence device performance by altering the electrical contacts. In recent years molybdenum oxide (MoOx) has been widely used as an interlayer to modify the work function of metallic electrodes and as an active component in transparent electrodes. Insulator/metal/insulator stacks containing MoOx have been shown to be flexible and have lower sheet resistances than indium tin oxide, making them promising transparent conducting electrode candidates.

We have used neutron reflectometry to study the buried interfaces present in the layered transparent electrode stacks and between OPV active layers and MoOx. The influence of typical thermal annealing protocols and prolonged exposure to ambient atmosphere were recorded. It was found that the use of zinc sulphide in place of MoOx as the capping material for the electrode stacks increases their stability towards exposure to ambient atmosphere and subsequent thermal annealing. The organic-inorganic interface between P3HT:PC61BM and PCDTBT:PC71BM bulk heterojunctions and MoOx was monitored in situ during thermal annealing and this revealed that the accumulation of the fullerene phase observed previously at the P3HT:PC61BM/SiO2 interface is not a common feature of oxide surfaces.

9567-57, Session PMon

Time-resolved terahertz spectroscopy (TRTS) of conducting metal-organic frameworks (MOFs) doped with redox active species

Brian G. Alberding, Edwin Heilweil, National Institute of Standards and Technology (United States)

Metal-Organic Frameworks (MOFs) are three-dimensional coordination polymers that are well known for large pore surface area and their ability to adsorb molecules from both the gaseous and solution phases. In general, MOFs are electrically insulating, but promising opportunities for tuning the electronic structure exist because MOFs possess synthetic versatility; the metal and organic ligand subunits can be exchanged or dopant molecules can be introduced into the pore space. Two such MOFs with demonstrated electrical conductivity are Cu3(1,3,5-benzenetricarboxylate)2, a.k.a HKUST-1, and Cu[Ni(1,4-pyrazinedithiolate)2]. Herein, these two MOFs have been infiltrated with the redox active species 7,7,8,8-tetracyanoquinodimethane (TCNQ) and iodine under solution phase conditions and shown to produce redox products within the MOF pore space. Vibrational bands assignable to TCNQ anion and triiodide anion have been observed in the Mid-IR and Terahertz ranges using FTIR Spectroscopy. The MOF samples have been further investigated by Time-Resolved Terehertz Spectroscopy (TRTS). Using this technique, the charge mobility, separation, and recombination dynamics have been followed on the picosecond time scale following photoexcitation with visible radiation. The preliminary results show that the MOF samples have small inherent photoconductivity with charge separation lifetimes on the order of a few picoseconds. In the case of HKUST-1, the MOF can also be supported by a TiO2 film and initial results show that charge injection into the TiO2 layer occurs with a comparable efficiency to the N3 dye sensitizer and therefore this MOF has potential as a new light absorbing and charge conducting material in photovoltaic devices.

Plasmon-induced selectively chemical growth of flexible and transparent silver nano-network electrode for organic optoelectronic devices

Haifei Lu, The Chinese Univ. of Hong Kong (Hong Kong, China); Di Zhang, Xingang Ren, The Univ. of Hong Kong (Hong Kong, China); Jian Liu, Univ of Hong Kong (Hong Kong, China); Wallace C. H. Choy, The Univ. of Hong Kong (Hong Kong, China)

While great efforts have been devoted to develop enabling nanowire electrodes, reduce contact resistance of the metal nanowires and improve the electrical stability under continuous bias operation are the key issues for practical applications in flexible optoelectronics. Here, we propose and demonstrate a novel approach of selective nucleation and growth of silver nanoparticles at the junctions of silver nanowires at room temperature and atmosphere for chemically forming a silver nano-network. The selective integration of silver nanoparticles at the junctions of silver nanowires is realized through plasmon-induced chemical growth under a very low power density of light irradiation (as low as 5 mW/cm2) without using sophisticated equipment and expensive material. As a result, silver nano-networks with very good electrical conductivity and optical transmittance are obtained. Compared to the silver nanowire electrodes treated with thermal annealing, our nano-networks from the selective integration of in situ grown silver nanoparticles with silver nanowires exhibit better electrical stability under continuous external bias. In addition, the silver conductive nano-network peels off itself from the substrate when immersed in water, which can be easily transferred to other substrate s for versatile applications. To conceptually demonstrate the potential application of our silver nano-network, semitransparent P3HT:PCBM organic solar cell is fabricated by using silver nano-network as the top electrodes and performances are close to reference device [1]. Consequently, silver nano-network formed through our novel approach has exhibited great potential as highly conductive transparent electrode with the attractive features of low cost and high operational stability which are desirable in practical optoelectronic and electronic applications.

ZnO:Al films modified by Zn1-xMgxO:Al surface layer as low work function transparent electrodes

Grzegorz Luka, Institute of Physics (Poland); Wojciech Lisowski, Janusz W. Sobczak, Aleksander Jablonski, Institute of Physical Chemistry (Poland); Petro S. Smertenko, V.E. Lashkaryov Institute of Semiconductor Physics (Ukraine)

Electrode work functions and their proper adjustment have an impact on the performance of organic solar cells. So far widely used metals like magnesium, calcium, lithium, or their alloys are chemically reactive and sensitive to oxygen. The commonly used indium tin oxide (ITO) material for transparent electrode applications typically has the work function of 4.2 – 4.8 eV. Aluminum-doped zinc oxide (ZnO:Al, AZO) films, which are becoming very competitive to ITO, have the work function of about 4.1 eV. This promotes their use as transparent electrodes in inverted type organic devices. By alloying AZO films with magnesium, a further decrease of the work function is achieved. Such films, however, have higher resistivities comparing to ITO or non-alloyed AZO films.

We covered AZO films with very thin (~5 nm) Zn1-xMgxO:Al layers grown by atomic layer deposition. A highly conductive state of the AZO film was combined with a lower work function of the electrode due to the

alloyed layer at the AZO surface. Depending on the growth conditions, the magnesium content at the film surface varied from x = 0 to x = 0.6. This gave a work function decrease up to 0.6 eV and resulted in a decrease of the reverse currents (by 1-2 orders of magnitude) and a rectification improvement of the prepared organic single layer devices. Based on current-voltage measurements and a differential approach, we analyzed carrier injection properties of the so-obtained electrodes.

The research was supported by The National Science Centre (NCN, Poland) under decision DEC-2012/07/D/ST3/02145.

Understanding the degradation of polymer solar cells: A comparative study realized on working devices

Mario Prosa, Istituto per lo Studio dei Materiali Nanostrutturati (Italy); Mirko Seri, Istituto per la Sintesi Organica e la Fotoreattività (Italy); Marta Tessarolo, Istituto per lo Studio dei Materiali Nanostrutturati (Italy)

Over recent years, scientific interest gradually converged to Bulk Heterojunction (BHJ) solar cells since sustainable and economic benefits are simultaneously achieved. Despite worldwide research lead to interesting power conversion efficiencies greater than 10%, the rather limited stability of the devices slowed down the commercialization of this technology. In this view, a deeper understanding of the issues concerning the device stability is required. Recent publications highlight the detrimental role of light and temperature on encapsulate devices but, most of the works focus the attention mainly on a single layer or a particular interface. However, it is well known that the mechanisms inducing the degradation are not limited to a specific layer (interface) nevertheless the investigation of a complete working device is not trivial. Here, we present a complete description on the stability of BHJ solar cells in which spectroscopic as well as microscopic techniques are combined to study working devices and, an overall understanding of degradation mechanisms involved in complete solar cells is provided. Moreover, we show how a single interface (layer) contributes to the losses of performances. In particular, different i) active layers, ii) interfacial layers and iii) device architectures were combined to show the role of each layer (interface) and its influence to the lifetime of the resulting device under thermal and light soaking degradation tests. Finally, guidelines for the fabrication of time stable BHJ solar cells are presented.

Efficient perovskite solar cells and their application to semitransparent devices

Hoyeon Kim, Jaewon Ha, KAIST (Korea, Republic of); Hui-Seon Kim, Nam-Gyu Park, Sungkyunkwan Univ. (Korea, Republic of); Seunghyup Yoo, KAIST (Korea, Republic of)

Advent of photovoltaic (PV) cells utilizing inorganic-organic lead halide perovskites has recently gained a great attention and led the community to put intensive efforts on boosting their overall performance. As a result, their power conversion efficiency showed a rapid increase reaching the value close to 20%, demonstrating their great potential for next-generation PV technologies balanced with both high performance and affordability. However, the geometry of highly efficient devices has been limited to a few configurations and reports on realization of efficient perovskite semitransparent PV cells were relatively scarce.

In this work, we demonstrate efficient perovskite solar cells in which nano-porous TiO2 layers are prepared on ITO substrates instead of FTO substrates, which are more commonly adopted in perovskite research. In the anode side, expensive Au or Ag top electrodes are also replaced with MoO3/Al electrodes without performance tradeoff. As a result, devices having power conversion efficiency of avg. 16.4% (champion cell with 17.3%) under 100mW/cm2 (AM 1.5G) are demonstrated with reverse voltage sweep (from forward bias to short circuit) at scan rate of 0.2V/s. Hysteresis on the current-voltage curve and external quantum efficiency on both AC and DC measurement modes are examined. Furthermore, efficient see-through perovskite solar cells are achieved with little optical haze thanks to the high optical quality of ITO electrodes. With a top semitransparent Ag electrode capped with a high-index MoOx layer, semitransparent MAPbI3-based perovskite photovoltaic devices are shown to exhibit the power conversion efficiency of avg. 10%. Optical analysis based on transfer matrix formalism is also presented to elucidate the competition between device efficiency and transparency.

Thiazolo [5,4-d]thiazole based D-A-D type Chromophore with furan spacer for BHJ organic solar cells

Mohammed Nazim, Sadia Ameen, Mohammed S. Akhtar, Hyung Kee Seo, Hyung Shik Shin, Chonbuk National Univ. (Korea, Republic of)

Organic small molecule containing thiazolo[5,4-d]thiazole-core acceptor with furan spacer (RFTzR) was designed, synthesized and applied as electron donor material for solution-processed bulk-heterojunction (BHJ) small molecule organic solar cells (SMOSCs). The synthesized small molecule had a good thermal stability of >350 and crystalline nature also. It also has shown the self-assembly behaviour due to the presence of terminal alkyl chains. It has shown a good absorption band about ~473 nm in chloroform solvent. The introduction of furan spacer improved its absorption and solubility in the common organic solvents. RFTzR exhibited a good oxidation stability with HOMO and LUMO energy levels of -5.36 eV and -3.14 eV, respectively. The solution-processed organic solar cell devices of RFTzR were optimized with PCBM in different donor:acceptor blend ratios (1:1, 2:1, 3:1, w/w). Low value of FF affects adversely on the solar cell devices which is responsible for lowering the efficiency than the expected one. The fabricated cells of RFTzR (donor) and PC60BM (acceptor) as photoactive materials showed relatively smooth thin film morphology of devices which gives a maximum PCE of 2.72% (RFTzR:PC60BM, 2:1, w/w) optimized ratio with good open-circuit voltage of 0.756 V and high photocurrent density of 10.13 mA/cm2. This study makes a way for the furan bridged chromophores in small molecule organic solar cells.

Optimization of interfacial layer for double and triple junction polymer solar cell

Abu Mitul, South Dakota State Univ. (United States)

Solution processed tandem polymer solar cell has drawn a great deal of attention due its low cost, ease of production and capability of harvesting solar energy more efficiently. In solution processed tandem polymer solar cell, the most challenging part is the optimization of interfacial layer. In this work, we have investigated the robustness of PEDOT:PSS/AZO/PEIE interfacial layer to develop tandem polymer solar cell. While developing triple junction polymer solar cell, temperature of second interfacial layer has also a great impact on overall device performance. Here, the performance of tandem polymer solar cell was investigated on different temperature of interfacial layer. Triple junction polymer solar cell was fabricated at lowest possible temperature of interfacial layer. Voc of 1.4 V was achieved in triple junction polymer solar cell while single junction Voc was 0.6 V. Optimization of thickness and more robust PEDOT:PSS/AZO/PEIE interfacial layer can overcome the losses in triple junction polymer solar cell.

9567-66, Session PMon

Non-oligoacence molecules exhibiting singlet fission in organic photovoltaic devices

Yong-Jin Pu, Yamagata Univ. (Japan)

We demonstrate singlet fission phenomena in a series of thienoquinoidal compounds by magnetic field dependence of photocurrent in OPVs. In the three thienoquinoidal compounds, thiophene (Th), thieno[3,2-b] thiophene (TTh), and bithiophene (BTh) are incorporated as a core between two fluorene (BF) units with double bonds, respectively: ThBF, TThBF, and BThBF. The thienoquinoidal structure leads a biradical character, and consequently their E(T1) decreases. TD-DFT calculations using the single-crystal structure of the compounds indicated that the E(T1) of TThBF and BThBF are lower than half of the E(S1). We fabricated OPV devices using the thienoquinoidal compounds as a donor, C60 and PDIF-CN2 as an acceptor, respectively. With PDIF-CN2 having enough deep LUMO level for charge separation of triplet excitons in the donor, the photocurrents obtained by the excitation of the donor decreased with increasing magnetic field. This result indicates that the magnetic field suppressed singlet fission rate because of Zeeman splitting of triplet state, resulting in the reduction of the triplet excitons and the photocurrent from their charge separation. On the other hand, in devices with C60, the photocurrents under the excitation of the donor increased with increasing magnetic field. This result is because suppression of the singlet fission by magnetic field reduced the triplet excitons that cannot be separated to charges because of shallow LUMO level of C60.

Hybrid perovskite solar cells based on zinc oxide scaffolds synthesized by different methods

Fangzhou Liu, Qi Dong, Man Kwong Wong, Aleksandra B. Djuri?i?, The Univ. of Hong Kong (Hong Kong, China); Annie Ng, Charles Surya, The Hong Kong Polytechnic Univ. (Hong Kong, China); Wai Kin Chan, The Univ. of Hong Kong (Hong Kong, China)

Investigations on solid-state organic-inorganic perovskite based solar cells have drawn worldwide attention in the recent years. Considerably high power conversion efficiencies have been achieved in the cells with TiO2 employed as the electron-selective contact or mesoporous scaffold.1 On the other hand, regarding that TiO2 materials unavoidably require high temperature processing at 450oC-500oC, research efforts have been made to explore other alternatives allowing low-temperature processing with desirable efficiencies. ZnO, with its comparable energy levels and higher electron mobility than TiO2, is a potential alternative to TiO2 for the applications in hybrid perovskite based solar cells. ZnO also possesses a variety of its nanoscaled morphologies and processing methods which provides numerous possibilities for device design. Preliminary efforts on this research topic have been made so far with considerable efficiencies achieved in perovskite solar cells based on ZnO nanorods.2

Due to the richness in morphologies and synthesis approaches, similar ZnO nanostructures can be prepared using different methods, and the properties of the as-grown materials are largely affected by synthesizing methods. In this work, we studied the perovskite solar cells with ZnO as the electron-selecting and mesoporous scaffold materials prepared by different methods, including hydrothermal growth, vapor-phase deposition, and electron beam deposition. The power converting efficiencies with optimized cell structures are compared and their correlations to other material properties are discussed.

Sn/Pb binary perovskite solar cells with improved stability in air and organic amine-free perovskite solar cells with improved stability against light exposure

Koji Nishinaka, Yuhei Ogomi, Kyushu Institute of Technology (Japan); Qing Shen, The Univ. of Electro-Communications (Japan); Kosei Fujiwara, Keita Sakaguchi, Kyushu Institute of Technology (Japan); Taro Toyoda, The Univ. of Electro-Communications (Japan); Shuzi Hayase, Kyushu Institute of Technology (Japan)

Perovskite solar cells have recently attracted interest because of the high efficiency reaching 20 %. The perovskite works as light absorber and the light absorption spectrum edge for MAPbI3 (MAPbI, MA: mechylammonium cation) was 800 nm. It has been reported that Sn halide perovskites have the light absorption up to 1200nm. However, it has been reported that CH3NH3SnI3 (MASnI) was too unstable to handle in air. We found that the Sn halide perovskite became stable in air when Pb halide perovskite was added. This prompted us to evaluate binary Sn/Pb perovskite solar cells. We have already reported the binary MASnPbI3 with 4.18 % efficiency1-3. In this report we discuss photovoltaic performances for binary MASnPbI perovskite solar cells with gradient structure from the bottom to the top. The gradient structure was given by the slower diffusion of PbI2 than SnI2 into nanopores of porous titania layers and the structure gave unique long carrier life time with msec order. We also reported organic amine free-CsPbI solar cells with about 2 % efficiency, expecting enhanced stability toward light exposure. Hysteresis I-V curves were observed for the CsPbI solar cells. Therefore, we concluded that dipole of MA is not sole cause for the hysteresis. Urbach energy measurement suggested that decrease in defect density of the binary MASnPbI and CsPbI perovskite solar cells are needed for enhancing the efficiency. In this report, we show the potential for amine free CsPbI and binary MASnPbI solar cells with improved stability.

Overcoming the “light-soaking” issue in organic solar cells

Sara Trost, Bergische Univ. Wuppertal (Germany); Philip Reckers, Thomas Mayer, Technische Univ. Darmstadt (Germany); Tim Becker, Andreas Behrendt, Andreas Polywka, Ralf Heiderhoff, Patrick Görrn, Thomas Riedl, Bergische Univ. Wuppertal (Germany)

It is a general phenomenon that organic solar cells (OSCs) using TiOx or ZnO as electron extraction layers require “activation” by UV light . Otherwise, poor, s-shaped I/V characteristics with low fill-factors and overall low power conversion efficiency are found. In principle the AM1.5 solar spectrum provides enough UV radiation to activate TiOx or ZnO. However, in cases where the UV-spectral region of the solar spectrum is missing (e.g. with UV-blocking substrates, down-shifting concepts, indoor PV, multi-junction cells) OSCs with interlayers of TiOx or ZnO will remain inefficient. Thus, the development of charge extraction materials that do not rely on UV activation is a critical challenge to achieve highly efficient and long term stable OSCs.

We will unveil the root cause of the “light-soaking” phenomenon using photoelectron spectroscopy and kelvin probe analysis. We will show that UV activation can be avoided by using electrically doped metal-oxides (e.g. Al:ZnO)[1] or by the application of plasmonic sensitization of the metal-oxides, by introducing silver nanoparticles in the immediate vicinity of the metal-oxide/organic interface.[2] Very recently, we discovered that pristine SnOx as electron extraction layer, prepared at temperatures as low as 80°C, provides a facile avenue to light soaking-free OSCs. The work-function of

these SnOx layers is low (4.1eV) even without illumination. The absence of an electron extraction barrier is verified for a range of organic photo-active systems.

Effects of organic and inorganic templating layers on phthalocyanine/C60 planar and bulk heterojunction organic solar cells

Sibi Sutty, Hany Aziz, Univ. of Waterloo (Canada)

Various templating layers have been used to control the molecular orientation of organic solar cell (OSC) materials and fabricate planar heterojunction (PHJ) OSCs. The templating layer forces the donor molecules of a PHJ OSC to lie flat on the substrate, which improves its absorption and charge transport properties. As a result, templated PHJ OSCs have higher efficiencies due to improved short-circuit current and fill-factor. Several organic and inorganic templating layers such as perylene-3,4,9,10-tetracarboxylic dianhydride (PTCDA) and copper iodide (CuI) respectively have been used to improve OSC performance to date. However, there are no studies comparing the effects of the different types of templating layers on the morphology and molecular orientation of a donor material and the associated impacts on OSC performance. Furthermore, the suitability of organic and inorganic templating layers for various donor materials has also not been studied. In our work, we assess the key differences between organic and inorganic templating layers. First, we study the differences in morphology and molecular orientation of various metal substituted phthalocyanine donor materials deposited on these two types of templating layers. Then, we analyze the subsequent effects on the performance of phthalocyanine/C60 PHJ and bulk heterojunction (BHJ) OSCs. Finally, we correlate changes in morphology and molecular orientation to OSC performance and determine the best templating layer for each metal-phthalocyanine/C60 PHJ or BHJ OSC.

Advanced imaging characterization and modelling of defects in organic solar cells

Roland Rösch, Daniel Fluhr, Rolf Öttking, Burhan Muhsin, Harald Hoppe, Technische Univ. Ilmenau (Germany)

Lifetime and production yield remains a challange of organic photovoltaics (OPV). Various degradation scenarios exist, for example shunting due to impurities or electromigration. Furthermore photooxidation and morphological decomposition of the active layer materials, corrosion of the metal electrodes or deposition mismatch can strongly affect device performance.

Finite element models (FEM) enables studyingcurrent pathways and resistive losses in laterally extended organic solar cells.

The FEM calculations yield spatial distributions of current densities and according resistive power losses. The peaking current distribution within the shunting defect is locally resolved, however, considerable currents are still spread over the entire device area.

From the resulting resistive loss patterns, the heat distribution and emission was derived and directly compared with lock-in thermography imaging.

On the opposite, so-called pinholes within the metal back electrode offer pathways for ingress of water and oxygen. These attack the metal-organic interface, introducing delamination through the formation of insulating metal oxides. As charge injection and extraction is suppressed at delaminated areas, the active device area is reduced and so is the overall efficiency.

The reduction of the active area is experimentally investigated concerning the influence of different environmental conditions. Imaging experiments provide information on location and size of insulated areas induced by pinholes in the metal back contact. Time resolved measurements during degradation of the devices reveal the dynamics and rate of growth of these individual defects.

Overall, imaging in combination with simulation offers advanced defect analysis, promoting OPV market introduction.

Multiscale analysis of the effect of micro phase separation on the charge transfer at the PEDOT:PSS and P3HT:PCBM layer interface

Min Huang, Tongji Univ. (China)

The influence of micro phase behavior on the charge transfer at the interface between PEDOT:PSS and P3HT:PCBM layers was studied using multiscale analysis. Calculated Flory-Huggins parameters indicated that the PEDOT attracts P3HT and repulses PCBM that agrees well with the experimental observation of the development of P3HT rich interface during the BHJ layer formation. Based on the calculated Flory-Huggins parameters, mesoscale DPD simulations were conducted for PEDOT:PSS and P3HT:PCBM layers. Results were mapped to the CG (coarse grained) and then atomistic scales where atomistic details of the interface were studied. The density of nonbonding close contacts including that from reorientation between PEDOT and P3HT was quantified, vibronic coupling and carrier transfer efficiency were discussed.

Control of ultrafast singlet exciton fission in antradithiophene derivatives: From 1 exciton to 2 exciton generation

Chaw Keong Yong, Olga Bubnova, Stavros Athanasopoulos, Univ. of Cambridge (United Kingdom); Jenny Clark, The Univ. of Sheffield (United Kingdom); John Anthony, Univ. of Kentucky (United States); Henning Sirringhaus, Univ. of Cambridge (United Kingdom)

Singlet exciton fission is a process that occurs in certain organic materials whereby one singlet exciton splits into two independent triplet excitons. In photovoltaic devices these two triplet excitons can each generate an electron, producing quantum yields per photon of >100%. We use ultrafast transient absorption spectroscopy to study the singlet fission dynamics in the thin film of antradithiophene derivatives. By controlling the intermolecular packing in the film via various solution processing routes and molecular side-chain engineering, we provide direct evidence for the control of the singlet exciton fission rate in the antradiothiophene neat films over a broad range from 10ps to 2ns, and eventually, no singlet exciton fission is observed in the amorphous neat film. Temperature dependent photoluminescence characterization further reveals peculiar radiative recombination rate. While singlet exciton fission is dominant at room temperature, the photoluminescence is dominated by the triplet-triplet annihilation and exhibits excimer-like spectra. The radiative recombination rate decreases as the substrate temperature is reduced to 120K. When the substrate temperature is further reduced to 5K, the photoluminescence is dominated by superradiance with the radiative recombination rate enhanced by a factor of 46, with respect to the radiative recombination rate observed at 120K. This work provides the foundation for ways to tailor the multicarrier generation in organic semiconductor by controlling the intermolecular interaction via solution processing routes and molecular side-chain engineering.

9567-77, Session PMon

Copper (I) oxide (Cu2O) as a hole transport layer for inverted perovskite solar cells

Rodrigo Szostak, Ivo B. Freitas, Ana Flavia Nogueira, Univ. Estadual de Campinas (Brazil)

Perovskite solar cells emerged six years ago with an efficiency of 3,0% and today an efficiency of 15% is easily achieved, reaching up to 20%. Several materials have been used in perovskite solar cells seeking high efficiency and low cost. Copper (I) oxide (Cu2O) is a p-type semiconductor, non-toxic, abundant and readily available. Cu2O can be synthesized easily by thermal oxidation of metallic copper. In this work, we report for the first time the introduction of Cu2O as hole transport layer in inverted perovskite solar cells with the ITO/Cu2O/CH3NH3PbI3/PC71BM/Al configuration. A thin layer of copper metal was deposited on ITO by thermal evaporation and the film is oxidized in air at room temperature. Perovskite was deposited by a two-step method. The band gap of the Cu2O film 2.52 eV. P-type conductivity and hole density in the order of 1017 cm-3 were determined from the Hall measurements. Valence-band of Cu2O is very close to the perovskite CH3NH3PbI3, so a comparable open circuit voltage (Voc) is expected. The inverted solar cells exhibited Voc of 0.83V and 0.74 V, Jcs of 0.34 and 0.32 mA/cm2, FF of 34.9 and 37.2%, in both forward and reverse bias with a delay time of 50 ms.

9567-78, Session PMon

Understanding the photo current generation in organic tandem solar cells utilizing a 3-terminal device architecture

Daniel Bahro, Manuel Koppitz, Adrian Mertens, Konstantin Glaser, Jan Mescher, Alexander Colsmann, Karlsruher Institut für Technologie (Germany)

Tandem architectures are one of the most promising concepts to boost organic solar cells towards competitive power conversion efficiencies. To develop a better understanding of the charge carrier generation and extraction mechanisms in organic tandem solar cells, it is of pivotal importance to access the subcells of the tandem device and to monitor their spectral response. Therefore we built 3-terminal devices with direct electric access to the PEDOT:PSS/ZnO recombination zone. By introducing this fully operational intermediate contact we overcome many drawbacks of previously published methods. By carefully choosing the thickness of the intermediate electrode, we maintain the optical field distribution and the optoelectronic properties and power conversion efficiencies (> 7%) of the corresponding 2-terminal device architectures. Utilizing this method, we developed models for the photovoltaic properties and the EQE under normal and oblique light incidence. To demonstrate the power of this approach, we focused on homo-tandem solar cells, which require more advanced optical characterization.

9567-79, Session PMon

Automated spray deposition for plastic electronics

Kirsty A. Roy, James Bannock, Neil Treat, John de Mello, Martyn McLachlan, Imperial College London (United Kingdom)

Spray deposition is a promising technique for the solution processing of plastic electronic devices, owing to the potential for high-speed, large-scale device fabrication using low capital cost equipment. To date most reports of spray-deposited electronic devices have used ultrasonic systems for film deposition to minimise surface roughness, but such systems suffer from low materials throughput, and are consequently ill-suited to industrial manufacturing. Pressure-driven spray heads enable higher throughput materials delivery but typically result in an unacceptably rough film due to the hard-impact nature of the deposition system.

Here we describe a new automated pressure-driven spray coater for the controlled deposition of a broad variety of solution processed electronic materials, which overcomes many of the disadvantages of conventional pressure-driven spray coaters. Key features of the system include: a novel, high performance 3D-printed spray-head for the generation of ultrafine sprays; full-three dimensional position and velocity control of the spray-head; integrated temperature control, and independent control of solution and gas rates.

The system allows for the controlled fabrication of thin film semiconducting polymers from non-chlorinated solvents. We investigate the influence of deposition variables such as solution carrier gas pressure, solvent composition and substrate temperature as well as post deposition treatments on the properties of the polymer films. We also demonstrate sequential deposition of oxide and organic materials, solvent annealing of polymer films and gradient doping of both organic and inorganic films.

9567-80, Session PMon

Selective non-contact modification of the polymer chain orientation and morphology in conducting polymers by femtosecond laser writing

Hyo Jung Kim, Sang Min Chae, See Wo Lee, Pusan National Univ. (Korea, Republic of); Jiyeon Choi, Korea Institute of Machinery & Materials (Korea, Republic of); Hyun Hwi Lee, Pohang Univ. of Science and Technology (Korea, Republic of)

We propose a novel direct writing technique with a femtosecond laser enabling selective modification of not only the morphology of conducting polymer thin films but also the orientation and alignment of the polymer crystals. Surface relief gratings resulting from photoexpansion on poly(3-hexylthiophene)(P3HT):[6,6]-phenyl-C61-butlyric methyl ester (PCBM) thin films were fabricated by a femtosecond laser direct writing. The photoexpansion was induced at laser fluence below the ablation threshold of the thin film. The morphology (size and shape) of photoexpansion could be quantitatively controlled by laser writing parameters such as focused beam size, writing speed, and laser fluence. Grazing incidence x-ray scsattering results showed that the amount of face-on P3HT crystals were largely increased in the photoexpansion in comparison with pristine region of the thin film. In addition, the P3HT polymer chains in the photoexpansion were highly aligned along the polarization of the laser. The micro-RAMAN spectra confirmed that neither chemical composition change nor the polymer chain breaking was observable after femtosecond laser irradiation. We believe that this laser direct writing technique opens a new door to the fabrication of more efficient organic semiconductor devices via non-contact, toxic-free approach.

Study of PEDOT: PSS and BCP thicknesses effect on SubPc/C60 organic solar cell efficiency

Nesrine Zoulikha Mendil, Mebarka Daoudi, Zakarya Berkai, Abderrahmane Belghachi, Univ. Tahri Mohammed Béchar (Algeria)

Most of the power generated nowadays is produced using fossil fuels, which emit tons of carbon dioxide and other pollution every second [1]. In order to make the development of our civilization sustainable and cause less harm to our environment, scientific people are looking for new source of substitute clean energy. The photovoltaic solar energy industry is one of the fastest growing forces in the market; therefore, the research of new

technology which uses cheap photovoltaic materials as well as fabrication methods to collect solar energy becomes more and more important. In 1986, the first organic thin-film solar cell with reasonable efficiency (up to 1%) was created and reported by Tang [1]. Since then, great interest has been devoted to the advantages of using organic materials in the solar cells field. The performance of organic solar cells depends on many parameters, such as absorption, charge transport, the diffusion length excitant, the status of interfaces, etc.

The choice of photo-active materials and metal electrodes is required to achieve good conversion efficiency. The latter can be improved by using organic semiconductor having a high absorption coefficient, good electrical conductivity and an adequate structuring of the photo-active layer, as well as the use of interpenetrating network concept in forming the cell. In this context, we chose the Fullerene (C60) used as the organic electron-acceptor for its high stability and high carrier mobility with a0=1.42nm and energy gap about 1.5eV [2]and Boron Subphthalocyanine Chloride (SubPc) as the electron-donor due to its high peak absorption coefficient (2.12?105cm-1 at ~590 nm) and with a0=1.2nm and energy gap about 2eV at ambient conditions[3]. The cell that we studied is composed of the following structure: ITO(30nm)/PEDOT:PSS(xnm)/SubPc(25nm)/C60(35nm)/ BCP(ynm)/Al(30nm), with different value of x=5,10,12,15,20 nm and y=8,10,12,14,16. So, the aim of our work is to investigate the effect of PEDOT: PSS and BCP thicknesses on the efficiency of this organic solar cell.

9567-82, Session PMon

Bulk-heterojunction morphologies of solution processed BODIPY solar cells

Alexander Colsmann, Jens Ludwig, Martin Hochberg, Karlsruher Institut für Technologie (Germany); Alexandre Cheminal, Jérémy Léonard, Univ. de Strasbourg (France); Stefan Haacke, Univ. de Strasbourg (France); Laure Biniek, Martin Brinkmann, Institut Charles Sadron (France); Nicolas Leclerc, Antoine Mirloup, Raymond Ziessel, Univ. de Strasbourg (France); Markus Kohlstädt, Uli Würfel, Nils Hofmann, Fraunhofer-Institut für Solare Energiesysteme (Germany); Patrick Lévêque, Univ. de Strasbourg (France); Thomas Heiser, Univ. de Strasbourg (France)

Because of reproducible syntheses and high material purities, light harvesting molecules with low molecular weight may enable organic solar cells with improved long-term stability. In contrast to polymers, however, low molecular weight organic compounds often show poor film forming properties due to strong molecular aggregation. In this work, we present 5% organic solar cells and corresponding mini-modules, fabricated from solution, comprising light harvesting BODIPY molecules. The devices exhibit long-time stable bulk-heterojunction morphologies and hence enhanced device life-time. The morphology can be adjusted by applying proper processing temperatures or suitable additives. We investigated the bulk-heterojunction morphology and performance by means of AFM, KPFM and conductive AFM. Photophysical investigations revealed the charge carrier dynamics within the active layer.

Using hydrogen-bond mediated supramolecular self-assembly to direct the formation of organic bulk heterojunction

Jiangeng Xue, Ronald K. Castellano, Nathan T. Shewmon, Davita L. Watkins, Weiran Cao, Benjamin M. Schulze, Xueying Zhao, Scott S. Perry, Johan F. Galindo, Adrian E. Roitberg, Univ. of Florida (United States)

Intermixing the organic donor and acceptor materials to form the so-called bulk heterojunction (BHJ) helps to circumvent the exciton diffusion bottleneck; however the overall photovoltaic properties critically depends on the BHJ morphology, which often is irregular and is hard to predict due to the complex interplay between thermodynamics and kinetics. Minor changes in molecular structures or processing conditions could lead to significant changes in morphology and device performance. Here, we report a supramolecular self-assembly approach to control the morphology of bulk hetejunctions to yield optimal charge generation and transport simultaneously. The design is based on convalently linking an appropriate hydrogen bonding unit to a donor chromophore, which directs the formation of star-shaped trimer rosettes through self-complementary H-bonding, as confirmed by both computation and STM characterization. Using grazing incidence X-ray scattering, we confirmed that the donor trimers preferentially stack along the substrate normal. The surface of the mixed film of H-bonding modified oligothiophene donor and C60 does not show any apparent lateral phase separation under AFM, further confirming the existence of one-dimensional donor columns and the interdigitated BHJ morphology. Compared to comparator molecules that do not enable intermolecular H-bonding, these H-bonding enabled molecules result in near doubling in the external quantum efficiency in solar cells, which coupled with the red-shifted absorption as a result of enhanced stacking leads to a more than two-fold increase in the overall power conversion efficiency. We expect that this H-bonding mediated supramolecular assembly approach could be a general platform to separately optimize the morphology of BHJs and the optoelectronic properties of the donor chromophores.

Study of electrical transport properties of P3HT using impedance spectroscopy

Camilo A. Otalora, Andres F. Loaiza, Gerardo Gordillo, Univ. Nacional de Colombia (Colombia)

In this work the electrical transport properties of devices with structure ITO/P3HT/M (M=Al or Ag) were studied using impedance spectroscopy. It was found that P3HT forms ohmic contacts with ITO and Ag while Schottky contact was observed with Al. The concentration of aceptor impurities in P3HT was determined; this proved to be about of 5,2x1016cm-3 in samples exposed to air for a short time, while an increment was observed by increasing the time of exposition. A study of the influence of the solvent type used to prepare the P3HT samples on the mobility of minority carriers (electrons) and majority carriers (hole) was additionally done. The higher mobilities were obtained on samples prepared using mesitylene; these have electron mobilities around 3,6x10-3 cm2V-1s-1 for electrons and 6,04x10-6 cm2V-1s-1 for hole. It was also determined that the charge carrier mobility strongly decreases with increasing exposure time.

Accurate correlation between panchromaticity and power conversion efficiencies in small molecule organic photovoltaic devices

Chenyu Zheng, Anirudh Raju Penmetcha, Brandon Cona, Jeremy Cody, Christopher J. Collison, Rochester Institute of Technology (United States)

Squaraines are targeted for application with bulk heterojunction devices since they can easily be chemically tailored while maintaining reproducibility in manufacturing compared to polymers, based on their singular molecular weight distribution.

Squaraines in solution have very narrow absorption spectra with very high extinction coefficients but are particularly attractive for photovoltaic application because of the substantial panchromaticity in the thin film, such that extinction coefficients are maintained over a very broad region of the solar spectrum. However, despite the promise of very high short circuit currents that would accompany broad absorption efficiency, large power conversion efficiencies have not materialized.

In this work we will present a full description of the excited state

populations and broadening mechanisms that give rise to the spectra of blended squaraine:PCBM active layers. The assignments of monomers and aggregates will be made for optical data from (i) mixed solvent nanoparticle studies, (ii) solid solution spectroscopy and (iii) comparisons before and after annealing of films. We will further confirm assignments with theoretical validation.

Given that aggregate states can be manipulated through choice of squaraine and processing conditions, we can probe the charge transfer process at the bulk heterojunction interface. Beyond panchromaticity, we describe how excited states must be predictably managed to positively influence the mechanism for improved efficiencies.

Nanostructure control in crystalline polymer-fullerene blends and its impact on the charge carrier dynamics in bulk heterojunction solar cells

Swaminathan Venkatesan, Qiquan Qiao, Devendra Khatiwada, Cheng Zhang, South Dakota State Univ. (United States); Jihua Chen, Oak Ridge National Lab. (United States)

High boiling point selective solvent additives are widely used for tailoring the nanomorphology in bulk heterojunction solar cells consisting of either crystalline or amorphous donor polymers. This study focuses and differentiates the role of solid additive namely 2,3-Pyridinediol (PD) on tailoring the nanostructure of bulk heterojunction solar cells consisting of donor polymers which are able to crystallize during film formation. Blend films cast from solutions consisting PD lead to formation of smaller domains and finer phase segregation between donor and acceptor as observed from AFM topography,phase and kelvin probe force microscopy (KPFM) images. Such a morphology leads to efficient solar cells attributed to significant enhancement in fill factor. However when PD is added to blend solutions consisting of amorphous polymers such as PBDTTT-C-T, the performance is drastically reduced compared to devices processed without any additive or with DIO additive. The importance of domain aggregation and phase separation for charge transport (mobility, carrier density and bimolecular recombination) will be highlighted for both crystalline and amorphous donor polymer-fullerene blends using photo-CELIV spectroscopy.Detailed understanding on the working mechanism of solid and liquid additive in film formation will also be shown. EFTEM and GIWAXS of blend films with liquid and solid additive will be compared to provide more insight on domain mixing, crystallization and orientation in several donor-acceptor blends.

Thermal and photo-stability of non-halide lead precursors in perovskite material

Fadi Kamal Aldibaja, Univ. degli Studi di Roma La Sapienza (Italy); Eva Unger, Lund Univ. (Sweden)

We present the use of halide (PbCl2) and non-halide lead precursors (Pb(OAc)2 (OAc=CH3CH2COO-), Pb(NO3)2, Pb(acac)2 (acac=(CH3COCHCOCH3)-) and PbCO3) for the preparation of perovskite solar cells. We have confirmed by X-ray diffraction the growth of CH3NH3PbI3 in all the analyzed cases, except for PbCO3, independently of the lead precursor used for the synthesis of the perovskite. In addition, different cell configurations, thin film and mesoporous scaffolds, TiO2 or Al2O3, have also been prepared. We have observed that the lead precursor influences strongly in the structural properties of perovskite (grain size), as well as on the solar cell performance. Photovoltaic conversion efficiencies comparable to those achieved when using the commonly employed PbCl2 have been obtained with Pb(OAc)2 as lead source. Stability studies of the perovskite films and devices have also been carried out; demonstrating that the lead precursor also influences this aspect. Stability is strongly affected by atmosphere and illumination conditions, but also by the lead precursor employed for the perovskite synthesis, detecting higher stability when using PbCl2 instead of Pb(OAc)2. These results highlight that other lead sources, different to the commonly used PbCl2 and PbI2, are also suitable for the development of PSCs, opening a new way for device performance optimization.

The comparison of photoinduced excited energy transfer and electron transfer in organic-inorganic compound

Wenping Yin, Yan Cui, Hee-won Shin, Jungwoon Yang, Sungkyunkwan Univ. (Korea, Republic of); Arkady P. Yartsev, Lund Univ. (Sweden); Tae Kyu Ahn, Sungkyunkwan Univ. (Korea, Republic of)

A family of ZnP-Tri-SWNT conjugates as Donor-Linkage-Acceptor (D-L-A) photosynthetic mimics was designed and synthesized, achieving efficient intramolecular excited energy transfer (EET), as well as deeper understanding of the competition between energy transfer (ENT) and electron transfer (ET) dynamics.

We composited Znic(II)-porphyrin(ZnP) with different single walled carbon nanotube(SWNT) via high selective copper-catalyze azide-alkyne cycloaddition (CuAAC) reaction— with a single change in their connection without excessive destroy the delocalized electron structure in SWNT. Due to the D-L-A systems store energy mainly according to the drive of higher net electron transfer rate, achieving long term charge separate state, which can be severely affected by the linkage different. We demonstrated phenyl (ZnP-ph-SWNT) and bi-phenyl (ZnP-biph-SWNT) linkage dependent photoinduced excited energy transfer in each sample according to XPS, FTIR, Photoluminescence, Time Correlated Single Photo Counting (TCSPC), Streak Camera and femto-second Transient Absorption (fsTA) analysis.

In order to get rid of the possibility of non-covalent effect between ZnP and SWNT, we mixt ZnP and SWNT using physical method. Although both of non-covalent and covalent showed PL quenching effect, with about 20% and 80-90%. ZnP-SWNT has a much faster delay life time, less than 10ps, which comes from photoinduced EET. Uv-vis and NIR fsTA proved the ion pair exsit more than 300ps after electron transfer from ZnP to SWNT. We also tried to follow the kinetic change of porphyrin fluorescence peak at 660nm in fsTA, which showed more information of electron injection of each sample.

The variation in charge separation and charge recombination dynamics is mainly associated with the electronic properties of the conjugates, including orbital energies, electron affinity and the energies of the excited states. The charge of the electronic coupling is in turn, a consequence of the different connectivity patterns at the triazole moieties. Excited energy transfer is correlation with the length of linkage, as the basic for bond but not space electron transfer. Our study in ENT and ET comparative analysis is not only used in the energy since, but also used in industrial research, such as the nonlinearity of CNT itself, and even in clinical medicine.

9567-91, Session PMon

Sterically protected small molecules as novel donors for efficient bulk heterojunction solar cells

Swaminathan Venkatesan, Qiquan Qiao, South Dakota State Univ. (United States); Jihua Chen, Oak Ridge National Lab. (United States); Cheng Zhang, South Dakota State Univ. (United States)

The effect of steric ring protection on the morphology, structural, optical and device performance of a previously reported small molecular semiconductor is investigated and compared to small molecule without ring protection. Pristine films show significant large domains and surface roughness for small molecules without ring protection (SC371). Further

XRD and optical measurements show high aggregation and ordering of polymer in edge on orientation for small molecules thin films without ring protections. Films consisting of small molecule with ring protection (SC354) show smaller domains, smoother surface and completely amorphous nature. When blended with fullerene and cast as films similar properties are observed as in the case of pristine films. Bulk heterojunction solar cells consisting of SC371:PCBM active layer show high fill factor owing to interconnected pathways for electron and hole transport. SC354:PCBM cells show enhanced short circuit current density and open circuit voltage compared to SC371:PCBM cells attributed to higher extent of intermixing and finer phase separation. When 0.3% DIO is used as a solvent additive SC354:PCBM devices show comparable efficiency (~2.5%). Further charge carrier mobility, density and device stability of the two blends will be compared and evaluated. Sterically protecting organic semiconductors can serve as an effective strategy to tailor molecular structure for isotropic charge transport in low temperature processed organic electronics.

Impact of the Poole-Frenkel effect on charge transport in PDTSiTzTz:PCBM based photovoltaic devices

Oleksiy Slobodyan, Kelly Liang, Eric Danielson, Marlene Gutierrez, Sarah Moench, Bradley Holliday, David Vanden Bout, Ananth Dodabalapur, The Univ. of Texas at Austin (United States)

While organic solar cell (OSC) power conversion efficiencies >10% are a crucial threshold for industrial viability, active industrial scale production will likely require active material thickness greater than typically reported in literature. Of many of donor-acceptor copolymers, bulk heterojunction (BHJ) with (2-ethylhexyl)dithieno [3,2-b:2',3'-d] silole)-2,6-diyl-alt-(2,5-bis 3-tetradecylthiophen-2-yl thiazolo 5,4-d thiazole)-2,5diyl] (PDTSiTzTz) is one of the rare few reported to maintain high fill factors with thick active layers. The performance of PDTSiTzTz-containing OSCs coupled with its tolerance for higher layer thicknesses, make it an attractive materials system to study transport and recombination physics. We have extensively studied transport and recombination in PDTSiTzTz:PCBM using lateral photovoltaic structures. This materials system displays strongly reduced bimolecular recombination, with a bimolecular reduction factor <10-2. From our measurements, we obtain both electron and hole mobilities, and show that these values are carrier concentration dependent. Most unusually, the electron mobility displays a negative Poole-Frenkel effect. Numerical modeling of the lateral structure shows that accounting for the Poole-Frenkel behavior has a significant effect on charge carrier behavior within the active material channel. Applying numerical modeling to the vertical OSC structure demonstrates that results from lateral structures also provide insight into charge carrier transport in structures employed for collecting sunlight, thereby highlighting the importance of considering the Poole-Frenkel effect these photovoltaic devices.

Efficient perovskite solar cells employing polymers as effective hole transport layer

Ashish Dubey, Nirmal Adhikari, Swaminathan Venkatesan, Devendra Khatiwada, Qiquan Qiao, South Dakota State Univ. (United States)

Perovskite based solar cells have shown to be an highly efficient solution processable device, because of its broad band light absorbing property and high charge diffusion length. However, a long term stable perovskites still remains a challenge, yet to overcome. Perovskite, inherently absorbs moisture, and its solar cell device design utilizes most widely used hole transport layer, spiro-OMeTAD, which is doped with lithium salt and tert-butyl pyridine, causing further degradation. Herein, we report stable p-type polymer as effective hole transport layer sandwiched between perovskite thin film and top electrode. In this work we have optimized the device structure by studying the perovskite film morphology with varying annealing time, varying polymer concentration and hole transport layer thickness. These low temperature solution processed polymer film showed excellent photovoltaic properties with power conversion efficiency greater than 8%. With further optimization in device design, by introducing effective interfacial layers can enhance extraction of electrons and holes from the solar cell leading to high PCE.

9567-94, Session PMon

Surface modification of electron selective metal oxide thin films in organic solar cells for enhanced efficiency and stability

Swaminathan Venkatesan, Evan C. Ngo, Qiquan Qiao, Cheng Zhang, South Dakota State Univ. (United States)

P3HT:PCBM solar cells with bi-layer interfaces consisting of metal oxide thin films with cationic polymer modification namely Polyethylenimine ethoxylated (PEIE) showed enhanced lifetime compared to bare metal oxide interfaces. The device characteristics are periodically investigated in illuminated and dark conditions for 180 days. It is found that performance of devices with zinc oxide (ZnO) and aluminum doped zinc oxide (AZO) drops to 56% of initial efficiency after ageing. While the devices with PEIE modification showed above 75% of their initial efficiency after 180 days of ageing. The higher degradation in ZnO and AZO based devices arises mainly due to lower fill factor. Kelvin probe measurement show small reduction in work function of the bare oxide films. Kelvin probe microscopic images show a significant reduction in surface potential of bare ZnO with 7 days of ageing. The reduction in surface potential is shown to be due to surface oxidation which leads to p-type of doping of of metal oxide. This oxidative doping leads to higher trap assisted recombination between P3HT-ZnO interface detrimental to the device lifetime. Hence passivation of charge selective interfaces is crucial to enhance the bulk heterojunction solar cell's stability and paves path to a low cost solution based approach for large scale roll to roll processing.

Inkjet printing of organic photovoltaics using a water-based active layer ink

Anirudh Penmetcha, James Sinka, Chenyu Zheng, Christopher J. Collison, Rochester Institute of Technology (United States)

Chlorinated and Aromatic solvents typically used for the processing of Organic Photovoltaics, may not be used in large scale manufacturing of OPVs as they pose serious risks towards human health and the environment. Thus there is a need to develop a medium by which the OPV materials may be processed safely.

In this study, we focus on improving the processability of the active layer materials (P3HT:PCBM). By using a miniemulsion process, we fabricated and dispersed P3HT:PCBM nanoparticles in a "safe" solvent i.e water. We choose P3HT:PCBM the materials of choice due to them being benchmark materials in literature. Blend ratios of the P3HT:PCBM nanoparticles are characterized using UV-Vis and Fluorescence spectroscopy; we show that the blend ratio of the nanoparticle can be optimized (1:0.8) by modifying the initial concentrations of the donor and acceptor in the miniemulsion phase.

We modified the nanoparticle dispersion's surface tension to convert them into inks for inkjet printing; we improve the wettability of the ink on the PEDOT:PSS layer of the OPV. The nanoparticle ink was printed onto PEDOT:PSS coated ITO slides. Aluminum cathodes were evaporated ontop of the printed active layer to complete the OPV device structure. The OPVs were characterized for their Power Conversion Efficiency; the best device had a PCE of 0.07%. This proof of concept result is very promising as it is a stepping stone between lab-based prototype devices and large scale manufacturing.

9567-96, Session PMon

Photo-stability of crystalline large-grain planar perovskite solar cell

Wanyi Nie, Hsinhan Tsai, Amanda Neukirch, Jean-Christophe Blancon, Hsing-Lin Wang, Jared Crochet, Gautam Gupta, Los Alamos National Lab. (United States); Muhammad Alam, Purdue Univ. (United States); Sergei Tretiak, Aditya Mohite, Los Alamos National Lab. (United States)

Organometallic perovskite based planar solar cell have emerged the most promising thin film solar cell technology largely due to high power conversion efficiency. However, photo-stability of perovskite solar cells under constant illumination for several hours of outdoor operation is yet to be realized. Here, we demonstrate the synthesis of large grain size (mms) perovskite solar cells and study the photo-stability of these devices. We measured the JSC, VOC and FF under constant illumination with device maintained at A) open circuit B) short circuit and C) at forward bias with no illumination and record the J-V scan under one-Sun illumination. The results show that the VOC does not degrade for all conditions. However, under open-circuit condition, there is a degradation of the JSC by ~40%, whereas at short-circuit condition ~10% degradation in JSC is observed. All the figures of merit return to their original value, when the device is maintained in dark (>60 mins) suggesting that the large grain perovskite crystal structure does not degrade with long-term illumination. We attribute the degradation in the JSC to photo charging of the device by the filling of sub-gap trap states, which accumulate at open circuit and cause degradation in JSC under flat band condition. However, under short circuit condition, photo-generated charges can drift out of these states due to the build-in potential thus preventing charge accumulation and no significant loss in the JSC. Under dark (C point), the captured free carrier can drift out, which in complete recovery of the key parameters. We validate our observation using Capacitance-Voltage measurement by extracting the charge density profile. We also demonstrate that by operating at a certain desired power point results in relatively photo-stable perovskite solar cells.

9567-97, Session PMon

Efficient vacuum-deposited tandem organic solar cells with fill factor higher than single junction subcells

Hyun-Sub Shim, Seoul National Univ. (Korea, Republic of); Francis Lin, National Taiwan Univ. (Taiwan); Jihun Kim, Bomi Sim, Tae-Min Kim, Chang-Ki Moon, Yongsok Seo, Seoul National Univ. (Korea, Republic of); Chun-Kai Wang, Ken-Tsung Wong, National Taiwan Univ. (Taiwan); Jang-Joo Kim, Seoul National Univ. (Korea, Republic of)

Tandem structures have been used to enhance device performance because of the use of broader solar spectra converted into the current. Moreover, open circuit voltage (VOC) or short circuit current density (JSC) can be increased if the sub-cells are connected in the series or parallel structures, respectively.

The vacuum deposition have several advantages such as the ease of purification via the sublimation, no use of solvents which might damage pre-deposited layer and the precise control of the thickness of layers in the nanometer scale. Despite of these advantages, most vacuum-deposited OPVs show lower efficiency compared with solution-processed OPVs due to the difficulty in forming charge transporting path in the blended active layer, resulting in the lower JSC and fill factor (FF).

In this paper, we demonstrates efficient vacuum-deposited tandem OPVs whose device structures are 80 nm-thick sub-cells connected by the interconnection unit (ICU) composed of electron-transporting layer (ETL)/ metal/p-doped hole-transporting layer (p-HTL). The p-doped layer in the ICU enables tuning the sub-cell position in the devices to have the maximum optical field distribution for increasing JSC without any electrical loss. Moreover, it enhances FF due to the reduction of the contact resistance caused by the p-doped layer in the ICU. As a result, power conversion efficiency (PCE) of 9.2% with JSC of 8.7 mA/cm2 and VOC of 1.7 V is obtained. FF of 0.62 is achieved, which is higher than the one of the single junctions although the thickness of the sub-cells is relatively thick with 80 nm.

9567-98, Session PMon

Application of metal nanoparticle-conducting polymer composite to organic based solar cells

Sungho Woo, Wook Hyun Kim, Shi-Joon Sung, Daegu Gyeongbuk Institute of Science & Technology (Korea, Republic of)

Recently, organic based solar cells, those are using organic light absorption materials such as organic solar cells (OSCs) and dye-sensitized solar cells (DSSCs), have attracted a lot of attention due to their unique advantages including low cost, solution processability, and mechanical flexibility. Although their power conversion efficiencies (PCE) have been improved dramatically, there are still many limitations for practical applications.

In OSCs, the difficulty of increasing the active layer thickness due to the limitation of the exciton diffusion length and the poor charge transport property leads to insufficient absorption of incident light. To improve light absorption in the organic photoactive layer, the application of surface plasmons (SPs) based on metal nanoparticles (NPs) has been reported.

In flexible DSSCs, the thermally reduced Pt counter electrode (CE) should be replaced by low temperature process and material, because most flexible plastic substrates cannot bear at high temperature up to 400 ?. Hence it is strongly required to develop a process that can reduce the annealing temperature.

Here, we made metal NPs generated via in-situ method inside PEDOT:PSS conducting polymer solutions. The prepared Ag or Au NPs-PEDOT:PSS composite was applied to hole transport layer in OSCs, and Pt NPs-PEDOT:PSS composite was applied to CE in DSSCs. The improvement of device performance was mainly attributed to the high specific surface area and catalytic activity due to the support of small amounts of metal NPs incorporated in the PEDOT:PSS media.

9567-99, Session PMon

Dye anchoring functional groups on performance of dye sensitized solar cells: Comparison between alkoxysilyl and carboxyl groups

Sri Kasi V N R. Matta, RMIT Univ. (Australia); Yasuhiro Tachibana, RMIT Univ. (Australia) and Osaka Univ. (Japan); Kenji Kakiage, Yano Toru, Adeka Corp. (Japan)

Performance of dye sensitized solar cells (DSSCs) is driven by photo-induced charge transfer processes mimicking natural photosynthetic reaction systems. Following excitation of a dye sensitizer, efficient forward and slow reverse charge transfer processes are required. These reaction kinetics are controlled at the interfaces of materials and charge transport processes in the cell. Interfacial material design is therefore crucial to improve the performance of DSSCs.

Herewith, two dye anchoring functional groups, alkoxysilyl and carboxyl groups, were compared to investigate their influence on the performance of DSSCs. Dimethylaminoazobenzene was selected as a chromophore possessing a donor-accepter transition for the light absorption. Electrochemical and optical measurements were performed for 4-dimethylaminoazobenzene-4'-carboxylic acid and 4-dimethylaminoazobenzene-4'-triethoxysilane attached TiO2 films. Electrochemical measurements and DFT calculation indicated almost identical potential energy levels and electron density of HOMO and LUMO

states between these two dyes. Solar cell APCE spectra and charge recombination kinetics at the dye/TiO2 interface revealed almost identical charge transfer rates/yields from and to the dye. The difference observed on improvement of an open circuit photovoltage (Voc) by 60 mV and on the lifetimes of an electron in the TiO2 conduction band for the dye with the alkoxysilyl functional group, suggesting that an alkoxysilyl functional group is more attractive to retard the charge recombination reaction between an electron in the TiO2 conduction band and an oxidized form of an electrolyte redox couple. The highest solar energy conversion efficiency of 2.6 % was achieved for DSSCs based on an azobenzene dye sensitizer under AM1.5G, one sun condition.

9567-100, Session PMon

Improved hole transport layers in perovskite solar cells based on functionalized carbon nanostructures doped P3HT

Teresa Gatti, Univ. degli Studi di Padova (Italy); Simone Casaluci, Univ. degli Studi di Roma "Tor Vergata" (Italy) and Ctr. for Hybrid and Organic Photovoltaics (Italy); Aldo Di Carlo, Univ. degli Studi di Roma "Tor Vergata" (Italy); Enzo Menna, Univ. degli Studi di Padova (Italy)

Perovskite solar cells (PSCs) fabricated with two step deposition have been prepared and tested using P3HT as hole transport layer (HTL). P3HT was dissolved in chlorobenzene and blended with single walled carbon nanotubes (SWCNTs) and rGO graphene nanoplatelets (GNPs) bearing on the external surface covalently bound para-methoxyphenyl substituents, aimed at improving their homogeneous mixing with the semiconducting polymer. The SWCNTs and GNPs used for P3HT doping have been functionalized using aryl diazonium chemistry, keeping the amount of functionalities in a range which allows to gain better solubility but do not affect their electronic properties. Caution was taken in order to obtain blends with no insoluble GNPs residues, by applying a thorough protocol of sonication/centrifugation steps before spin coating the HTL on top of the hybrid junctions. Different weight percentages of functionalized GNPs/P3HT were deposited, in order to determine the optimum percentage. Such doping of the P3HT layer resulted in increased efficiencies and prolonged stabilities of the resulting PSCs with respect to devices with undoped P3HT HTLs. The best solar cells showed a power conversion efficiency (PCE) up to 11.7 %. These promising results prompted us to test the effect of functionalized SWCNTs and GNPs doping on other hole-conductors, such as spiro-OMeTAD, in order to improve results of stability tests.

9567-101, Session PMon

High-performance planar-heterojunction perovskite solar cell using surface modified hole-transport layer

Santanu Bag, UES, Inc. (United States); Michael F. Durstock, Air Force Research Lab. (United States)

Perovskite solar cells based on organic/inorganic hybrid methyl-ammonium lead trihalide absorber materials are attractive for low-cost energy harvesting because of their advantages in solution processability, mechanical flexibility, rapid improvement of power conversion efficiencies to greater than 15%, and lack of rare elements. However, fabrication of most high-performance perovskite solar cells often involves use of compact or mesoporous metal-oxides as charge-selective layers that require high temperature (>400°C) sintering and prevent their applicability to flexible plastic based devices. Thus, perovskite device structures devoid of metal-oxide interlayers are highly desirable for integration of devices into flexible form factors. Among various alternatives, poly(3,4-ethylenedioxythiophene):poly(4-styrenesulfonate) (PEDOT:PSS) is an attractive hole-transporting interlayer (HTL) material due to its low-temperature solution processability, commercial availability, tunable conductivity and extraordinary bending property. Although promising, the perovskite film growth on PEDOT:PSS has to overcome certain challenges in a planar heterojunction architecture in order to achieve higher efficiencies. Formation of crystallite islands of perovskite on top of PEDOT:PSS often leads to pinhole generation and incomplete surface coverage resulting in low device performance. Here we will demonstrate a new surface passivation strategy to improve the perovskite film coverage on PEDOT:PSS hole-transport layer and thereby increase the photovoltaic power conversion efficiencies. A simple passivation method based on thiourea treatment on a very thin PEDOT:PSS layer in a glass/ITO/PEDOT:PSS/CH3NH3PbI3/PCBM/C60/Al device structure shows enhanced efficiency close to 10%. These findings highlight the importance of surface modification for achieving high performance metal-oxide free solution processed perovskite solar cells.

9567-102, Session PMon

Harnessing atomic layer deposition to directly map the morphology of organic photovoltaic bulk heterojunctions

Stas Obuchovsky, Gitti Frey, Technion-Israel Institute of Technology (Israel)

Investigating the morphology of OPV BHJ is extremely challenging, as no direct high-resolution characterization methods are available for such systems. We show that atomic layer deposition (ALD), a conventional thin-film processing technique, can be used as a characterization tool to directly map the morphology of OPV BHJs. ALD is commonly used for producing conformal coatings on top of a given substrate. However, when applying metal-oxide ALD onto organic materials with no surface reactivity, the precursors diffuse into the organic film and generate a sub-surface deposition of the metal oxide.

Here we demonstrate the use of ALD for studying OPV BHJ morphology by ZnO precursor diffusion and in-situ conversion in P3HT:PCBM blends. We find that PCBM and ZnO compete over the amorphous domains of P3HT, mapping the location of ZnO by HRSEM can be used to identify the vertical distribution and solubility limit of PCBM in P3HT. We find that during film processing PCBM segregates to the bottom interface, its solubility in P3HT is ~17%. This study demonstrates a new, alternative and general method for the visual characterization of organic functional blends.

9567-304,

Recent progress on hybrid organic-inorganic and perovskite-based solar cells

Yang Yang, Univ. of California, Los Angeles (United States)

By combining the attributes from both organic and inorganic species, the light-harvesting hybrid perovskite (e.g. CH3NH3PbI3) materials possess amazing physical properties that led to high performance solar cells within only a few years of research. Film formation and interface engineering of perovskite materials are crucial parameters that determine the resulting solar cell efficiency. Besides single junction perovskite-based solar cells, research has turned to the tandem devices that combine another low band gap material such as Si in order to achieve even higher efficiency. My presentation will summarize recent progress in this field and report on new results from UCLA (e.g. interface engineering, perovskite-based photodetectors and tandem solar cells).

Design principles in polymer-fullerene bulk-heterojunction solar cells: A focus on PBDTTPD and wide-bandgap analogs *(Invited Paper)*

Pierre M. Beaujuge, King Abdullah Univ. of Science and Technology (Saudi Arabia)

With published power conversion efficiencies (PCE) >8% in bulk-heterojunction (BHJ) solar cells with fullerene acceptors (single cells), and PCEs >10% in tandem devices, solution-processable ϖ-conjugated polymers continue to garner much interest across the PV community. In this context, forging a better understanding of the critical material parameters that impact BHJ device performance is of paramount importance. Our recent work with poly(benzo[1,2-b:4,5-b']dithiophene–thieno[3,4-c] pyrrole-4,6-dione) (PBDTTPD) and wide-bandgap analogs blended with phenyl-C61/71-butyric acid methyl ester (PCBM) sheds light on several structural parameters that critically impact polymer performance, such as the combination of side-chain substituents and the identity of the functional groups appended to the main chain.[1-11] In many instances, morphological aspects are convoluted with the unique pattern of electronic and self-assembling properties of the polymer donor, and broader systematic analyses can help improve our understanding of those correlated effects. [1-11] In parallel, our recent developments show that PBDTTPD and wide-bandgap analogs (harvesting sunlight in the range 400-650 nm) are some of the most promising systems for use in the high-band-gap cell of tandem and triple-junction solar cells. High-efficiency wide band-gap polymers are required in order to continue improving upon currently reported PCEs in multi-junction solar cells.

9567-4, Session 1

Aggregation and morphology control enables polymer solar cells with efficiencies near 11.5%

He Yan, Hong Kong Univ. of Science and Technology (Hong Kong, China)

Current high-efficiency (>9.0%) PSCs are restricted to materials combinations that are based on limited donor polymers and only one specific fullerene acceptor, PC71BM. Furthermore, best-efficiency PSCs are mostly based on relatively thin (100 nm) active layers. Here we first report multiple cases of high-performance thick-film (300 nm) PSCs (efficiencies up to 10.8%, fill factors up to 77%) based on conventional PCBM and many non-PCBM fullerenes. Our simple aggregation control and materials design rules allowed us to develop, within a short time, three new donor polymer, six fullerenes (including C60-based fullerenes), and over ten polymer:fullerene combinations, all of which yielded higher efficiency than previous state of art devices (~9.5%). The common structural feature of the three new donor polymers, the 2-octyldodecyl (2OD) alkyl chains sitting on quaterthiophene, causes a temperature-dependent aggregation behavior that allows for the processing of the polymer solutions at moderately elevated temperature, and more importantly, controlled aggregation and strong crystallization of the polymer during the film cooling and drying process. This results in a well-controlled and near-ideal polymer:fullerene morphology (containing highly crystalline, preferentially orientated, yet small polymer domains) that is controlled by polymer aggregation during warm casting and thus insensitive to the choice of fullerenes. The 2OD structural motif is then further applied to several other polymer backbones and produces three additional polymers with efficiencies between 10-11.5%. Our best efficiency (11.5%) is achieved via the combination of new structural designs, interface and optical engineering and optimizations on the solvents and additives of the polymer:fullerene solution.

9567-44, Session 1

Poly(sulfobetaine methacrylate)s as electrode modifiers for inverted solar cells *(Invited Paper)*

Hyunbok Lee, Egle Puodziukynaite, Todd Emrick, Alejandro L. Briseño, Univ. of Massachusetts Amherst (United States)

We demonstrate the use of polymeric zwitterions, namely, poly(sulfobetaine methacrylate) (PSBMA), as solution-processable work function reducers for inverted organic electronic devices. A notable feature of PSBMA is orthogonal solubility relative to solvents typically employed in the processing of organic semiconductors. A strong permanent dipole moment on the sulfobetaine moiety was calculated by density functional theory. PSBMA interlayers reduced the work function of a broad range of electrodes [indium tin oxide (ITO), Au, Ag, poly(3,4-ethylenedioxythiophene):poly(st yrenesulfonate) (PEDOT:PSS), Cu, Al, and even graphene] by over 1 eV. By employing an ultrathin interlayer of PSBMA, one can reduce the electron injection barrier between ITO and C70 by 0.67 eV. As a result, the device performance of OPVs with PSBMA interlayers are significantly improved, and enhanced electron injection is demonstrated in electron-only devices with ITO, PEDOT:PSS and graphene electrodes. This work makes available a new class of dipole-rich, counterion-free, pH insensitive interlayers for use as strong work function reducers for any electrode.

9567-5, Session 2

Fabricating thin-film photovoltaic devices using ultra-sonic spray-coating *(Invited Paper)*

David G. Lidzey, The Univ. of Sheffield (United Kingdom)

The scale-up of thin-film electronic devices requires a manufacture tool set that is capable of fabricating thin films at high speed over large areas. One such technique capable of such a task is ultra-sonic spray coating. Here, a target solution is fed onto a vibrating tip that breaks the solution up into very fine droplets, with such droplets being carried to a surface by a gas stream. Such ultra-sonic coating processes are already widely used in Electronics, Medical and Displays industries to create films having excellent smoothness and homogeneity.

In this talk, I describe the use of ultra-sonic spray-coating to deposit a range of materials for thin-film optoelectronics. As our spray-coating system operates in air, it was first necessary to explore the relative sensitivity of various conjugated polymer / fullerene blends to an air-based process route. It is found that carbazole based co-polymers are particularly stable, and can be processed in air (by spin-coating) into organic photovoltaic devices (OPV) without any apparent loss in device efficiency. I then show that spray-coating can be used to deposit a range of semiconductor materials into smooth, thin-films, including PEDOT:PSS, MoOx (from a precursor) and

a series of polymer:fullerene blends. Using such a technique, we are able to scale up an array of devices having an area of 7 cm2, and using a PBDTTT-EFT:PC70BM blend, obtain OPVs having a power conversion efficiency (PCE) of 8.7%. I then discuss spray-coating as a method to fabricate photovoltaic devices based on CH3NH3PbI(3-x)Clx perovskite films. Here, by optimization of deposition parameters, devices are created having a PCE of 11.1%.

9567-6, Session 2

Activating grain boundaries for high-performance hybrid perovskite solar cells

Bin Yang, Oak Ridge National Lab. (United States); Ondrej Dyck, The Univ. of Tennessee Knoxville (United States); Jonathan Poplawsky, Jong Keum, Alexander Puretzky, Oak Ridge National Lab. (United States); Sanjib Das, The Univ. of Tennessee Knoxville (United States); Ilia Ivanov, Christopher Rouleau, Oak Ridge National Lab. (United States); Gerd Duscher, The Univ. of Tennessee Knoxville (United States); David Geohegan, Kai Xiao, Oak Ridge National Lab. (United States)

Grain boundaries (GBs) in the crystal structure detrimentally decrease power conversion efficiency (PCE) in hybrid organometal halide-perovskite solar cells, where defects, traps as well as energetic disorder cause significant non-radiative recombination energy loss. In this talk, we will show that, rather attempting to passivate or eliminate GBs, we activate GBs as active carrier collection channels for increased carrier collection efficiency.1 Space-charge-regions between each grain can suppress non-radiative recombination and enhance carrier collection efficiency. Solar cells with activated GBs yielded average PCE of 16.3±0.9%, comparable to the best solution-processed perovskite devices. Optimizing the morphology and activating the GBs of perovskite solar cells appears to be a promising pathway toward theoretical maximum PCE through industrially realistic processing techniques.

This research was conducted at the Center for Nanophase Materials Sciences ((CNMS)), which is a DOE Office of Science User Facility.

9567-7, Session 2

Additive controlled solution process for high efficiency perovskite solar cells *(Invited Paper)*

Kai Zhu, National Renewable Energy Lab. (United States)

Methylammonium lead halide perovskites represent a novel class of absorbers for solar conversion applications. Solar conversion efficiencies over 15%–17% have been demonstrated by multiple groups. Various perovskite absorbers (e.g., CH3NH3PbI3, CH3NH3PbI3-xClx, and CH3NH3PbBr3) and device architectures (e.g., mesoporous and planar cell configurations) have been examined with promising results by using either solution processing or thermal evaporation. Controlling the morphology and composition of the perovskite layer has been found critical for developing high-performance perovskite solar cells. Here we demonstrate that the use of chemical additive (e.g., CH3NH3Cl) in the precursor affects strongly the perovskite crystallization kinetics and film formation process for both the one-step and two-step sequential solution deposition approaches. For one-step deposition, the additive primarily serves as a glue or soft template to control the initial formation of a solid solution of precursor film. A subsequent thermal decomposition process leads to the formation of perovskite films with good surface coverage and device characteristics. The thermal decomposition process is also found beneficial for accelerating PbI2-to-perovskite conversion for two-step sequential deposition. The effect of using additive on the structural, optical, and electronic properties of perovskite films and device characteristics of perovskite solar cells are reported.

9567-9, Session 2

Perovskite thin film formation during solution processing: An In situ time-resolved multiprobe investigation *(Invited Paper)*

Aram Amassian, King Abdullah Univ. of Science and Technology (Saudi Arabia)

The efficiency of perovskite solar cells has risen at a remarkable pace in recent years. The solution-to-solid phase transformation process leading to the formation of the light harvesting perovskite layer is universally acknowledged as being important to control to achieve efficient perovskite solar cells and has understandably been the subject of several ex situ investigations looking at understanding the perovskite conversion process and the influence of processing conditions, formulations, environmental conditions and surface modifications on the nucleation and growth of perovskite thin films. Yet, despite this great interest in the phase transformation process there are important technical challenges which have prevented in situ time-resolved investigations during the actual solution process (e.g., spin-coating, blade-coating or spray-coating).

We have successfully performed time-resolved in situ grazing incidence wide angle x-ray scattering (GIWAXS) measurements during the spin-coating and subsequent thermal annealing of planar and mesostructured perovskite thin films based on three different halides (chlorine, bromine and iodine). The GIWAXS measurements are complemented by in situ optical reflectometry and transmission measurements which can also be performed during spin-coating, making it possible to estimate the solvent evaporation rate, the time-evolution of solution concentration and link the onset of nucleation and subsequent growth of perovskite phases (as detected by GIWAXS and/or UV-vis absorption) to the solution drying process. We will discuss our findings with respect to perovskite thin film formation kinetics and mechanisms for different halides, solution compositions, environmental conditions and substrates.

9567-14, Session 3

Sub-ns triplet state formation in polymer:fullerene photovoltaic blends *(Invited Paper)*

Frédéric Laquai, Max Planck Institute for Polymer Research (Germany)

I will present recent results on charge generation, recombination, and triplet state formation in various bulk heterojunction photovoltaic blends investigated by femto- to microsecond broadband Vis-NIR transient absorption (TA) pump-probe spectroscopy. Specifically, we looked into the processes following exciton dissociation in low-bandgap polymer and small molecule solar cells using either fullerene or non-fullerene acceptors. As a first example I will show results obtained on the donor-acceptor copolymers PCPDTBT and its silicon-substituted analogue PSBTBT.[1] Here, broadband TA experiments in combination with sophisticated data analyses techniques such as evolving factor analysis (EFA) and multivariate curve resolution with alternating least squares (MCR-ALS) [2] revealed that after exciton dissociation and free charge formation is completed fast sub-nanosecond non-geminate recombination occurs and leads to a substantial population of the polymer's triplet state. The extent to which triplet states are formed depends on the initial concentration of free charges, which itself is controlled by the microstructure of the blend, especially in case of PCPDTBT:PC60BM. Interestingly, PSBTBT:PC70BM blends showed a higher charge generation efficiency, but less triplet state formation at similar free charge carrier concentrations. This indicates that the solid-state morphology and interfacial structure of PSBTBT:PC70BM blends reduce non-geminate recombination and thus triplet state formation, leading to increased

device performance compared to optimized PCPDTBT:PC60BM blends. Based on the aforementioned observations I will extend the discussion to other material systems relevant for organic photovoltaic devices such as PBDTTPD:PCBM,[3] PBDTTT-C:PCBM and DPP-based copolymers.

9567-15, Session 3

2D- and trap-assisted 2D-Langevin recombination in polymer:fullerene blends

Mathias Nyman, Oskar J. Sandberg, Ronald Österbacka, Åbo Akademi Univ. (Finland)

We have clarified the impact of trapping on the recombination dynamics in polymer:fullerene blends using the highly ordered bulk heterojunction blend poly[2,5-bis(3-tetradecylthiophen-2-yl)thieno[3,2-b]thiophene] (PBTTT) and [6,6]-phenyl-C61-butyric acid methyl ester (PCBM) at different weight ratios as a model system. The recombination dynamics are determined using both transient charge extraction and steady state techniques. In addition, the theory of 2-dimensional Langevin recombination is extended to the case with high trap density.

Using photo-CELIV we show that both the recombination dynamics and the recombination reduction factor in PBTTT:PCBM at a 1:4 weight ratio are consistent with 2D-Langevin. In a 1:1 weight ratio, however, the recombination is much less reduced although the dynamics still roughly follow a t^-3/2 dependence. In order to further elucidate the recombination mechanisms the so called light ideality factor is a useful tool. The light ideality factor describes the slope of the exponential dependence of the recombination rate on voltage and is distinctly different for different recombination mechanisms. Systems displaying 2D-Langevin should have a light ideality factor m = 0.8 whereas m = 1 is expected in the 3D-Langevin case. We measured m = 0.87 in the 1:4 case and m = 1.15 in the 1:1 case.

The recombination capture coefficients are derived both for trap-assisted and band-to-band recombination and it can be seen that anisotropic charge transport reduces the capture coefficients in both cases resulting in a reduced overall recombination.

9567-16, Session 3

Manipulation of the dielectric constant of non-fullerene organic semiconductors *(Invited Paper)*

Paul L. Burn, Jenny Donaghey, Ardalan Armin, Paul Meredith, The Univ. of Queensland (Australia)

Inorganic (crystalline) semiconductors used in solar cells have a high dielectric constant (?r > 10) that results in a low exciton binding energy (C.f. Si: 15.0 meV; GaAs: 4.2 meV; CdTe: 10.5 meV). Such low binding energies make inorganic devices operate in a ‘non-excitonic’ regime at room temperature. Conversely, organic semiconductors have typically low dielectric constants (?r < 4) and exciton binding energies of several hundreds meV. Thus, homojunction organic diodes tend to have low efficiency as neither thermal activation nor external electric field are sufficient to efficiently overcome the strong Coulombic interaction of the excitons. Recently, Hummelen et al have shown that the introduction of triethylene glycol monoethyl ether (TEG) chains to fulleropyrrolidines resulted in a 46% increase in dielectric constant [1]. In this presentation we discuss how non-fullerene acceptors can be engineered to give high film dielectric constants and how the dielectric constant affects the optoelectronic properties.

9567-17, Session 3

Exciton binding energy limitations in organic materials and potentials for improvements

Stefan Kraner, Reinhard Scholz, Technische Univ. Dresden (Germany); Eric Müller, Martin Knupfer, Leibniz-Institut für Festkörper- und Werkstoffforschung Dresden (Germany); Christian Koerner, Karl Leo, Technische Univ. Dresden (Germany)

In current organic photovoltaic devices, the loss in energy caused by the inevitable charge transfer step leads to a low open circuit voltage, which is one of the main reasons for rather low power conversion efficiencies. A possible approach to avoid these losses is to tune the exciton binding energy below 25 meV, which would lead to free charges upon absorption of a photon, and therefore increase the power conversion efficiency towards the Shockley Queisser limit for inorganic solar cells. We determine the size of the excitons for different one-dimensional organic small molecules or polymers by electron energy loss spectroscopy (EELS) measurements and by DFT calculations. Using the measured dielectric constant and exciton extension, the exciton binding energy is calculated for the investigated molecules, leading to a lower limit of the exciton binding energy for ladder-type polymers. We discuss and propose potential ways to increase the ionic and electronic part of the dielectric function in order to further lower the limit of the exciton binding energy in organic materials. Furthermore, the influence of charge transfer states on the exciton size and its binding energy is calculated with DFT methods for the ladder-type polymer poly(benzimida zobenzophenanthroline) (BBL) in a dimer configuration.

9567-18, Session 3

Conditions for charge transport without recombination in low mobility organic solar cells and photodiodes

Martin Stolterfoht, Ardalan Armin, The Univ. of Queensland (Australia); Bronson Philippa, Ronald D. White, James Cook Univ. (Australia); Paul L. Burn, Paul Meredith, The Univ. of Queensland (Australia); Gytis Ju?ka, Vilnius Univ. (Lithuania); Almantas Pivrikas, The Univ. of Queensland (Australia)

Organic semiconductors typically possess low charge carrier mobilities and Langevin-type recombination dynamics, which both negatively impact the performance of organic solar cells and photodetectors. Charge transport in organic solar cells is usually characterized by the mobility-lifetime product. Using newly developed transient and steady state photocurrent measurement techniques we show that the onset of efficiency limiting photocarrier recombination is determined by the charge that can be stored on the electrodes of the device. It is shown that significant photocarrier recombination can be avoided when the total charge inside the device, defined by the trapped, doping-induced and mobile charge carriers, is less than the electrode charge. Based upon this physics we propose the mobility-recombination coefficient product as an alternative and more convenient figure of merit to minimize the recombination losses. We validate the results in 3 different organic semiconductor-based light harvesting systems with very different charge transport properties. The findings allow the determination of the charge collection efficiency in fully operational devices. In turn, knowing the conditions under which non-geminate recombination is eliminated enables one to quantify the generation efficiency of free charge carriers. The results are relevant to a wide range of light harvesting systems, particularly those based upon disordered semiconductors, and require a rethink of the critical parameters for charge transport.

9567-10, Session 4

Colored ultra-thin hybrid photovoltaics with high quantum efficiency for decorative PV applications *(Invited Paper)*

L. Jay Guo, Univ. of Michigan (United States)

This talk will describe an approach to create architecturally compatible and decorative thin-film-based hybrid photovoltaics [1]. Most current solar panels are fabricated via complex processes using expensive semiconductor materials, and they are rigid and heavy with a dull, black appearance. As a result of their non-aesthetic appearance and weight, they are primarily installed on rooftops to minimize their negative impact on building appearance. Recently we introduced dual-function solar cells based on ultra-thin dopant-free amorphous silicon embedded in an optical cavity that not only efficiently extract the photogenerated carriers but also display distinctive colors with the desired angle-insensitive appearances [1,2]. The angle-insensitive behavior is the result of an interesting phase cancellation effect in the optical cavity with respect to angle of light propagation [3]. In order to produce the desired optical effect, the semiconductor layer should be ultra-thin and the traditional doped layers need to be eliminated. We adopted the approach of employing charge transport/blocking layers used in organic solar cells to meet this demand. We showed that the ultra-thin (6 to 31 nm) undoped amorphous silicon/organic hybrid solar cell can transmit desired wavelength of light and that most of the absorbed photons in the undoped a-Si layer contributed to the extracted electric charges. This is because the a-Si layer thickness is smaller than the charge diffusion length, therefore the electron-hole recombination is strongly suppressed in such ultra-thin layer. Reflective colored PVs can be made in a similar fashion. Light-energy-harvesting colored signage was demonstrated. Furthermore, a cascaded photovoltaics scheme based on tunable spectrum splitting can be employed to increase power efficiency by absorbing a broader band of light energy. Our work provides a guideline for optimizing a photoactive layer thickness in high efficiency hybrid PV design, which can be adopted by other material systems as well. Based on these understandings, we have also developed colored perovskite PV by integrating an optical cavity with the perovskite semiconductors [4]. The principle and experimental results will be presented.

Nano-photonic organic solar cell architecture for advanced light management utilizing dual photonic crystals *(Invited Paper)*

Akshit Peer, Rana Biswas, Iowa State Univ. (United States) and Ames Lab. (United States)

Organic solar cells have rapidly increasing efficiencies, but typically absorb less than half of the incident solar spectrum. To increase broadband light absorption, we rigorously design experimentally realizable solar cell architectures based on dual photonic crystals. Our optimized architecture consists of a polymer microlens at the air-glass interface, coupled with a photonic-plasmonic crystal at the metal cathode. The microlens focuses light on the periodic nanostructure that generates strong light diffraction. Waveguiding modes and surface plasmon modes together enhance long wavelength absorption in P3HT-PCBM. The architecture has a period of 500 nm, with absorption and photocurrent enhancement of 49% and 58%, respectively.

9567-13, Session 4

Nanophotonic light management strategies for ultrathin solar cells *(Invited Paper)*

Mark L. Brongersma, Geballe Lab. for Advanced Materials (GLAM) (United States)

Nanophotonics is an exciting new field of science and technology that is directed towards making the smallest possible structures and devices that can manipulate light. In this presentation, I will start by showing how semiconductor and metallic nanostructures can mold the flow of light well below the free-space wavelength of light. I will then discuss how dense arrays of such nanostructures can effectively enhance light absorption in ultrathin solar cells, especially when the size and spacing between the structures is at a deep-subwavelength scale. The use of subwavelength arrays is distinct from conventional light trapping strategies that are aimed at coupling sunlight to quasi-guided modes of the high-index semiconductor layer(s) of a solar cell. I will explain how the size, shape and arrangement of nanostructures can be engineered to achieve near-unity absorption across a broad spectrum.

9567-19, Session 5

Photocurrent hysteresis and switchable organometal trihalide perovskite photovoltaic

Jinsong Huang, Univ. of Nebraska-Lincoln (United States)

The large photocurrent hysteresis observed in many organometal trihalide perovskite (OTP) solar cells has become a major hindrance impairing the ultimate performance and stability of these devices. Here we will report two device structures with completely different behaviors upon photocurrent scanning: one with eliminated photocurrent hysteresis (1), and the other with completely switchable photocurrent direction (2).

We showed the trap states on the surface and grain boundaries of the perovskite materials to be the origin of photocurrent hysteresis and that the fullerene layers deposited on perovskites can effectively passivate these charge trap states and eliminate the notorious photocurrent hysteresis. Fullerenes deposited on the top of the perovskites reduce the trap density by two orders of magnitude and double the power conversion efficiency of CH3NH3PbI3 solar cells to near 19%. The elucidation of the origin of photocurrent hysteresis and its elimination by trap passivation in perovskite solar cells provides important directions for enhancements to device efficiency.

In another device structure without fullerene, we showed that in OTP-based photovoltaic devices with vertical and lateral cell configurations, the photocurrent direction can be switched repeatedly by applying a small electric field of <1 V ?m?1. The switchable photocurrent, generally observed in devices based on ferroelectric materials, reached 20.1 mA cm?2 under one sun illumination in OTP devices with a vertical architecture, which is four orders of magnitude larger than that measured in other ferroelectric photovoltaic devices. This field-switchable photovoltaic effect can be explained by the formation of reversible p–i–n structures induced by ion drift in the perovskite layer.

9567-20, Session 5

A comparison of perovskite and colloidal quantum dot solar cells *(Invited Paper)*

Brandon R. Sutherland, Edward H. Sargent, Univ. of Toronto (Canada)

In this talk, we review the progress of perovskite and colloidal quantum dot solar cells and discuss their future prospects. We detail the fundamental differences in these two materials, the current challenges that they face and must overcome, as well as discuss their potential synergy in new and exciting architectures.

9567-21, Session 5

Hysteresis-free, stable and efficient perovskite solar cells achieved by vacuum-treated thermal annealing of CH3NH3PbI3

Feng-Xian Xie, Di Zhang, Wallace C. H. Choy, The Univ. of Hong Kong (Hong Kong, China)

CH3NH3I and PbCl2 mixture are the most commonly used materials in the deposition solution in one step planar structures. Since the crystallization process of CH3NH3PbI3 can be controlled during the phase of forming intermediate organometal mixed halide, the photovoltaic properties of the perovskite films are typically superior to those of films formed directly in one step precipitation process from a CH3NH3I and PbI2 mixture. Nevertheless, controlling the crystallization process of perovskite films remains a challenging issue. The CH3NH3PbI3 perovskite crystallization is strongly affected by the ambient, which in turn can compromise the performance and reproducibility of the perovskite device. Therefore, an effective approach for enhancing the morphology of perovskite films through controlling their crystallization process is highly desired.

Here, we propose a vacuum-assisted thermal annealing method for providing favorable environment for effectively controlling the crystallization of the perovskite films. Besides confirming the generation of MACl byproduct, our studies indicate that MACl plays a critical role during the perovskite film formation and device degradation. By promoting the release of MACl and suppressing residual MACl in the film through the vacuum-assisted thermal annealing, we are able to obtain pore-free and well crystallized pure triiodide (CH3NH3PbI3) perovskite films that contained no residual chloride species. As a result, we realize highly stable and efficient solar cells displaying excellent reproducibility (13.60 ± 0.92% among 60 devices; highest PCE: 14.52%) and a very small photocurrent hysteresis effect [1]. We believe that this approach will also enable further improvements in the performance of related perovskite materials.

9567-22, Session 6

Charge generation and charge transfer processes in organic and hybrid (organic-inorganic) solar cell materials *(Invited Paper)*

Natalie Banerji, Univ. de Fribourg (Switzerland)

The generation of free charge carriers is a key in the functioning of any solar cell. In all-organic polymer:fullerene materials, excitons are generated by light absorption and they must be dissociated by charge separation between the electron donor (polymer) and the electron acceptor (fullerene). We will address our recent advances in understanding the charge generation process in a variety of polymer:fullerene blends, where the phase morphology and microstructure were carefully controlled during film processing. Ultrafast transient absorption, electro-absorption (Stark effect) and fluorescence spectroscopies were used. We will also present preliminary results about charge transfer from methyl ammonium lead iodide to conjugated polymers, revealing information about the nature and generation of charges in the highly efficient perovskite materials.

9567-23, Session 6

The role of charge transfer states in organic photovoltaic blends

Remco W. Havenith, Hilde D. de Gier, Ria Broer, Univ. of Groningen (Netherlands)

Charge separation in organic photovoltaic blends occurs at the donor/acceptor interface. In these blends, a manifold of charge transfer (CT) states exists, and it is not clear whether the lowest charge transfer states are involved in charge carrier generation, or act as trap states.

We discuss here how we model these blends using a combined quantum mechanical and molecular dynamics approach, and present results on the nature of the different CT states, their dependence on the size of the model used, and how the environment influences them. The first two studies will show whether delocalisation effects are important in charge carrier generation. The latter study demonstrates how the local environment, which can be modified by the introduction of dipoles or polarisable groups, influences charge separation.

Furthermore, electronic couplings between the initially excited state on the polymer and the various CT states are calculated to estimate the rates of electron transfer to the different target CT states. From these rates, we can determine which of the states are involved in the charge separation process. These couplings are studied as a function of chemical composition of the blends, and for various conformations. The results of this study show how the charge transfer process is influenced by the local structure of the donor/acceptor interface. It will also reveal whether the lowest CT states act as trap states, and how that can be circumvented. This information is used in the design of the next generation organic photovoltaic blends with a higher efficiency.

Charge transfer and triplet states in OPV materials and devices *(Invited Paper)*

Vladimir Dyakonov, Julius-Maximilians-Univ. Würzburg (Germany)

Electron back transfer (EBT), potentially occurring after electron transfer from donor to acceptor may populate the lower lying donor or acceptor triplet state and serve as recombination channel.[1] Here we report on studies of charge transfer and triplet states in blends of highly efficient benzodithiophene PTB7 polymer in combination with the fullerene-derivative PC71BM using the spin sensitive optically detected magnetic resonance (ODMR) technique and compare the results with those obtained in P3HT (poly(3- hexylthiophene):PC61BM blends. Although PTB7:PC71BM absorbers yield much higher power conversion efficiencies in solar cells exceeding 7%, we found a significant increase of triplet exciton generation, which was absent in the P3HT based blends. We discuss this observation within the EBT scenario with the emphasis on the influence of morphology, fullerene load, HOMO/LUMO energy and presence of additives (DIO). Suppressing the EBT process by morphology and/or energetics of polymer and molecules is important to achieve the full potential of highly efficient OPV materials. [1] M. Liedtke, et al., JACS 133, 9088 (2011).

9567-25, Session 6

Charge transfer states as traps in organic solar cells

Andreas Arndt, Karlsruher Institut für Technologie (Germany); Marina Gerhard, Philipps-Univ. Marburg (Germany); Aina Quintilla, Ian Howard, Karlsruher Institut für Technologie (Germany); Martin Koch, Philipps-Univ. Marburg (Germany); Uli Lemmer, Karlsruher Institut für Technologie (Germany)

We investigate the NIR time-resolved photoluminescence of a series of P3HT:PC61BM solar cells with varying blend ratios after preferential excitation of the PC61BM and P3HT components respectively.

Besides the rapid and diffusion-limited quenching of singlet excitons we resolve a weak emission feature in the near-infrared that our measurements confirm comes from interfacial charge-transfer (CT) states. This CT state emission becomes stronger for samples with an excess of PC61BM, and also after selective excitation of the PC61BM component. In this way, we show that these NIR time-resolved photoluminescence measurements provide an accurate method of observing subtle changes in the formation and dynamics of CT states at organic heterojunctions due to its high selectivity, and suggest that PC61BM excitons are more likely to lead to geminately recombining CT states than are the excitons created on P3HT.

We also measure the temperature dependence of the transient NIR photoluminescence and find that while the intensity of the NIR emission is temperature dependent, its lifetime is not. This interesting observation suggests that the CT states we observe are formed through a precursor state which can either form separated charges or CT states, and that the relative yield of these two pools is temperature dependent. Furthermore, it indicates that charges within these relaxed CT states are trapped at the donor-acceptor interface and cannot contribute to free-charge generation via thermal activation anymore.

9567-26, Session 6

Charge-transfer absorption, emission, and the open-circuit voltage of organic solar cells *(Invited Paper)*

Koen Vandewal, Technische Univ. Dresden (Germany)

Electronic processes at the organic hetero-interface limit the photocurrent and photovoltage of organic solar cells. While devices with incident-photon-to-extracted-charge conversion yields of over 85%, and absorbed photon-to-extracted-charge conversion yields of 90-100% have been achieved, the difference between the optical gap of main absorber and open-circuit voltage (Voc) is much larger than for inorganic solar cells. The main improvements in the Voc of organic solar cells have so far been made by tailoring the donor-acceptor interfacial energetics, taking advantage of well-known principles of molecular design. Nevertheless, for most material systems we consistently find a large (>0.55 eV) difference between eVoc and the energy of the intermolecular charge transfer (CT) state. We present experimental evidence that this difference can be reduced by reducing the physical interfacial area available for free carrier recombination. We quantify this by analyzing the strength of the interfacial CT state absorption and emission signal at photon energies below the optical gap of the neat materials. We further discuss the influence of the measured electronic coupling, molecular reorganization and non-radiative recombination pathways on Voc. This work opens up unexplored possibilities for increasing the Voc of organic solar cells, bringing it closer to the optical gap of the main absorber.

9567-27, Session 6

Theory and assignment of intermolecular charge transfer states in squaraines and their impact on efficiency in bulk heterojunction solar cells

Christopher J. Collison, Chenyu Zheng, Rochester Institute of Technology (United States); Nicholas Hestand, Temple Univ. (United States); Brandon Cona, Anirudh Penmetcha, Susan Spencer, Jeremy Cody, Rochester Institute of Technology (United States); Frank Spano, Temple Univ. (United States)

Squaraines are targeted for organic photovoltaic devices because of their high extinction coefficients over a broad wavelength range from visible to near infra-red (NIR). Moreover, their side groups can be changed with profound effects upon their ability to crystallize, leading to improvements in charge mobility and exciton diffusion.

The broadening in squaraine absorption is often qualitatively attributed to H- and J-aggregates based on the exciton model, proposed by Kasha. However, such assignment is misleading considering that spectral shifts can arise from sources other than excitonic coupling. Our group has shown that packing structure influences the rate of charge transfer; thus a complete and accurate reassessment of the excited states must be completed before the true charge transfer mechanism can be confirmed.

In this work, we will show how squaraine H-aggregates can pack in complete vertical stacks or slipped vertical stacks depending upon sidegroups and processing conditions. Hence, we uncover the contribution of an intermolecular charge transfer (IMCT) state through essential states modeling validated by spectroscopic and X-Ray diffraction data.

We further show external quantum efficiency data that describe the influence of the IMCT state on the efficiency of our devices.

This comprehensive understanding of squaraine aggregates drives the development of more efficient organic photovoltaic devices, leading towards a prescription for derivatives that can be tailored for optimized exciton diffusion, charge transfer, higher mobilities and reduced recombination in small molecule OPV devices.

9567-28, Session 7

Rational material, interface, and device engineering for high-performance polymer and perovskite solar cells *(Invited Paper)*

Alex K-Y Jen, Univ. of Washington (United States)

The performance of polymer and hybrid solar cells is also strongly dependent on their efficiency in harvesting light, exciton dissociation, charge transport, and charge collection at the metal/organic/metal oxide or the metal/perovskite/metal oxide interfaces. Our laboratory employs a molecular engineering approach to develop processible low band-gap polymers with high charge carrier mobility that can enhance power conversion efficiency of the single junction solar cells to values as high as ~11%. We have also developed several innovative strategies to modify the interface of bulk-heterojunction devices and create new device architectures to fully explore their potential for solar applications.

In this talk, the integrated approach of combining material design, interface, and device engineering to significantly improve the performance of polymer and hybrid perovskite photovoltaic cells will be discussed. Specific emphasis will be placed on the development of low band-gap polymers with reduced reorganizational energy and proper energy levels, formation of optimized morphology of active layer, and minimized interfacial energy barriers using functional conductive surfactants. At the end, several new device architectures and optical engineering strategies to make tandem cells and semitransparent solar cells will be discussed to explore the full promise of polymer and perovskite hybrid solar cells.

9567-29, Session 7

Vacuum deposited triple absorber organic solar cells (OSCs)

Karsten Walzer, Heliatek GmbH (Germany)

Thanks to the availability of doped hole and electron transport layers, which allow the fabrication of nearly loss-free charge transport and charge conversion layers, vacuum deposited organic solar cells (OSCs) can be easily stacked as monolithically connected multiple devices, such as tandem or triple OSCs.

We report on triple absorber layer devices as a route to reliable and production relevant OSC stacks. Already in early 2013, Heliatek achieved an independently certified 12% efficiency device, which used using twice the same orange-red broad-band absorber in combination with an efficient green absorber. Recently, we found a class of infrared absorbers that can extend the solar harvesting of vacuum processable OSCs to the near infrared beyond 900 nm, which gives access to triple absorber devices using three different absorbers. Thus, both the energy rich visible and the NIR part of the solar spectrum can be absorbed by the OSC. We will report about the latest developments in such devices, as well as giving a brief update about the current status of the vacuum-based roll-to-roll volume production of small molecule tandem OSCs.

9567-30, Session 7

High performance x-ray imaging detectors on foil using solution-processed organic photodiodes with extremely low dark leakage current

Abhishek Kumar, Date Moet, Jan Laurens van der Steen, Albert van Breemen, Santhosh Shanmugam, Jan Gilot, Ronn Andriessen, Holst Ctr. (Netherlands); Matthias Simon, Philips Research (Netherlands); Walter Ruetten, Alexander Douglas, Philips Research (Netherlands); Rob Raaijmakers, Philips Healthcare (Netherlands); Pawel E. Malinowski, Kris Myny, IMEC (Belgium); Gerwin Gelinck, Holst Ctr. (Netherlands) and Technische Univ. Eindhoven (Netherlands)

We demonstrate high performance X-ray imaging detectors on foil suitable for medical grade X-ray imaging applications. The detectors are based on solution-processed organic photodiodes forming bulk-heterojunctions from photovoltaic donor and acceptor blend. The organic photodiodes are deposited using an industrially compatible slot die coating technique with end of line processing temperature below 100° C. These photodiodes have extremely low dark leakage current density of 10-7 mA/cm2 at -2V bias with very high yield and have peak absorption around 550 nm wavelength. We combine these organic photodiodes with high mobility metal oxide semiconductor based thin film transistor arrays with high pixel resolution of 200ppi on thin plastic substrate. When combined with a typical CsI(TI) scintillator material on top, they are well suited for low dose X-ray imaging applications. The optical crosstalk is insignificant upto resolution of 200 ppi despite the fact that the photodiode layer is one continuous layer and is non-pixelated. Low processing temperatures are another key advantage since they can be fabricated on plastic substrate. This implies that we can make X-ray detectors on flexible foil. Those detectors can be mechanically more robust and light weight when compared to amorphous Si based detectors fabricated on glass substrate.

9567-31, Session 7

High performance all polymer solar cells fabricated via non-halogenated solvents

Yan Zhou, Zhenan Bao, Stanford Univ. (United States)

The performance of organic solar cells consisting of a donor/acceptor bulk heterojunction (BHJ) has rapidly improved over the past few years.1. Major efforts have been focused on developing a variety of donor materials to gain access to different regions of the solar spectrum as well as to improve carrier transport properties.2 On the other hand, the most utilized acceptors are still restricted to the fullerene family, which includes PC61BM, PC71BM and ICBA.2b, 3 All-polymer solar cells, consisting of polymers for both the donor and acceptor, gained significantly increased interests recently, because of their ease of solution processing, potentially low cost, versatility in molecular design, and their potential for good chemical and morphological stability due to entanglement of polymers. Unlike small molecular fullerene acceptors, polymer acceptors can benefit from the high mobility of intra-chain charge transport and exciton generation by both donor and acceptor.

Despite extensive efforts on all-polymer solar cells in the past decade, the fundamental understanding of all-polymer solar cells is still in its inceptive stage regarding both the materials chemistry and structure physics.4 Thus, rational design rules must be utilized to enable fundamental materials understanding of the all polymer solar cells.

We report high performance all-polymer solar cells employing polymeric donors based on isoindigo and acceptor based on perylenedicarboximide. The phase separation domain length scale correlates well with the JSC and is found to be highly sensitive to the aromatic co-monomer structures used in the crystalline donor polymers. With the PS polymer side chain engineering, the phase separation domain length scale decreased by more than 45%. The PCE and JSC of the devices increased accordingly by more than 20%. A JSC as high as 10.0 mA cm?2 is obtained with the donor-acceptor pair despite of a low LUMO-LUMO energy offset of less than 0.1 eV. All the factors such as crystallinity, surface roughness, charge carrier mobility, and absorptions of the polymers blends are found irrelevant to the performance of these all polymer solar cells. This work demonstrates that a better understanding of tuning polymer phase separation domain size provides an important path towards high performance, all-polymer solar cells. The use of polymer side-chain engineering provides an effective molecular engineering approach that may be combined with additional processing parameter control to further elevate the performance of all-polymer solar cells. We obtained a record PCE of 4.8% (avarage from 20 devices), with an average JSC of 9.8 mA cm-2. The highest PCE shoots to 5.1%, with JSC as high as 10.2 mA cm-2, and VOC of 1.02 V. It is the highest performance ever published for an all-polymer solar cell.4

9567-32, Session 7

Design of low band gap small molecules with alkyldicyanovinyl acceptor and different donor groups for efficient bulk heterojunction organic solar cells

Sergey A. Ponomarenko, Institute of Synthetic Polymeric Materials (Russian Federation) and Lomonosov Moscow State Univ. (Russian Federation); Yuriy N. Luponosov, Institute of Synthetic Polymeric Materials (Russian Federation); Jie Min, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); Alexander N. Solodukhin, Maxim A. Shcherbina, Sergey N. Chvalun, Institute of Synthetic Polymeric Materials (Russian Federation); Tayebeh Ameri, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); Christoph J. Brabec, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany) and Bayerisches Zentrum für Angewandte Energieforschung e.V. (Germany)

Nowadays soluble small molecule organic semiconductors play a significant role in organic photovoltaics, leading to highly efficient solution-processable devices. In this work an approach to creation of a library of low band gap small molecules with alkyldicyanovinyl acceptor linked through (oligo) thiophene conjugated spacers to different donor groups, including but not limited to triphenylamine, tris(2-methoxyphenyl)amine or dithienosilole units, was elaborated. Due to intramolecular charge transfer and aggregation in the solid state they absorb the solar light in a wide spectral range, from 300-400 to 650-900 nm. Alkyldicyanovinyl groups differ from regular dicyanovinyl groups by better solubility and higher stability due to the absence of acidic proton. Systematic variations of the alkyl chain length and the number of conjugated thiophene rings in the molecules allowed to elucidate the relationship between their molecular structure and different physical properties, including their solubility, absorption spectra, phase behavior, morphology and structure in thin films, as well as semiconducting and photovoltaic properties. Bulk heterojunction organic solar cells (BHJ OSC) prepared from these molecules as donors and PCBM[70] as acceptor by solution processing showed power conversion efficiency up to 5.4 - 6.3%. The peculiarities of these molecules in BHJ OSC are high open circuit voltage Voc, up to 0.96 – 1.08 V, and relatively high fill factor FF, up to 54 – 69%, which can be achieved by special interface design or solvent vapor annealing. Some of these molecules form columnar mesophases, which bring an additional factor for further improving their efficiencies by possible ordering of the bulk heterojunction structure.

9567-33, Session 8

Harnessing the diffusion of small molecules in OPV films for processing and characterization of BHJs *(Invited Paper)*

Gitti Frey, Technion-Israel Institute of Technology (Israel)

The efficiency of OPVs critically depends on the nano- and meso-scale morphology of the donor:acceptor BHJ which is directed by the phase separation and mutual solubility of both constituents. The “soft” characteristics of the BHJ allows kinetic and/or thermodynamic modulations of the morphology. For example, it is post-processing thermal and solvent annealing are common processing protocols. Here we show how the tendency of small molecules to diffuse through “soft” materials can also be harnessed to direct and even study the morphology of OPV BHJs. This approach is demonstrated in two systems: i) the spontaneous migration of selected additives from within the active layers to form interlayers at the organic/metal interface. Using a plethora of techniques, we show that the migration, which occurs during the metal evaporation process, is driven by the metal-additives interactions and can enhance the Voc and device efficiency. ii) the diffusion of atomic layer deposition (ALD) precursors into the active layer can be used to directly map the morphology of OPV BHJs and to fabricate new hybrid PV structures. More specifically, we use the ALD of ZnO inside OPV films to spatially map the amorphous and crystalline domain of P3HT, the distribution of PCBM; and to fabricate new hybrid PV devices.

9567-34, Session 8

Impact of molecular mixing on open circuit voltage of bulk heterojunction solar cells

Swaminathan Venkatesan, Qiquan Qiao, Cheng Zhang, South Dakota State Univ. (United States); Wei Chen, Argonne National Lab. (United States); Jihua Chen, Oak Ridge National Lab. (United States)

Role of donor-acceptor ratios on the morphology and charge transport in bulk heterojunction solar cells consisting of highly self-ordered semiconducting polymers are studied. It is found that the open circuit voltage linearly increases when fullerene loading is increased from 1:1 to 1:4 donor-acceptor mixing ratio. The active layer morphology is characterized using AFM topography, phase, Kelvin probe force microscopy (KPFM) and energy filtered transmission electron microscopy (EFTEM). With higher fullerene mixing ratios smaller domains and finer phase separation is observed. Surface potential distribution from KPFM images reveal that higher fullerene loading leads to higher surface potential variation (higher FWHM). EFTEM results showed higher polymer aggregation in blends having 1:1 and 1:2 donor acceptor ratios. Further films were also characterized using grazing incidence wide angle x-ray scattering (GIWAXS) which showed highly ordered polymer domains having edge on orientation in 1:1 and 1:2 blend films. When fullerene loading was increased to 1:3 and 1:4, smaller crystallites of polymer domains are observed which orient in random directions. Device performance was studied for six different blend ratios and 1:4 ratio was found to be optimum for achieving best photovoltaic performance. Further photo-generated charge carrier extraction using linearly increasing voltage (P-CELIV) measurements show that the optimum mixing ratio leads to the highest charge carrier density, mobility and lowest bimolecular recombination. These results indicate the crucial role of fullerene loading for achieving the ideal morphology and avoiding polymer aggregation during film formation for efficient photovoltaic devices.

9567-35, Session 8

Morphology control for efficient and stable small molecule organic solar cells

Hideyuki Tanaka, Eiichi Nakamura, The Univ. of Tokyo (Japan)

Printable organic solar cells (OSCs) have received much attention because of their attractive advantage such as large scale, lightweight, low cost and facile fabrication process. In these solution-processable OSCs, bicontinuous network structure of phase-separated electron donor and acceptor materials in nanoscale becomes most crucial factor to realize high power conversion efficiency (PCE). The phase separation has been widely investigated with the bulk-heterojunction (BHJ) concept by use of pi-conjugated polymer and fullerene derivative. Small molecular materials also can be a good candidate material for the solution-processable OSCs, however, there are very few reports due to the difficulty constructing the nano scale phase separation despite it has practical advantages such as ease purification and high stability. Here, we demonstrate the new approach for fabricating efficient small molecular OSCs through controlling of phase-separation of binary blend of donor molecules and non-active soft materials. We found that the limited molecular diffusion of donor molecules within highly viscous soft matrix play a key role for the nano-scale phase separation. A 20–30 nm sized BP crystal can be created within a highly viscous matrix (TCTA), and that provides efficient charge carrier generation system showing high PCE of 7.8%.

9567-36, Session 8

Morphological study on small molecule acceptor-based organic solar cells with efficiencies beyond 7%

Wei Ma, Xi’an Jiaotong Univ. (China); He Yan, Hong Kong Univ. of Science and Technology (Hong Kong, China)

Despite the essential role of fullerenes in achieving best-performance organic solar cells (OSCs), fullerene acceptors have several drawbacks including poor light absorption, high-cost production and purification. For this reason, small molecule acceptor (SMA)-based OSCs have attracted much attention due to the easy tunability of electronic and optical properties of SMA materials. In this study, polymers with temperature dependent aggregation behaviors are combined with various small molecule acceptor materials, which lead to impressive power conversion efficiencies of up to 7.3%. The morphological and aggregation properties of the polymer:small molecule blends are studied in details. It is found that the temperature-dependent aggregation behavior of polymers allows for the processing of the polymer solutions at moderately elevated temperature, and more importantly, controlled aggregation and strong crystallization of the polymer during the film cooling and drying process. This results in a well-controlled and near-ideal polymer:small molecule morphology that is

controlled by polymer aggregation during warm casting and thus insensitive to the choice of small molecules. As a result, several cases of highly efficient (PCE between 6-7.3%) SMA OSCs are achieved. The second part of this presentation will describe the morphology of a new small molecule acceptor with a unique 3D structure. The relationship between molecular structure and morphology is revealed.

9567-37, Session 8

Mechanical stability of organic solar cells: Molecular and microstructural determinants

Darren J. Lipomi, Suchol Savagatrup, Adam D. Printz, Timothy F. O'Connor, Aliaksandr V. Zaretski, Univ. of California, San Diego (United States)

The mechanical properties of organic semiconductors and the mechanical failure mechanisms of devices play critical roles in the yield of modules in roll-to-roll manufacturing and the operational stability of organic solar cells (OSCs) in portable and outdoor applications. This talk begins by reviewing the mechanical properties—principally stiffness and brittleness—of pure films of organic semiconductors. It identifies several determinants of the mechanical properties including molecular structures, polymorphism, and microstructure and texture. Next, a discussion of the mechanical properties of polymer:fullerene bulk heterojunction blends reveals the strong influence of the size and purity of the fullerenes, the effect of processing additives as plasticizers, and the details of molecular mixing—i.e., the extent of intercalation of fullerene molecules between the side chains of the polymer. Mechanical strain in principle affects the photovoltaic output of devices in several ways, from strain-evolved changes in alignment of chains, degree of crystallinity, and orientation of texture, to debonding, cohesive failure, and cracking, which dominate changes in the high-strain regime. These conclusions highlight the importance of mechanical properties and mechanical effects on the viability of OSCs during manufacture and in operational environments. The talk—whose focus is on molecular and microstructural determinants of mechanical properties—concludes by suggesting several potential routes to maximize both mechanical resilience and photovoltaic performance for improving the lifetime of devices in the near term and enabling devices that require extreme deformation (i.e., stretchability and ultra-flexibility) in the future.

9567-38, Session 8

Ultrashort-pulsed laser processing and solution based coating in roll-to-roll manufacturing of organic photovoltaics

Christian J. Hördemann, Katrin Hirschfelder, Moritz Schäfer, Arnold Gillner, Fraunhofer-Institut für Lasertechnik (Germany)

The breakthrough of flexible organic electronics and especially organic photovoltaics is highly dependent on cost-efficient production technologies. Roll-2-Roll processes show potential for a promising solution in terms of high throughput and low-cost production of thin film organic components. Solution based material deposition and integrated laser patterning processes offer new possibilities for versatile production lines. The use of flexible polymeric substrates brings along difficulties in laser patterning which have to be overcome. One main challenge when patterning transparent conductive layers on polymeric substrates are material bulges at the edges of the ablated area. Bulges can lead to short circuits in the layer system leading to device failure. Therefore following layers have to have a sufficient thickness to cover and smooth the ridge. In order to minimize the bulging height, a study has been carried out on transparent conductive ITO layers on flexible PET substrates. Ablation results using different beam shapes, such as Gaussian beam, Top-Hat beam and Donut-shaped beam, as well as multi-pass scribing and double-pulsed ablation are compared. Furthermore, lab scale methods for cleaning the patterned layer and eliminating bulges are contrasted to the use of additional water based sacrificial layers in order to obtain an alternative procedure suitable for large scale Roll-2-Roll manufacturing. Besides progress in research, ongoing transfer of the process into a Roll-2-Roll demonstrator is illustrated. By using fixed optical elements in combination with a galvanometric scanner, scribing, variable patterning and edge deletion can be performed individually.

9567-39, Session 9

Dominant degradation mechanisms of organic photovoltaic devices *(Invited Paper)*

Thomas Heumueller, Markus Biele, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); Jens Adams, Bayerisches Zentrum für Angewandte Energieforschung e.V. (Germany); Timothy Burke, William Mateker, Stanford Univ. (United States); Michael Salvador, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); Andreas Distler, BELECTRIC OPV (Germany); Hans-Joachim Egelhaaf, Energie Campus Nürnberg (Germany) and BELECTRIC OPV (Germany) and Bayerisches Zentrum für Angewandte Energieforschung e.V. (Germany); Michael McGehee, Stanford Univ. (United States); Christoph J. Brabec, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany) and Bayerisches Zentrum für Angewandte Energieforschung e.V. (Germany) and Energie Campus Nürnberg (Germany)

We have studied the stability of a variety of organic photovoltaic (OPV) materials and observe three dominant intrinsic degradation mechanisms: Disorder induced Voc losses, dimerization related Jsc losses and FF losses due to interface defects. Alleviating those mechanisms we demonstrate lifetimes in excess of 10 years.

Using charge extraction and photocurrent spectroscopy we identify an increase of energetic disorder in aged solar cells. This increased energetic disorder lowers the open-circuit voltage by broadening the density of states. Both, the temperature and light intensity dependence of those disorder induced Voc losses can be described with an analytical model using only one fit parameter.

Fullerene dimerization is observed to cause short circuit current losses in organic solar cells. We show that this reaction depends on the fullerene morphology and thus only happens under certain circumstances. Changing the operating conditions of the investigated solar cell from Voc to Jsc significantly reduces the amount of dimerization related performance losses and illustrates the role of excited species in the degradation mechanism.

In several different systems a direct correlation between fill factor losses and interface defects at the contacts is observed. Solar cells with ZnO as interface material clearly show how contact deterioration primarily causes FF losses. An additional Ba(OH)2 layer on top of ZnO is able to stabilize the interface and prevent FF losses. For solar cells with standard architecture we replace the metal electrode after degradation and observe that the fill factor is being restored while the open circuit voltage stays low.

9567-40, Session 9

Degradation mechanism of planar perovskite solar cells

Chuanjiang Qin, Toshinori Matsushima, Chihaya Adachi, Kyushu Univ. (Japan)

Organic-inorganic hybrid halide perovskites are an interesting class of materials that have excellent semiconductor properties, and demonstrated promising applications on many fields, such as solar cells, water photolysis,

light emitting diodes, and amplified spontaneous emission. So far, the device lifetime is still short, and this is an important key issue faced for all researchers in this field.[1] The deep understanding of their durability and degradation mechanism is critical and necessary toward future applications.

Towards development of efficient and long-term stable perovskite solar cells (PSCs), we firstly studied the relationship between crystallization, morphology, device architecture, efficiency and durability of encapsulated PSCs. Furthermore, the degradation mechanism of the devices was elucidated by different experimental methods. The well crystallized and fully covered perovskite layer improves not only power conversion efficiency but also long-time durability. Compared to a widely used silver counter electrode, lithium fluoride/aluminum and gold electrode-based PSCs demonstrated better durability owing to less chemical degradation and interface changing. We also confirmed that the amount of accumulated charge carriers induces the degradation of the PSCs, which was proved by a thermally stimulated current technique. Finally, we realized a planar PSC with excellent durability by improving device encapsulation and optimizing device structures.

9567-41, Session 9

Predicting thermal stability of organic solar cells through real-time capacitive techniques

Marta Tessarolo, Istituto per lo Studio dei Materiali Nanostrutturati (Italy); Antonio Guerrero, Univ. Jaume I (Spain); Mirko Seri, Istituto per la Sintesi Organica e la Fotoreattività (Italy); Mario Prosa, Istituto per lo Studio dei Materiali Nanostrutturati (Italy); Margherita Bolognesi, Consiglio Nazionale delle Ricerche (Italy); Germà Garcia Belmonte, Univ. Jaume I (Spain)

Bulk Heterojunction (BHJ) solar cells have reached Power Conversion Efficiencies (PCE) over 10% but to be a competitive product long lifetimes are mandatory. In this view, guidelines for the prediction and optimization of the device stability are crucial to generate improved materials for efficient and stable BHJ devices. For encapsulated cells, degradation mechanisms can be mainly ascribed to external agents such as light and temperature. In particular, thermal degradation appears to be related not only to the BHJ morphology but also to the adjacent interfaces. Therefore, in order to have a complete description of the thermal stability of a BHJ cell, it is necessary to consider the entire stack degradation processes by using techniques enabling a direct investigation on working devices.

Here, five different donor polymers were selected and the OPV performance of the corresponding BHJ devices were monitored during the thermal degradation at 85°C, showing an exponential decay of the corresponding PCEs. In parallel, we measured the geometrical capacitance of analogous OPV devices as a function of temperature and we observed that at a defined temperature (TMAX), typical for each polymer-based device, the capacitance starts to decrease. Combining all these results we found an evident and direct correlation between TMAX and the PCE decay parameters (obtained from capacitance-temperature an thermal measurements, respectively). This implies that the capacitance-method here presented is a fast, reliable and relatively simple method to predict the thermal stability of BHJ solar cells without the need to perform time-consuming thermal degradation tests.

9567-42, Session 9

Perovskite solar cells: From device fabrication to device degradation *(Invited Paper)*

Jinli Yang, Dianyi Liu, Braden Siempelkamp, Timothy Kelly, Univ. of Saskatchewan (Canada)

Solar cells based on CH3NH3PbI3 have recently emerged at the forefront of solution-processable photovoltaic devices, with power conversion efficiencies as high as 20.1% having now been certified. In this presentation, I will discuss our research group's work in the area of perovskite solar cells. Our early work demonstrated that room temperature solution-processing techniques can be used to prepare devices on flexible substrates while retaining excellent power conversion efficiencies. Since then, we have examined issues related to charge carrier diffusion, interfacial contacts, and device flexibility, with our most recent efforts focusing on probing device failure mechanisms using in situ synchrotron-based techniques.

9567-43, Session 9

High-efficiency perovskite solar cells with long operation lifetime

Chenchen Yang, Weiran Cao, Nathan T. Shewmon, Jiangeng Xue, Univ. of Florida (United States)

Perovskite solar cells have attracted tremendous attention for their outstanding energy conversion efficiency in the past few years. Due to the development of active materials, device architectures and processing methods, power conversion efficiency (PCE) of perovskite solar cells is now growing up to 20%. Beyond the efficiency, to get rid of Lead, the widely-used toxic element in the perovskite layers, as well as to improve the device/module operation lifetime are the other two major challenges that need to be solved before their commercialization.

Here, we apply a layer of ZnO nanoparticles onto to a planar perovskite solar cell, which can not only improve the electron transport/extraction in the devices but highly improve the device operation lifetime. The devices were fabricated by spin-coating a poly(3,4-ethylenedioxythuiphene):poly styrene sulfonate (PEDOT:PSS) layer onto a glass/ITO substrate, followed by the deposition of a perovskite layer from a lead chloride (PbCl2) and methyl ammonium iodine (MAI) blend precursor solution. After that, a layer of [6,6]-phenyl-C61-butyric acid methyl ester (PCBM) and a layer of ZnO nanoparticles were successively deposited as the electron transport layers, and the device was finished by thermally evaporation Al as the cathode. Such planar perovskite solar cell with ZnO NPs exhibits a maximum PCE of up to 14.1%, which is about 35% higher than that without the ZnO layer. Moreover, the device remains 80% of its initial PCE after 2500 hours under 1 sum illumination, majorly due to the protection of ZnO layer that prevent the diffusion of oxygen and moisture molecules into the perovskite layers as revealed by x-ray photoelectron spectroscopy studies.

Photoactive and interfacial materials for flexible photovoltaic devices *(Invited Paper)*

Antonio F. Facchetti, Polyera Corp. (United States)

In this presentation we will report the molecular design by DFT computations, synthesis, and molecular and structural characterization of a new polymeric building block based on aromatic sulfonamides as donor for organic photovoltaic cells. Furthermore, we report results on using self-assembled interlayers and metal oxide blends with fine tuning of the conduction band to replace conventional spin-coated materials enabling improved performance or enable new functions. Finally, we will show recent studies on device performance achieved upon ambient processing and lifetime stability test under light soaking. Our results demonstrate that single-junction OPV cell with efficiencies surpassing 10% are possible and can exhibit considerable stability.

9567-45, Session 10

Polymer solar cells with efficiency >10% enabled via a facile solution-processed Al-doped ZnO electron transporting layer

Lethy K. Jagadamma, Mohammed Al-Senani, Aram Amassian, King Abdullah Univ. of Science and Technology (Saudi Arabia)

The present work details a facile and low-temperature (125C) solution-processed Al-doped ZnO (AZO) buffer layer functioning very effectively as electron accepting/hole blocking layer for a wide range of polymer:fullerene bulk heterojunction systems, and yielding power conversion efficiency in excess of 10% (8%) on glass (plastic) substrates. We show that ammonia addition to the aqueous AZO nanoparticle solution is a critically important step toward producing compact and smooth thin films which partially retain the aluminum doping and crystalline order of the starting AZO nanocrystals. The ammonia treatment appears to reduce the native defects via nitrogen incorporation, making the AZO film a very good electron transporter and energetically matched with the fullerene acceptor. Importantly, highly efficient solar cells are achieved without the need for additional surface chemical passivation or modification, which has become an increasingly common route to improving the performance of evaporated or solution-processed ZnO ETLs in solar cells.

9567-46, Session 10

Polymer-facilitated low temperature fusing of spray-coated silver nanowire networks as transparent top and bottom electrodes in small molecule organic photovoltaics

Franz Selzer, Nelli Weiß, David Kneppe, Ludwig Bormann, Christoph Sachse, Nikolai Gaponik, Alexander Eychmüller, Karl Leo, Lars Müller-Meskamp, Technische Univ. Dresden (Germany)

Networks of silver nanowires (AgNWs) are promising candidates for transparent conducting electrodes in organic photovoltaics (OPV), as they achieve similar performance as the commonly used indium tin oxide (ITO) at lower cost and increased flexibility. The initial sheet resistance (Rs) of AgNW electrodes typically needs to be reduced by a post-annealing step (90 min@200 °C), being detrimental for processing on polymeric substrates.

We present novel low temperature-based methods to integrate AgNWs in organic small molecule-based photovoltaics, either as transparent and highly conductive bottom-electrode or, for the first time, as spray-coated AgNW top-electrode. The bottom-electrodes are prepared by organic matrix assisted low-temperature fusing. Here, selected polymers are coated below the AgNWs to increase the interaction between NWs and substrate. In comparison to networks without these polymeric sublayers, the Rs is reduced by two orders of magnitude.

AgNW top-electrodes are realized by dispersing modified high-quality AgNWs in inert solvents, which do not damage small molecule layers. Accordingly, our AgNW dispersion can be spray-coated onto all kind of OPV devices. Both bottom- and top-electrodes show a Rs of <11 ?/? at >87 % transparency directly after spray-coating at very low substrate temperatures of <80 °C. We also demonstrate the implementation of our AgNW electrodes in organic solar cells. The corresponding devices show almost identical performance compared to organic solar cells exploiting ITO as bottom or thermally evaporated thin-metal as top-electrode.

9567-47, Session 10

A solution-doped small molecule hole transport layer for efficient ITO-free organic solar cells

Ludwig Bormann, Franz Selzer, Karl Leo, Lars Mueller-Meskamp, Technische Univ. Dresden (Germany)

Indium-tin-oxide-free (ITO-free) organic solar cells are an important, emerging research field because ITO transparent electrodes are a bottleneck for cheap large area devices on flexible substrates. Among highly conductive PEDOT:PSS and metal grids, percolation networks made of silver nanowires (AgNW) with a diameter in the nanoscale show a huge potential due to easy processing (e.g. spray coating), high aspect ratios and excellent electrical and optical properties like 15 Ohm/sq with a transmission of 83.5 % including the substrate.

However, the inherent surface roughness of the AgNW film impedes the implementation as bottom electrode in organic devices, especially fully vacuum deposited ones, where often shunts are obtained.

Here, we report about the solution processing of a small molecule hole transport layer (s-HTL) comprising N,N'-((Diphenyl-N,N'-bis)9,9,-dimethyl-fluoren-2-yl)-benzidine (BF-DPB, host material) and the proprietary NDP9 (p-dopant) deposited from tetrahydrofuran (THF) as non-halogenated, "green" solvent. We show, that the doping process already takes place in solution and that conductivities, achieved with this process at high doping efficiencies (4 * 10^-4 S/cm at 10 wt% doping concentration), are comparable to thermal co-evaporation of BF-DPB:NDP9 under high vacuum, which is the proven deposition method for doped small molecule films.

Applying this s-HTL to AgNW films leads to well smoothened electrodes, ready for application in organic devices.

Vacuum-deposited organic p-i-n solar cells with DCV2-5T-Me(3:3):C60 as active layer show a power conversion efficiency of 4.4% and 3.7% on AgNW electrode with 35nm and 90 nm wire diameter, compared to 4.1% on ITO with the s-HTL.

9567-48, Session 10

Transparent conductive thin-film encapsulation layers

Andreas Behrendt, Tobias Gahlmann, Sara Trost, Andreas Polywka, Patrick Görrn, Thomas Riedl, Bergische Univ. Wuppertal (Germany)

Gas diffusion barriers (GDB) are inevitable to protect sensitive organic materials or devices against ambient gases. Typically, thin-film gas diffusion barriers are insulators, e.g. Al2O3 or multilayers of Al2O3/ZrO2, etc.. A wide range of applications would require GDB which are at the same time transparent and electrically conductive. They could serve as electrode and moisture barrier simultaneously, thereby simplifying production. As of yet, work on transparent conductive GDB (TCGDBs) is very limited. TCGDBs based on ZnO prepared by atomic layer deposition (ALD) have been reported. Due to the chemical instability of ZnO, it turns out that their electrical conductivity severely deteriorates by orders of magnitude upon exposure to damp heat conditions after very short time. We will show that these issues can be overcome by the use of tin oxide (SnO2). Conductivities of up to 300 S/cm and extremely low water vapor transmission rates (WVTR) on the order of 10-6 g/(m2 day) can been achieved in SnOx layers prepared by ALD at low temperatures (<150°C). A sandwich of SnOx/Ag/SnOx is shown to provide an average transmittance of 82% and a low sheet resistance of 9 Ohm/sq. At the same time the resulting electrodes are extremely robust. E.g., while unprotected Cu and Ag electrodes degrade within a few minutes at 85°C/85%rH (e.g. Cu lost 7 orders of magnitude in electrical conductivity), sandwich structures of SnOx/(Cu or Ag)/SnOx remain virtually unchanged even after 100 h. The SnOx in this work will also provide corrosion protection for the metal in case of harsh processing steps on top these electodes (e.g. acidic). We demonstrate the application of these TCGDBs as electrodes for organic solar cells and OLEDs.

Conference 9568: Organic Field-Effect Transistors XIV

SPIE. OPTICS+ PHOTONICS ORGANIC PHOTONICS+ ELECTRONICS

Monday - Wednesday 10–12 August 2015

Part of Proceedings of SPIE Vol. 9568 Organic Field-Effect Transistors XIV; and Organic Sensors and Bioelectronics VIII

9568-101, Session 1

OFET surface treatments on copper and silver source and drain electrodes *(Invited Paper)*

Zhang Jia, Columbia Univ. (United States); Chang-Hyun Kim, Yvan Bonnassieux, Gilles Horowitz, Ecole Polytechnique (France); Luca Floreano, Alberto Verdini, INFM (Italy); Dean Cvetko, Ljubljana Univ. (Slovenia); Alberto Morgante, INFM (Italy); Ioannis Kymissis, Columbia Univ. (United States)

Organic field effect transistors (OFETs) offer a number of potential advantages for large area, low thermal budget, and flexible electronic systems. As the channel transconductance and current density in OFETs has improved over the past decade, the performance of transistor contacts has become a primary concern.

There is an increasing interest in the use of alternative metals to gold for transistor contacts. It is possible to engineer surface treatments for silver and copper electrodes that deliver similar advantages to surface treatments developed for use on gold electrodes. We will review how the understanding of surface treatments has evolved over the past decade, and in particular, discuss the use of photocurrent, structural analysis, and energy resolved X-ray techniques to understand surface treatment performance on device behavior. We will also discuss analysis of many of the same surface treatment strategies on silver and copper electrodes using printed and lithographic approaches, opening the door to potentially lower cost, higher throughput fabrication of OFETs with improved contact performance.

9568-102, Session 1

Scaling effects of organic thin-film transistors

Anita Risteska, Jacobs Univ. Bremen (Germany); Kris Myny, Sören Steudel, IMEC (Belgium); Masakazu Nakamura, Nara Institute of Science and Technology (Japan); Dietmar Knipp, Jacobs Univ. Bremen (Germany)

The influence of scaling of organic thin-film transistors on the operation of organic digital circuits was studied. Particularly, the influence of drain and source contact resistance on the static and the dynamic behaviour of the circuits was investigated. An analytical model describing the voltage transfer characteristics (static behaviour) and the propagation delay (dynamic behaviour) was developed. A static and dynamic experimentally measured data was modelled by a consistent set of data and good agreement between the model and the experiments was observed. For pentacene thin-film transistors with channel lengths in the range of few micrometers, the influence of contact effects has to be considered. Using the model, it was shown that for organic thin-film transistors with channel lengths of less than 10 ?m the contact resistance has negative influence on both, the static noise margin and the propagation delay. Scaling the lateral dimensions of the transistors down to few ?m limits the circuit performance due to contact effects, and the 1-10 MHz frequency range operation required by some applications can only be achieved by reducing the specific contact resistance, ?C, 10-100 times. This need for ?C reduction highlights the importance of improving charge injection in organic transistors that can usually be achieved by contact doping like in inorganic electronics or surface treatment with self-assembled monolayers.

9568-103, Session 1

Molecular-layer thick organic semiconductor materials and electronic devices

Liqiang Li, Suzhou Institute of Nano-Tech and Nano-Bionics (China)

Organic semiconductors (OSCs) are the key components of organic electronic devices. In conventional organic field-effect transistors (OFETs), thick organic semiconductor film (tens of nanomter) are adopted. It is known that the conductive channel (one to several molecular layers, several nanometers thick) in OFETs is located at the interface between OSCs and dielectrics, and is generally buried in the thick OSCs film. Therefore, it is difficult to characterize the conductive channel.

Molecular-layer thick OSCs ultrathin film may provide excellent model for both fundamental research and device applications, because in OFETs based on molecular layer thick OSCs ultrathin film, conductive channel is exposed. It would be favorable to investigate the structure-property relationships as well as to fabricate high performance sensors. However, the growth of such system is technologically challenging.

In our work, we demonstrated controllable growth of monolayer to multilayer organic semiconductor film in monolayer precision via dip-coating [Ref1], and further elucidated the growth mechanism for this unique phenomenon [Ref 2]. Moreover, high performance ammonia sensors were fabricated based on the ultrathin film [Ref 3].

9568-104, Session 1

Operation mechanism of the organic permeable base transistor

Felix Kaschura, Institut für Angewandte Photophysik (Germany) and Technische Univ. Dresden (Germany); Axel Fischer, Markus Klinger, Institut für Angewandte Photophysik (Germany); Duy Hai Doan, Weierstrass-Institut für Angewandte Analysis und Stochastik (Germany); Klaus Gärtner, Univ. della Svizzera italiana (Switzerland); Thomas Koprucki, Annegret Glitzky, Weierstrass-Institut für Angewandte Analysis und Stochastik (Germany); Daniel Kasemann, Institut für Angewandte Photophysik (Germany); Karl Leo, Institut für Angewandte Photophysik (Germany)

The Organic Permeable Base Transistor (PBT) is a promising device concept profiting from vertical current transport and thus short channel length. A perforated and insulated Base electrode is placed between Emitter and Collector, acting as control electrode regulating the current flowing through the openings of this electrode. In order to improve the device performance and tune the properties, a detailed understanding of the operation mechanism of the PBT is required.

In this contribution, we perform three-dimensional drift-diffusion simulations, to get an insight into the processes occurring in the device. We study the effect of different semiconductor and geometry parameters on the transistor characteristics, compare the simulation data to experimental

results, and outline the importance of charge carrier accumulation at the Base electrode for the high current densities obtained in these devices.

The operation of the PBT can be divided into two major regimes: At low current densities, the applied Base potential directly controls the collector current in the PBT. Hence, the number of charges allowed to pass the opening is the current limiting factor and this regime leads to an exponential current-voltage characteristics. At higher current densities, however, the opening does not act as a bottleneck any more. Instead, the intrinsic semiconductor cannot provide more current, manifesting in a saturation of the collector current in the in the on-state.

9568-105, Session 1

Hybrid light emitting transistors

Khalid Muhieddine, Mujeeb Ullah, Ebinazar B. Namdas, Paul L. Burn, The Univ. of Queensland (Australia)

Organic light-emitting diodes (OLEDs) are well studied and established in current display applications. Light-emitting transistors (LETs) have been developed to further simplify the necessary circuitry for these applications, combining the switching capabilities of a transistor with the light emitting capabilities of an OLED. Such devices have been studied using mono- and bilayer geometries and a variety of polymers [1], small organic molecules [2] and single crystals [3] within the active layers. Current devices can often suffer from low carrier mobilities and most operate in p-type mode due to a lack of suitable n-type organic charge carrier materials. Hybrid light-emitting transistors (HLETs) are a logical step to improve device performance by harnessing the charge carrier capabilities of inorganic semiconductors [4].

We present state of the art, all solution processed hybrid light-emitting transistors using a non-planar contact geometry [1, 5]. We will discuss HLETs comprised of an inorganic electron transport layer prepared from a sol-gel of zinc tin oxide and several organic emissive materials. The mobility of the devices is found between 1-5 cm2/Vs and they had on/off ratios of ~105. Combined with optical brightness and efficiencies of the order of 103 cd/m2 and 10-3-10-1 %, respectively, these devices are moving towards the performance required for application in displays.

9568-106, Session 2

On the use of organic transistors in flexible large-area sensor arrays *(Invited Paper)*

Brian Cobb, Abhishek Kumar, Holst Ctr. (Netherlands)

While much of the OTFT activity has been display-centric there is no doubt that as the OTFT technology matures the number of applications will continue to increase. Using our most recent flexible X-ray detectors we will discuss the prospect and challenges of organic transistors in sensor backplanes. For these application, the current mobility of ~0.1-2 cm2/Vs of OTFTs is currently not a problem. Their low leakage currents give them a distinct advantage over competing technologies, such as amorphous silicon TFT. Yet, challenges remain and these will be discussed.

9568-107, Session 2

New polymer dielectrics for low-voltage high transconductance organic transistors

Chao Wang, Desheng Kong, Wen-Ya Lee, Zhenan Bao, Stanford Univ. (United States)

Both high gain and transconductance at low operating voltages are crucial for organic field-effect transistors (OFETs) in practical applications. Here, we describe unexpected double-layer capacitance effect in polar elastomer dielectrics despite of very low ion concentration and ion conductivity, thus, significantly enhances OFET transconductances at low-voltages. In particular, we employed a special polar elastomer as the dielectric material. We obtained transconductance per channel width at -3V gate voltage 30 times higher as compared to the same organic semiconductors on a semicrystalline polymer. Compared with the previously reported high-transconductance OFETs using double-layer capacitance effects, our dielectric materials have the advantages of compatibility with standard manufacturing processes and high stability in air and water, resulting in highly stable operation in water with low bias stress effects.

9568-108, Session 2

Top-gate organic field-effect transistors and circuits on shape-memory polymer substrates

Sangmoo Choi, Canek Fuentes-Hemandez, Cheng-Yin Wang, Georgia Institute of Technology (United States); Andrew Wei, Walter E. Voit, The Univ. of Texas at Dallas (United States); Bernard Kippelen, Georgia Institute of Technology (United States)

Organic field-effect transistors (OFETs) have been intensively developed, and their characteristics and processibility have dramatically improved: carrier mobility (?) values in OFETs are now even higher than amorphous silicon thin-film-transistors (a-Si TFTs); threshold voltage values (VTH) have decreased near zero, which enables low voltage driving of OFET circuits; high operational and environmental stability has also been reported, particularly in top bilayer gate OFET geometries; and new fabrication methods, such as inkjet-printing, have been developed.

As the basic properties of OFETs are approaching the required performance for the realization of commercially viable products, applications of OFETs have become an important topic of research. One desirable property of OFETs is the realization of flexible electronic devices, such as wearable electronics. Towards this goal, researchers have been exploring new flexible substrate materials. Among these new substrates, shape-memory polymers (SMPs) have shown unique features: a variable Young's modulus dependent on temperature; the ability to fix two or more shapes when a thermal stimulus is applied; low cure stress, and biocompatibility. These features make SMPs good candidates as substrate materials for three-dimensional shape applications like human body-embedded sensors, but also present challenges for the direct fabrication of OFETs on its surface.

Here, we report on the direct fabrication of high-performance top-gate OFETs and circuits on biocompatible, low cure stress SMP substrates, and a comparison with the performance of OFETs on conventional glass substrates. Demonstration of OFET circuits on SMP substrates opens the door to potential applications that will be discussed.

9568-109, Session 2

Organic transistors for electrophysiology *(Invited Paper)*

Jonathan Rivnay, Ecole Nationale Supérieure des Mines de Saint-Étienne (France)

Efficient local transduction of biological signals is of critical importance for mapping brain activity and diagnosing pathological conditions. Traditional devices used to record electrophysiological signals are passive electrodes that require (pre)amplification with downstream electronics. Organic electrochemical transistors (OECTs) that utilize conducting polymer films as the channel have shown considerable promise as amplifying transducers due to their stability in aqueous conditions and high transconductance (>3 mS). The materials properties and physics of such transistors, however, remains largely unexplored thus limiting their potential. Here we show that the uptake of ionic charge from an electrolyte into a poly(3,4-ethylenedioxythiophene) doped with polystyrene sulfonate (PEDOT:PSS) OECT channel leads to a dependence of the effective capacitance on the entire volume of the film. Subsequently, device transconductance and time response vary with channel thickness, a defining characteristic that differentiates OECTs from field effect transistors, and provides a new degree of freedom for device engineering. Using this understanding we tailor OECTs for a variety of low (1-100 Hz) and high (1-10 kHz) frequency applications, including human electroencephalography, where high transconductance devices impart richer signal content without the need for additional amplification circuitry. We also show that the materials figure of merit OECTs is the product of hole mobility and volumetric capacitance of the channel, leading to design rules for novel high performance materials.

9568-110, Session 2

Transcap: A new integrated hybrid supercapacitor and electrolyte-gated transistor device *(Invited Paper)*

Clara Santato, Ecole Polytechnique de Montréal (Canada)

The boom in multifunctional, flexible, and portable electronics and the increasing need of low-energy cost and autonomy for applications ranging from wireless sensor networks for smart environments to biomedical applications are triggering research efforts towards the development of self-powered sustainable electronic devices. Within this context, the coupling of electronic devices (e.g. sensors, transistors) with small size energy storage systems (e.g. micro-batteries or micro-supercapacitors) is actively pursued.

Micro-electrochemical supercapacitors are attracting much attention in electronics for their capability of delivering short power pulses with high stability over repeated charge/discharge cycling.

For their high specific pseudocapacitance, electronically conducting polymers are well known as positive materials for hybrid supercapacitors featuring high surface carbon negative electrodes. The processability of both polymer and carbon is of great relevance for the development of flexible miniaturised devices.

Electronically conducting polymers are even well known to feature an electronic conductivity that depends on their oxidation (p-doped state) and that it is modulated by the polymer potential. This property and the related pseudocapacitive response make polymer very attracting channel materials for electrolyte-gated (EG) transistors.

Here, we propose a novel concept of “Trans-capacitor”, an integrated device that exhibits the storage properties of a polymer/carbon hybrid supercapacitor and the low-voltage operation of an electrolyte-gated transistor.

Well-balanced carrier mobilities of ambipolar transistors based on a low band gap small molecule semiconductor

Min Je Kim, Woonggi Kang, Sungkyunkwan Univ. (Korea, Republic of)

We synthesized a solution-processable low bandgap small molecule, Si1TDPP-EE-COC6 for semiconducting channel material in organic field-effect transistors (FETs). The Si1TDPP-EE-COC6 consisted of electron-rich thiophene-dithienosilole-thiophene (Si1T) units and electron-deficient diketopyrrolopyrrole (DPP) units. The change of the electrical properties of FETs induced by thermal annealing was systematically investigated. The hole and electron mobilities of as-spun Si1TDPP-EE-COC6 were 3.3 ? 10–4 and 1.7 ? 10–4 cm2/(Vs), respectively. A significant increase in carrier mobilities was obtained by thermal annealing at 150 °C: hole mobility of 0.003 cm2/(Vs) and electron mobility of 0.002 cm2/(Vs). This performance enhancement upon thermal annealing is strongly related with the enhanced layered edge-on structure and resulting reduced ϖ-ϖ intermolecular spacing, examined by grazing incidence X-ray diffraction (GIXD) and atomic force microscopy (AFM) measurements. Importantly, atomically-thin CVD-grown graphene source/drain electrodes led to dramatic increase in the carrier mobilities. For example, the FETs based on 150 °C-annealed Si1TDPP-EE-COC6 exhibited a hole mobility of 0.011 cm2/(Vs) and electron mobility of 0.015 cm2/(Vs), which are best performance among FETs with DPP-based small molecules. The CVD-grown graphene electrodes provide a facile method to improve the FET performance based on DPP-based small molecule semiconductor.

9568-138, Session PMon

High performance ferroelectric organic field-effect transistor using soft contact process

Min-Hoi Kim, Hanbat National Univ. (Korea, Republic of); Gyu Jeong Lee, Seoul National Univ. (Korea, Republic of); Jae-Hyun Lee, Hanbat National Univ. (Korea, Republic of); Jin-Hyuk Bae, Kyungpook National Univ. (Korea, Republic of)

Nonvolatile memory based on ferroelectric organic field-effect transistors (FeOFETs) has attracted much attention due to cost effective processing compatibility. Although the device performance of the FeOFETs have been drastically improved over the past decades, low memory on-off ratio, which is caused by the low mobility, hinders the practical applications such as identification tags and memory embedded sensors. In this work, we demonstrated the high performance FeOFET with high memory on-off ratio by the simple soft-contact-process.

For a gate electrode of the FeOFETs, aluminum was thermally deposited on a cleaned glass substrate through a shadow mask. For a ferroelectric gate insulator, poly(vinylidene fluoride) copolymer with trifluoroethylene (75/25 mol %) [P(VDF-TrFE)], dissolved in cyclopentanone in 10 wt %, was spin-coated on the substrate. The samples were cured at 140 °C for 2 h. During the curing process, for the SCP-processed OFETs, the surface of the ferroelectric insulator was pressed by the elastomer, polydimethylsiloxane, under the pressure of about 9.8 N/cm2. A p-type organic semiconductor of pentacene of 50 nm and gold of 65 nm was sequentially formed on the gate insulator through a shadow mask by thermal.

Through the soft contact process, the rms roughness of the ferroelectric insulator was reduced from 15nm to 5nm. The mobility of the soft-contact-processed FeOFETs exhibits more than ten times increased mobility (0.04 cm2/Vs,), which results in the ten times increased memory on-off ratio.

Indium gallium zinc oxide-based stretchable organic-inorganic hybrid transistors using stiff island structure

Soon-Won Jung, Jae Bon Koo, Chan Woo Park, Bock Soon Na, Ji-Young Oh, Sang Seok Lee, Electronics and Telecommunications Research Institute (Korea, Republic of)

In this study, stretchable organic–inorganic hybrid thin-film transistors (TFTs) are fabricated on a polyimide (PI) stiff-island/elastomer substrate using blends of poly(vinylidene fluoride-trifluoroethylene) [P(VDF-TrFE)] and poly(methyl methacrylate) (PMMA) and oxide semiconductor In-Ga-

Zn-O as the gate dielectric and semiconducting layer, respectively. Carrier mobility, Ion/Ioff ratio, and subthreshold swing (SS) values of 6.1 cm2V-1s-1, 107, and 0.2 V/decade, respectively, were achieved. For the hybrid TFTs, the endurable maximum strain without degradation of electrical properties was approximately 49%. These results correspond to those obtained in the first study on fabrication of stretchable hybrid-type TFTs on elastomer substrate using an organic gate insulator and oxide semiconducting active channel structure, thus indicating the feasibility of a promising device for stretchable electronic systems

9568-140, Session PMon

Improvement of micro-contact patterning fidelity of organic semiconductors through ultraviolet ozone treatment on nanoporous stamps

Hea-Lim Park, Bo-Yeon Lee, Chang-Min Keum, Se-Um Kim, Seoul National Univ. (Korea, Republic of); Min-Hoi Kim, Hanbat National Univ. (Korea, Republic of); Sin-Doo Lee, Seoul National Univ. (Korea, Republic of)

Among various kinds of organic semiconductor (OSC) materials, 6,13-bis(tr iisopropylsilylethynyl) pentacene (TIPS-PEN) has widely been investigated due to its relatively high mobility and possibility of cost-effective fabrication by solution process. In spite of these advantages, the practical application of TIPS-PEN for the large-area devices still struggles to satisfy the industrial figures of merit, since it is challenging to obtain the precise pattern together with the uniform film properties of solution-processed TIPS-PEN. It should be noted that the patterning of OSC films with high pattern fidelity is significant to eliminate the undesirable current pathway and thus to ensure the performance reliability between individual device components.

In this work, we demonstrated the effect of ultraviolet ozone (UVO) treatment of a polydimethylsiloxane (PDMS) stamp on the micro-contact patterning fidelity of TIPS-PEN film. Here, TIPS-PEN was blended with an insulating organic polymer to enhance the uniformity of TIPS-PEN films. For patterning, the UVO-treated PDMS stamp having micrometer-scale patterns was contacted with a thin film of blended TIPS-PEN uniformly coated on a substrate by spin-coating. During this process, the nanoporous PDMS stamp absorbed the TIPS-PEN monomers through the contact area, generating the complementary patterns of TIPS-PEN. It was found that the pattern fidelity was greatly improved by increasing the UVO treatment time on PDMS stamps from 0 to 30 minutes. Our approach for achieving high pattern fidelity by a simple and low-cost patterning technique will provide a useful platform for integration of solution-processed organic electronic devices.

This work was supported in part by Samsung Display, Inc.

Tunable solubility parameter of poly(3-hexyl thiophene) with hydrophobic side-chains to achieve rubbery semiconducting films

Mi Jang, Hyeonji Bae, Hoichang Yang, Joongyu Ahn, Inha Univ. (Korea, Republic of)

A highly ϖ-conjugated nanofibrillar network of poly(3-hexyl thiophene) (P3HT) embedded in polydimethylsiloxane (PDMS) elastomer films on dielectrics was facilely developed via solution-blending of an ultrasonicated P3HT solution with a PDMS followed by spin-casting and curing. In contrast, simple blending without ultrasonication yielded large agglomerates in cast films owing to a great difference in solubility parameter (P3HT = 9.5 cal1/2cm-3/2, PDMS = 7.3 cal1/2cm-3/2). Via ultrasonicating, P3HT could develop nanofibrils surrounded by side-chains with the same solubility parameter value as that of PDMS, yielding homogeneous P3HT/PDMS blend films. Blend films could yield high electrical properties, as well as excellent environmental stability.

Air-processable silane-coupled polymers to modify a dielectric for solution-processed organic field-effect semiconductors

Mi Jang, Young Chang Yu, Ji Ho Youk, Hoichang Yang, Inha Univ. (Korea, Republic of)

Poly(styrene-r-3-methacryloxypropyltrimethoxysilane) (PSMPTS) copolymers were synthesized by the free radical polymerization of styrene and 3-methacryloxypropyltrimethoxysilane (MPTS) for use as surface modifiers. PSMPTS copolymers were spun-cast onto a hydrophilic SiO2 layer and were then annealed at 150 °C in ambient air. The polystyrene (PS)-based copolymer with approximately 30 MPTS coupling sites, was easily grafted onto the SiO2 surface after annealing periods longer than 1 min. On the untreated and polymer-treated dielectrics, spin-casting of an ultrasonicated poly(3-hexyl thiophene) solution yielded highly interconnected crystal nanofibrils. We believe that ambient-air-processable silane-coupled copolymer can be used as a solution-based surface modifier for continuous, large-scale OFET fabrication.

Analysis of different deposition patterns for semiconductor at organic field-effect transistors using inkjet printing technique

Josiani Cristina Stefanelo, Lilian Soares Cardoso, Roberto Mendonça Faria, Univ. de São Paulo (Brazil)

Inkjet printing is a potential tool that can be applied to fabricate organic field-effect transistors (OFETs) because it has several advantages, such as, easiness to print well-defined patterns with deposition accuracy and in small dimensions. Moreover, it allows different materials to be deposited on the same substrate. This last advantage favors the fabrication of organic digital logic inverters, such as, organic CMOS (complementary metal oxide semiconductor). Here, we show the OFETs fabrication using the inkjet printing technique. The poly(3-hexylthiophene) (P3HT) semiconductor was printed using functional materials printer. The semiconductor was deposited using different line deposition patterns, with the same or variable dispensing direction. Patterns of parallel and perpendicular lines with respect to direction of electronic conduction were printed. This study evaluated the influence of deposition patterns in the OFETs performance, using the architecture top gate-bottom contact. Other printing parameters were kept, as well as the polymeric dielectric layer, produced via spin-casting, and the evaporated metal electrodes. High-performance OFET devices were obtained for the case which parallel lines regarding direction of electronic conduction had the same dispensing direction. These obtained devices reached on/off ratio up to 104 and swing subthreshold of 3 V/dec. In OFETs with perpendicular lines regarding electronic conduction, the performance was similar to the two types of dispensing direction. This study showed that the best performance of OFETs was obtained for the printed parallel pattern in respect to direction of electronic conduction, due to its lower channel resistance.

Photo-physics and charge transport in hetero-structure organic light emitting transistors

Fatemeh Maasoumi, Mujeeb Ullah, Paul E. Shaw, The Univ. of Queensland (Australia); Jun Li, National Univ. of Singapore (Singapore); Paul L. Burn, Paul Meredith, Ebinazar B. Namdas, The Univ. of Queensland (Australia)

Organic light emitting field effect transistors (LEFETs) are multifunctional devices. They not only have the electroluminescent properties of an organic light emitting diode (OLED) but also the switching capabilities of a transistor in a single device architecture. This dual functionality of LEFETs has the potential for new applications such as simplified pixels for flat panel displays, integrated sensor architectures and potentially electrically driven lasers. They are also useful structures for basic optoelectronic studies. Although LEFET brightnesses have improved in the last decade, their electrical switching ON/OFF ratio and EQE at high brightnesses still needs to be improved [1-4]. This is due to the lack of ideal materials and LEFET design, and the absence of a comprehensive understanding of charge transport, radiative recombination processes, and light out coupling in such devices.

A useful probe for studying charge transport in light emitting organic semiconducting materials is to measure the optoelectronic characteristics as a function of temperature. In this work, we demonstrate for the first time, simultaneous probing of charge transport (for both electron and holes), charge injection, contact resistance and radiative recombination in bilayer light emitting and charge transporting polymer films in an LEFET configuration. We employed temperature dependent measurements on bilayer LEFETs consisting of charge transporting ambipolar DPP based polymer and a yellow-green emissive polymer. The bilayer LEFETs show decreases in the source-drain current, mobility (both electron and hole) and brightness with decreasing temperature. In contrast, the external quantum efficiency (EQE) was found to increase by an order of magnitude. We correlate temperature dependent mobility and drain current measurements with thermally activated processes, which is consistent with hopping charge transport in disordered semiconductors. We demonstrate that increases in EQE at low temperatures are predominately due to an increase in the recombination efficiency.

Gate dielectric surface treatments for performance improvement of poly(3-hexylthiophene-2,5-diyl) based organic field-effect transistors

Ali Nawaz, Cristiane D. Col, Isidro C. Cruz, Univ. Federal do Parana (Brazil); Anshu Kumar, Anil Kumar, Indian Institute of Technology Bombay (India); Ivo A. Hümmelgen, Univ. Federal do Parana (Brazil)

While organic field effect transistors (OFETs) remain as the center of extensive research, several techniques are being developed for performance improvement. Correspondingly, we investigate the role of passivation of charge traps present on cross-linked poly (vinyl alcohol) (cr-PVA) surface using hexadecyltrimethylammonium bromide (CTAB), sodium dodecyl sulfate (SDS) and vitamin C (ascorbic acid) treatments in OFETs prepared using bottom-gate top-contact geometry. The OFETs constitute of cr-PVA as gate dielectric and poly(3-hexylthiophene-2,5-diyl) as channel semiconductor. CTAB and SDS are cationic and anionic surfactants respectively, known for formation of micelles with positively and negatively charged heads above critical micelle concentration (CMC), which contribute to the passivation of charge traps. Vitamin C is a reducing agent which contributes to the passivation of positively charged defects. Without compromising the low power consumption, the passivation of charge traps present on the surface of cr-PVA results in ca. 50% higher specific dielectric capacitance and significant improvements in field-effect mobility (?FET), on/off current ratio, subthreshold swing and transconductance. ?FET of 0.35, 0.34 and 0.29 cm2 V-1.s-1 are presented for vitamin C, CTAB and SDS treated devices respectively, as compared to the ?FET of 0.09 cm2 V-1.s-1 for untreated device.

Natural dielectrics in flexible organic field-effect transistors

Tzung-Fang Guo, Chun-Ting Yeh, Tzung-Da Tsai, National Cheng Kung Univ. (Taiwan)

Our previous study had demonstrated the fabrication of organic field-effect transistors (OFETs) and invertors by applying the chicken albumen (natural dielectrics) film directly from a fresh egg as the gate dielectrics (Adv. Mater. 2011, 23, 4077). Additionally, albumen dielectrics shows the enhanced ultraviolet fluorescence through plasmon resonance energy transfer of gold nanoparticles under the photo excitation (Sci. Rep. 2013, 3, 1505). In this presentation, the denaturation of albumen was modulated by varying the process of thermal treatment, resulting in the changes of the electrical, mechanical, and surface properties of chicken and duck albumen dielectrics and the optimization of OFET device performance.

The second part of presentation studies the OFETs fabricated with the other natural dielectrics from the porcine (pig) protein. The dielectric constant of porcine protein is approximate, 9.2-9.8, relatively higher than that of chicken albumen. The OFETs made of the porcine protein dielectrics exhibits the decent output characteristics, of an on-off ratio of roughly 10 4-10 5, a threshold voltage below -0.5 V. The porcine protein dielectrics-based complementary inverters were also fabricated in this study. A complementary inverter made of a pentacene p-channel OFET and a C60 n-channel OFET with porcine protein operated at the supply voltage (VDD) of 6 V is successfully demonstrated. The inverted output voltage is at 2.9 V as VDD of 6.0 V, in which the gain has reached a decent level of 25. Our results highlight the benefits of utilizing biomaterial dielectrics in fabricating organic and flexible electronics for applications.

9568-147, Session PMon

Dimensional extendibility in conjugation and ordering of solution-processed semiconducting polymers

Hoichang Yang, Mi Jang, Inha Univ. (Korea, Republic of); Ji-Hoon Kim, Pusan National Univ. (Korea, Republic of); Yun-Hi Kim, Gyeongsang National Univ. (Korea, Republic of); Do-Hoon Hwang, Pusan National Univ. (Korea, Republic of); Minjung Lee, Inha Univ. (Korea, Republic of)

Various conjugated polymers were synthesized with well-defined molecular weights, and their ϖ-conjugation extendibility were investigated. Crystal nanostructures of these conjugated polymers in films were controlled from rods, fibrils to percolated layers, depending on the backbone/side chains and film procedures. Electrical properties of these films in organic field-effect transistors (OFETs) supported that the both intra- and inter-molecular ϖ-conjugation of these polymers plays an important role in yielding better charge transport. Among these polymers synthesized, diketopyrrolopyrrole-based copolymers could develop highly percolated, conjugated layers on gate dielectrics, and the corresponding films showed high field-effect mobility up to 4 cm2V-1s-1 in OFETs.

9568-303,

Ultraflexible organic thin-film devices for wearable and implantable electronics

Takao Someya, The Univ. of Tokyo (Japan)

Mechanically flexible and stretchable devices are expected to open new possibilities in fields of wearable and implantable electronics. Especially, conformability, ruggedness, lightweight, biocompatibility, and large-area are all important to create new electronic applications that can be directly mounted on the surface of human skins and/or even inside the body. From this viewpoint, ultraflexible organic thin-film devices, such as organic thin-film transistors (OTFTs), organic photovoltaic cells (OPVs), and organic light-emitting diodes (OLEDs), have attracted much attention recently. In this talk, we report recent progress of ultraflexible organic thin-film devices that are manufactured on ultrathin plastic film with the thickness of 1 ?m. We will also describe emerging applications using ultraflexible and stretchable electronic systems in the fields of biomedical electronics.

9568-111, Session 3

Fundamental aspects in single crystal OFETs and large area crystalline films for applications *(Invited Paper)*

Marta Mas-Torrent, Freddy Del Pozo, Raphael Pfattner, Francisco Otón, Jaume Veciana, Concepció Rovira, Institut de Ciència de Materials de Barcelona (Spain)

Organic-based devices are currently attracting great attention for applications where low-cost, large area coverage and flexibility are required. In addition, the versatility of organic synthesis allows for the preparation of materials “à la carte”. That is, since by chemically modifying their molecular structure and functionality, the solid state structure and the resulting macroscopic properties are altered, it is feasible to synthesize tailored materials for specific uses. Tetrethiafulvalenes (TTF) have shown to exhibit excellent OFET mobility (up to 6 cm2/Vs) as well as easy processability. Thus, TTFs offer a suitable platform to perform structure-mobility correlation studies, due to the fact that their chemistry is very well-known making it possible to synthesize a large variety of very similar molecules exhibiting different solid-state organization or different electronic structure. Here we will describe our recent work related to explore the influence of crystal structure, polymorphism, electronic structure and device configuration and interfaces in TTF OFETs. Further, we demonstrate the fabrication of large area coverage devices based on solution processed blends of a TTF derivative with an inert polymer that exhibits an excellent performance and exceptionally environmental stability.

9568-112, Session 3

Polymorphism in the organic charge-transfer complex dibenzotetrathiafulvalene-7,7,8,8-tetracyanoquinodimethane (DBTTF-TCNQ) and its effect on optical and electrical properties

Katelyn P. Goetz, Wake Forest Univ. (United States); Jun Ya Tsutsumi, National Institute of Advanced Industrial Science and Technology (Japan); Sujitra Pookpanratana, National Institute of Standards and Technology (United States); Jihua Chen, Oak Ridge National Lab. (United States); Tatsuo Hasegawa, National Institute of Advanced Industrial Science and Technology (Japan) and The Univ. of Tokyo (Japan); Oana D. Jurchescu, Wake Forest Univ. (United States)

We present the structural, optical, and electronic properties of two polymorphs of the charge-transfer complex dibenzotetrathiafulvalene-7,7,8,8-tetracyanoquinodimethane (DBTTF-TCNQ). The structures were resolved using electron diffraction. One is a rectangular-shaped platelet and exhibits ambipolar transport with gold contacts in organic field-effect transistors (OFETs). The second polymorph grows as a thin, circular platelet and shows p-type transport within the same OFET structure. The difference in electrical characteristics originates from two factors. First, the position of the HOMO level of the rectangular polymorph lies 0.07 eV below that of the circular polymorph, as determined by ultraviolet photoelectron spectroscopy (UPS). Second, using X-Ray photoelectron and Raman spectroscopies we find that the degree of charge transfer between the donor DBTTF and acceptor TCNQ varies from 0.4e ± 0.1e for the rectangular crystals to 0.1e ± 0.1e for the circular crystals. Additional differences between the two polymorphs arise when measuring the absorbance of the crystals. First, the peak corresponding to intermolecular charge transfer is offset by 0.05 eV between the two polymorphs, in agreement with UPS measurements. Additionally, the polarization angle dependence of the intermolecular CT band for the rectangular crystal is shifted by 60deg with respect to the angle dependence of the intramolecular transition. In contrast, this shift was only 20deg for the circular polymorph. These angle dependences allowed us to couple the anisotropy of the electrical characteristics to the optical measurements. Our results demonstrate how slight modifications in crystal structure yield drastic differences in optical and electrical properties in organic semiconducting materials.

9568-113, Session 3

Fabrication of water-stable organic transistors using crystalline rubrene thin-film and polymer-treated dielectric

Jaejoon Kim, KAIST (Korea, Republic of); Hyoek Moo Lee, LG Chem, Ltd. (Korea, Republic of); Sung Oh Cho, KAIST (Korea, Republic of)

For the real application of organic electronics, stable operation of electronic devices in humid or aqueous condition is essential and desirable. However, most of organic semiconductors were very weak to the oxygen or water and especially, cannot be operated well in aqueous condition without an encapsulation.

Here, we present water-stable organic thin-film transistors with highly crystallized rubrene and polymer-treated dielectrics. These high water-stability could be achieved by two factors. First, rubrene, a well-known p-type semiconducting material, showed high air and water stability after the crystallization of ‘abrupt heating’. By the fabrication and aqueous operation of rubrene thin film transistor, we could show the water stability of crystallized thin-film rubrene. Such high environmental stability is attributed to the fact that rubrene has comparatively low HOMO level of -5.4 eV and large bandgap energy of 3.2 eV and that the rubrene thin-film is composed of well-interconnected orthorhombic rubrene crystals.

Second, the polymer-treatment of dielectrics can enhance long-term water stability of fabricated rubrene thin-film transistor. By the complete immersion test of transistors, we could characterize the increase of water-stability after the treatment of dielectrics with cross-linked polymer. For this purpose, polystyrene is cross-linked by electron irradiation and the water penetration into semiconductor/dielectric interface was decreased due to the decreased surface energy of polymer dielectric compared to the SiO?.

The fabricated rubrene thin-film transistors showed a field-effect mobility of ~0.5 cm?V??s?? and long-term stability under ambient and aqueous conditions. Also, we investigated their potential applications in chemical or bio sensors.

9568-114, Session 3

Charge transport and device physics of layered-crystalline organic semiconductors *(Invited Paper)*

Tatsuo Hasegawa, The Univ. of Tokyo (Japan)

Here we present and discuss our recent investigations into the understanding of microscopic charge transport, novel film processing technologies, and a development of layered-crystalline organic semiconductors for high performance OTFTs. We first discuss the microscopic charge transport in the OTFTs, as investigated by field-induced electron spin resonance spectroscopy. The technique can detect signals due to tiny amount of field-induced carriers, accumulated at the semiconductor-insulator interfaces. Following aspects are presented and discussed; 1) Carrier motion within the crystalline domains can be understood in terms of the trap-and-release transport, 2) charge trap states are spatially extended over several sites depending on the trap levels, and 3) the intra- and inter-domain transport can be discriminated by anisotropic electron spin resonance measurements. Next we discuss novel print production technologies for organic semiconductors showing high layered crystallinity. The concept of “printed electronics” is now regarded as a realistic paradigm to manufacture light-weight, thin, and impact-resistant electronics devices, although production of highly crystalline semiconductor films may be incompatible with conventional printing process. We here present printing techniques for manufacturing high performance OTFTs; 1) double-shot inkjet printing for small-molecule-based semiconductors, and 2) push-coating for semiconducting polymers. We demonstrate that both processes are useful to manufacture high quality semiconductor layers with the high layered crystallinity.

9568-115, Session 4

Characterizing the channel properties and operation of organic transistors with non-ideal behavior *(Invited Paper)*

David J. Gundlach, National Institute of Standards and Technology (United States)

Field effect transistors based on organic semiconductor thin films (OTFTs) are of interest for a number of electronic applications where mechanical ruggedness, flexibility, and specific functionality is required. Continued improvement in materials design and novel processing have yielded several impressive technological demonstrations, and more recently, OTFTs with electrical properties significantly improved from previous reports. In this presentation, we examine device operation and critical electronic parameters by using impedance spectroscopy and quasi-static capacitance-voltage to disentangle and quantify the contributions of the contacts and channel as a function of applied voltage. To remove ambiguity associated with film formation and resulting microstructure we fabricated and characterized organic single crystal field effect transistors using the well-studied organic semiconductor Rubrene. Rubrene single crystals were grown by vapor transport and laminated on top of oxidized silicon substrates with source and drain electrodes patterned by using photolithograpy, thermal evaporation, and lift-off process. Capacitance-voltage analysis was used to investigate channel accumulation and threshold voltage, and classical transmission line theory and modeling was used to quantify the contact and channel properties along with their response to the applied gate bias. The findings are compared with commonly employed DC electrical measurements to provide greater insight into intrinsic channel properties and highlight caveats in parameterizing the electronic properties of OTFTs which exhibit non-ideal electronic behavior.

9568-116, Session 4

Charge transport and device operation mechanisms in field-effect transistors with high mobility donor-acceptor polymer semiconductors *(Invited Paper)*

Takayuki Okachi, Tomoya Kashiki, Kenichiro Ohya, Sumitomo Chemical Co., Ltd. (Japan)

The field-effect transistors based on our donor-acceptor alternating polymer semiconductor were fabricated and the charge transport mechanisms were investigated. It was found that the electric field and the temperature dependences of the mobility can be fitted by a Poole-Frenkel model of charge transport. The mobility was increased with decreasing the channel length of the devices i.e., with increasing the lateral electric field, due to its small contact resistance. The mobility of higher than 1 cm^2/Vs was achieved at room temperature with the channel length of smaller than 10 um. Although an apparent “band-like” negative temperature coefficient of the mobility has not been observed, an almost temperature independent mobility was observed in the transistors with a channel length of 5 um and the high mobility as large as 0.4 cm^2/Vs was obtained even at 4 K due to its very low activation energy. Based on this material, the next generation polymer semiconductor with higher mobility and higher air stability has been successfully developed. The device operation mechanism of the transistors with high mobility donor-acceptor alternating polymers will be also discussed. It was revealed that the trapped electrons injected from the drain electrode prevent complete pinch-off in the saturation region in p-type transistors and can cause an inaccurate estimation of the intrinsic mobility.

9568-117, Session 4

Study on contact and channel resistance of pentacene-based ambipolar organic thin-film transistors

Tsung Jun Ho, Horng-Long Cheng, Guo En Yan, National Cheng Kung Univ. (Taiwan)

In this work, we investigated the electrical characteristics of pentacene-based ambipolar organic thin-film transistors (OTFTs) by modifying the channel length. We fabricated a top contact device structure with sliver as the source and drain electrodes and heavy doped p-type silicon wafer as the gate electrode. The channel length of the pentacene-based ambipolar OTFTs are 50, 100, 250, and 400 μm; the channel width is fixed. The output current of the n-channel and p-channel decreases with increasing channel length. The saturated mobility and threshold voltage of both channels increase with the increase in channel length. The increase rate of saturated mobility and threshold voltage of the n-channel is larger than that of the p-channel. The influence of channel length on the electrical properties of the p-channel and n-channel is different. Furthermore, we utilized the gated-transfer length method to study the contact resistance between sliver and pentacene and the channel resistance of pentacene. Contact and channel resistance decrease with the increase in gate voltage in the saturation region. The total resistance of pentacene-based ambipolar OTFTs increases with channel length at a fixed gate voltage. However, n-channel total resistance has stronger gate voltage and channel length dependence than p-channel total resistance. This result reveals that electron transport in the device channel requires a larger driving voltage than in the hole. Selecting a suitable channel length is critical to obtain a well-balanced performance of the dual carriers that transport ambipolar OTFTs and to avoid a large loss in injection barrier.

9568-118, Session 4

Charge transport physics of high mobility conjugated polymers *(Invited Paper)*

Deepak Venkateshvaran, Univ. of Cambridge (United Kingdom)

Over recent years there has been tremendous progress in developing low-temperature, solution-processible organic semiconductors that provide high charge carrier mobilities for both n-type and p-type device operation, good operational stability and other functionalities such as efficient electroluminescene, sensing or memory functions for a variety of applications. Here we are interested in understanding the charge transport physics of high mobility conjugated polymers and the relationship between molecular structure, polymer microstructure and charge transport. Many of the recently discovered high mobility polymers, in particular donor-acceptor copolymers, are characterised by a puzzling lack of pronounced crystalline order. In this presentation we will present our current understanding of the transport physics of these materials and of the reasons why these materials exhibit such high carrier mobilities.

9568-119, Session 5

Sub-15-nm patterning of asymmetric metal electrodes and devices by adhesion lithography *(Invited Paper)*

David Beesley, Thomas D. Anthopoulos, John C. de Mello, Imperial College London (United Kingdom)

Coplanar electrodes formed from asymmetric metals separated on the nanometre length scale are essential elements of nanoscale photonic and electronic devices. Existing fabrication methods typically involve electron-beam lithography—a technique that enables high fidelity patterning but suffers from significant limitations in terms of low throughput, poor scalability to large areas and restrictive choice of substrate and electrode materials. Here, we describe a versatile method for the rapid fabrication of asymmetric nanogap electrodes that exploits the ability of selected self-assembled monolayers to attach conformally to a prepatterned metal layer and thereby weaken adhesion to a subsequently deposited metal film. The method may be carried out under ambient conditions using simple equipment and a minimum of processing steps, enabling the rapid fabrication of nanogap electrodes and optoelectronic devices with aspect ratios in excess of 100,000.

9568-120, Session 5

Fabrication of a high-resolution roll for gravure printing of 2μm features

Gerd Grau, Rungrot Kitsomboonloha, Vivek Subramanian, Univ. of California, Berkeley (United States)

High-resolution features are key to achieve high performance printed electronics devices such as transistors. Gravure printing is very promising to achieve high resolution in combination with high printing speeds on the order of 1m/s. High-speed gravure has recently been shown to print high resolution features down to linewidths and spacing of 2μm. Whilst this was a tremendous improvement over previous reports, these results had been obtained using silicon printing plates. These silicon printing plates are fabricated using microfabrication techniques which offers several advantages over traditional metal gravure cylinders where the features are defined by techniques such as stylus engraving, laser engraving or etching. This offers much greater precision and design freedom in terms of feature size, surface roughness, cell placement and cell shape. However, rigid silicon printing plates cannot be used in a roll-to-roll printing process that would truly enable low-cost printed electronics. Here we demonstrate for the first time a gravure printing roll that combines the precision of silicon printing plates with the form factor of a metal cylinder.

The fabrication process starts with a silicon master whose pattern is replicated by polymer molding. The actual metal printing plate is then built up on the polymer negative of the pattern by a combination of electroless and electroplating. After separation of the polymer and the metal, the metal printing plate can be mounted on a magnetic roll for printing. Printing of highly scaled 2μm features is demonstrated. Different metal surfaces were explored to optimize printing performance and wear during printing.

9568-121, Session 5

Orthogonal lithography and doped organic semiconductors and their application in organic transistors

Daniel Kasemann, Alrun Günther, Xuhai Liu, Technische Univ. Dresden (Germany); Björn Lüssem, Kent State Univ. (United States); Karl Leo, Technische Univ. Dresden (Germany)

Organic field effect transistors (OFET) have been in the focus of research for more than two decades and their performance increases steadily. However, due to a lack of performance, flexibility in parameter design, and issues with upscaling the current processing techniques, they have not yet left the prototype stage for applications. In this contribution, we demonstrate the realization of novel organic transistor concepts to overcome the current limitations of OFET.

The performance of organic transistors as well as the potential for upscaling to large-area processing can be significantly enhanced by improved device geometry and structuring techniques. The transconductance and cut-off frequency of horizontal OFET are substantially limited by the charge carrier mobility and channel length, requiring channel lengths in the range of 1 µm. While difficult to realize in planar devices, we demonstrate that these dimensions can be easily achieved in vertical devices like vertical organic field effect transistors (VOFET)[1, 2] and organic permeable base transistors (PBT)[3]. In these devices, the contacts and the organic semiconductor are structured by a novel orthogonal photolithography [4], allowing for a precise vertical alignment as well as an upscaling to large areas. Furthermore, the controlled deposition of molecular dopants for selective manipulation of the semiconductor fermi level and a reduction of contact resistance.

The study for hydrogen bond rich dendron as dielectric layer for N-type OTFTs device

You-Yi Syu, National Taiwan Univ. (Taiwan)

A series of hydrogen bond rich (malonamide linkaged) dendrons were served as dielectric layer in organic thin-film transistors (OTFTs) device. The intramolecular hydrogen bond were generated between the malonamide linkage and imide linkage from the dendrons (as dielectric layer) and naphthalene diimide derivatives (NDI-R) (n-type semiconductor). The molecular packing of NDI-R were induced and enhanced during vacuum deposition process because of the intermolecular hydrogen-bonded interaction. The interaction of hydrogen-bonded interface was characterized by ATR-FTIR, DSC and contact angle. The investigation of thin film morphology were performed by AFM and GIWAXS, the better enhanced regularity for NDI-R molecules could be found when G1 as dielectric layer. The mobility of those OTFTs were in the range of of 10-4-10-3 cm2/V•s. The properties are better than the standard device made by octadecyltrimethoxysilane (ODTS) as modification layer. The best performance is G1 as dielectric layer (mobility was 3.24x10-3 cm2/V•s, on-off current ratio was 3.1x104, and the threshold voltage was 22.59 V).In this study, the interaction between the dielectric layer and semiconducting layer can be enhanced by hydrogen-bonded dendrons. Modification of molecular generation will fine tune the electrical properties of OTFTs. Semiconducting layer with specific linkage for forming hydrogen bond will expect useful for this concept.

9568-123, Session 5

Fully printed flexible thin film transistor arrays *(Invited Paper)*

Adrien Pierre, Mahsa Sadeghi, Ana Claudia Arias, Univ. of California, Berkeley (United States)

Blade coating and slot die coating are alternative thin film deposition methods to inkjet printing that enable higher throughputs at the expense of inherently being a one-dimensional coating method. We have developed printing methods and optimized material formulations for the fabrication of fully printed and flexible arrays of organic thin film transistors (OTFTs). In our work, all layers are processed from solution and deposited and patterned by printing. These printed devices exhibit high reliability, low variability, ideal electrical behaviour and good mechanical properties. Blade coating on surface energy patterned (SEP) plastic substrates combines the scalable properties of a roll-to-roll compatible printing technique used to fabricate high quality homogeneous thin films with the practicality of generating two-dimensional patterns.

Using this technique, scalable self-aligned blade-coated source and drain (SD) electrodes with minimal variability can be very reliably printed. The high reliability and good performance of these arrays was achieved by characterizing the printability of each layer on the OTFT stack. The high yields combined with high device performance indicate that SEP blade coating is a scalable and robust technique which can be used to design electronic circuits where device reliability is required and could lead to all-printed systems on plastic.

9568-124, Session 6

Higher-dimensional organic semiconductors *(Invited Paper)*

John E. Anthony, Thilanga Liyanage, Anthony Petty, Univ. of Kentucky (United States)

The majority of high-performance organic semiconductors used in thin-film transistors are comprised of linearly-fused aromatic or heteroaromatic units, comprising a one-ring-wide ribbon of conjugated surface. While perylene derivatives are near-ubiquitous in organic electronics, other fused-ring systems with widths greater than one ring are much less common, typically due to the difficulties in synthesis of these types of compounds. In this talk, I will discuss our approach to wider aromatic ribbons, their scalable synthesis, their crystal engineering, and the evaluation of their stability and charge-transport properties.

9568-125, Session 6

Novel nature-inspired conjugated polymers for high performance transistors and solar cells *(Invited Paper)*

Hugo A. Bronstein, Kealan Falon, Univ. College London (United Kingdom); Nir Yaacobi-Gross, Raja Shahid Ashraf, Iain McCulloch, Thomas D. Anthopoulos, Imperial College London (United Kingdom)

Novel, extremely narrow band-gap polymer with a structure based on natural indigo has been synthesised and exhibits high crystallinity, high ambipolar transport in OFET devices, and OPV device efficiencies up to 2.35% with light absorbance up to 950 nm, demonstrating potential in near-IR photovoltaics. We demonstrate that the use of a potentially bio-sustainable monomer unit in a conjugated polymer can give balanced ambipolar OFET mobilities in excess of 0.5 cm2/Vs. This novel monomer, and polymers are synthesized by rigidifying the structure of indigo by condensation with an aromatic acidic acid. The materials display high crystallinity which can be further enhanced by annealing and demonstrate that it can be used as a potentially biosustainable alternative to the commonly used DPP and iso-indigo monomers. We believe this is the first attempt to tackle the issue of sustainability in conjugated polymer synthesis.

9568-126, Session 6

Controlling conjugation and solubility of diketopyrrolopyrrole derivative copolymers for organic field-effect transistors

Mi Jang, Inha Univ. (Korea, Republic of); Ji-Hoon Kim, Do-Hoon Hwang, Pusan National Univ. (Korea, Republic of); Hoichang Yang, Inha Univ. (Korea, Republic of)

Diketopyrrolopyrrole (DPP)-based copolymers, including poly[2,5-bis(2-octyldodecyl)pyrrolo[3,4-c]pyrrole-1,4(2H,5H)-dione-alt-(E)-1,2-di(2,2'-bithiophen-5-yl)ethene (PDDBE) and poly[2,5-bis(2-octyldodecyl) pyrrolo[3,4-c]pyrrole-1,4(2H,5H)-dione-alt-(E)-1,2-bis(6-hexylthieno[3,2-b] thiophene-2-yl)ethene (PDTTE), were synthesized by alternating a DPP-derivative acceptor (A) block with different donor (D) blocks, such as (E)-1,2-di(2,2'-bithiophen-5-yl)ethene and (E)-1,2-bis(6-hexylthieno[3,2-b] thiophene-2-yl)ethene. These copolymers had drastically different crystal structures on polymer-grafted SiO2 dielectrics. Multiple-layered crystallites of PDDBE had a long-range, ϖ-conjugated extension but a wide conjugated distance, d(010), of 3.90 Å. Nanorod-percolated agglomerates of PDTTE had a much shorter d(010) of 3.71 Å, originating from the alternating structures of the DPP derivative with slightly different D blocks. The corresponding crystallites yielded a wide range of mobilities from 0.01 to 1.40 cm2V-1s-1 in the OFETs.

9568-127, Session 6

Intertwined co-assemblies in liquid-crystalline semi-conducting materials: Towards a new class of nanostructured supramolecular organic semiconductors

Fabrice Mathevet, Yiming Xiao, Danli Zeng, Univ. Pierre et Marie Curie (France); Martin Brinkmann, Institut Charles Sadron (France); Benoît Heinrich, Bertrand Donnio, Institut de Physique et Chimie des Matériaux de Strasbourg (France); Jeong Weon Wu, Jean-Charles Ribierre, Ewha Womans Univ. (Korea, Republic of); Emmanuelle Lacaze, David Kreher, André-Jean Attias, Univ. Pierre et Marie Curie (France)

The self-organization of ϖ-conjugated organic materials forming highly ordered supramolecular architectures has been extensively investigated in the last two decades in view of optoelectronic applications. Indeed, the control of both the mesoscopic and nanoscale organization within thin semiconducting films is the key issue for the improvement of charge transport properties and achievement of high charge carrier mobilities. These well-ordered materials are currently either self-organized semiconducting polymers or liquid crystals.

In this context, we endeavored to investigate the self-organization of semiconducting liquid crystalline materials incorporating different kind of ϖ-conjugated systems in unique molecular or macromolecular architectures. Here we describe the design and synthesis of (i) dyads and triads combining discotic or calamitic ϖ-conjugated mesogens, and (ii) side-chain liquid crystal semiconducting polymers where the backbone is a ϖ-conjugated polymer and the side groups are ϖ-conjugated discotic mesogens.

In this work, we will give the details on the synthesis, structural characterization and morphology studied by Polarized-light Optical Microscopy (POM), Differential Scanning Calorimetry (DSC), Temperature-dependent small-angle X-ray diffraction, Grazing-incidence X-ray scattering (GIXS) and Atomic Force Microscopy (AFM). Moreover, their charge transport properties studied in OFET configuration will also be depicted.

9568-128, Session 6

Printable semiconductors for all-polymer transistors and circuits *(Invited Paper)*

Antonio F. Facchetti, Polyera Corp. (United States)

In this presentation we will describe the design rationale, synthesis, characterization, of several organic semiconducting polymers for printed thin-film transistors (TFTs) and understand their charge-transport characteristics as a function of the device architecture. Furthermore, we will disclose new interfacial modifications dramatically enhancing the electron injection efficiency. Finally we will report the realization of printed organic TFTs and complementary circuits with high charge carrier mobilities where all the TFT components are polymers.

9568-129, Session 7

Charge transport in highly aligned conjugated polymers *(Invited Paper)*

Brendan O'Connor, Xiao Xue, Tianlei Sun, North Carolina State Univ. (United States)

Charge transport in conjugated polymers has a complex dependence on film morphology. Aligning the polymer chains in the plane of the film simplifies the morphology of the system allowing for insight into the morphological dependence of charge transport. Highly aligned conjugated polymers have also been shown to lead to among the highest reported field effect mobilities in these materials to date. In this talk, a comparison will be made between aligned polymer films processed using two primary methods, nanostructured substrate assisted growth and mechanical strain. A number of polymer systems including P3HT, pBTTT, N2200, and PCDTPT are considered, and the processed films are analyzed in detail with optical spectroscopy, AFM, TEM, and X-ray scattering providing insight into the molecular features that allow for effective alignment. By contrasting the morphology of these films, several insights into underlying charge transport limitations can be made. A number of key morphological features that lead to high field effect mobility and charge transport anisotropy in these films will be discussed. In addition, several unique features of organic thin film transistor device behavior in these systems will be examined including the commonly observed gate voltage dependence of saturated field effect mobility.

9568-130, Session 7

Percolation, tie-molecules, and microstructural origins of charge transport in semicrystalline conjugated polymers

Sonya A. Mollinger, Brad Krajina, Stanford Univ. (United States); Rodrigo J. Noriega-Manez, Univ. of California, Berkeley (United States); Alberto Salleo, Andrew J. Spakowitz, Stanford Univ. (United States)

Semiconducting polymers play an important role in a wide range of optical and electronic material applications. Polymer thin films that result in the highest performance typically have a complex semicrystalline morphology, indicating that considerable device improvement can be achieved through optimization of microstructural properties. However, the connection between molecular ordering and device performance is difficult to predict due to the current need for a mathematical theory of the physics that dictates charge transport in semiconducting polymers. It is experimentally suggested that efficient transport in such films occurs via connected networks of crystallites. We present an analytical and computational description of semicrystalline conjugated polymer materials that captures the impact of polymer conformation on charge transport in heterogeneous thin films. We first develop an analytical theory for the statistical behavior of a polymer emanating from a crystallite and predict the average distance to the first kink in the chain that traps a charge. We use this analysis to define the conditions for percolation and the consequent efficient transport through a semicrystalline material. We then establish a charge transport model using Monte Carlo simulations that predicts the multi-scale charge transport and crystallite connections. We approximate the thin film as a two-dimensional grid of crystallites embedded in amorphous polymer. The chain conformations in the amorphous region are determined by the wormlike chain model, and the crystallites are assigned fixed mobilities. We use this model to identify limits of charge transport at various time scales for varying fraction of crystallinity.

9568-131, Session 7

Organic blend semiconductors and transistors with hole mobility exceeding 10 cm2/Vs

Alexandra F. Paterson, Thomas D. Anthopoulos, Imperial College London (United Kingdom)

Plastic electronics that can be manufactured using solution-based methods are the subject of great research interest due to their potential for low-cost, large-area electronic applications. The interest in this field has led to considerable research and subsequent advances in device performance. To this end solution-processed organic thin-film transistors (OTFTs) have shown impressive improvements in recent years through the increasing values of charge carrier mobility. Here we report the development of next generation organic blend materials for OTFTs with hole mobilities of 10 cm2/Vs. These high performance devices have been achieved using a novel semiconducting blend system comprising of an amorphous-like conjugated polymer and a high mobility small molecule. The combination of a highly crystalline small molecule with the polymer binder aids the formation of uniform films as well as enables an element of control over the nucleation and growth of the small molecule. The polymer binders investigated belongs to the family of indacenodithiophene-based copolymers which are renowned for their high carrier mobilities regardless of their apparent structural disorder. The addition of the polymer with carefully chosen small molecules is found to further increase the hole mobility of the resulting blend OTFT to over 10 cm2/Vs. These organic devices provide an interesting insight into this rather complex blend system, highlighting the correlation between the morphology developed following solution processing and device performance, as well as exploring the role of each of the two components in the blend in terms of their contribution to charge transport.

9568-132, Session 7

Decoupling the semiconductor crystallization from the coating process to the benefit of solution-processed small-molecule organic thin film transistors *(Invited Paper)*

Aram Amassian, King Abdullah Univ. of Science and Technology (Saudi Arabia)

Recent progress in the design and processing of organic semiconductors (OSC) has made it easier to routinely fabricate high performance organic thin film transistors (OTFTs) with carrier mobility in the 1-10 cm2/Vs range. Here, we take a closer look at the crystallization behavior of small molecule OSCs with respect to the solvent evaporation behavior in different processes and reveal - in certain circumstances - a surprising new mechanism of nucleation reminiscent of two-step nucleation previously only seen in proteins, colloids and other soft matter, whereby an intermediate disordered phase of the solute forms prior to crystallization. The two-step nucleation in effect decouples the solvent drying and film formation from the crystallization process, leading to dramatically improved microstructure and morphology which can be credited with substantially improved performance. We demonstrate the universality of this method for a wide range of OSCs and OSC-polymer blends. We also take this idea to the next

level wherein we demonstrate how it can be exploited in the case of certain OSCs to induce crystallization on demand according to predetermined patterns, e.g., along the channel of an OTFT, with significant benefit to performance and to its spread.

9568-133, Session 8

Thermocleavable side chains: A gateway to new processing routes for semiconducting polymers *(Invited Paper)*

Bob C. Schroeder, Zhenan Bao, Stanford Univ. (United States)

Solubilising side chains are an essential part of semiconducting polymers and their engineering has shifted into focus over the last couple of years. The solution processability of conjugated polymers is one of the major advantages over silicon based semiconductors and would not be possible without the use of solubilising side chains. However with ongoing research, it became apparent that by careful side chain engineering certain properties of the conjugated backbone could be enhanced or supressed depending on the application. Nowadays side chain design is crucial to achieve high performing organic field effect transistors (OFET) and often significant synthetic efforts are taken to balance the semiconducting properties of conjugated polymers by means of side chain engineering. Despite their importance, side chains do not actively contribute to the semiconducting properties of the polymer. Their electrically insulating character could actually hinder charge transport between adjacent polymer chains and if poorly designed disrupt the solid state packing in the material.

To circumvent these problems, we developed thermocleavable side chains. This allows us to deposit the polymer from conventional organic solvents and to remove the side chains by post-deposition thermal annealing. By taking this two-step approach, we are able to maintain the advantages of solution processability, but at the same time allow the polymer chains to pack closely to achieve superior charge transport characteristics. Furthermore, stripping the polymer of its side chains significantly alters its solubility, making the use of orthogonal solvents for subsequent layer unnecessary, thus open-up new and potentially “greener” processing routes.

9568-134, Session 8

Oligothiophene-based monolayer OFETs by Langmuir techniques

Sergey A. Ponomarenko, Institute of Synthetic Polymeric Materials (Russian Federation) and Lomonosov Moscow State Univ. (Russian Federation); Elena V. Agina, Alexey S. Sizov, Institute of Synthetic Polymeric Materials (Russian Federation); Daniil S. Anisimov, Lomonosov Moscow State Univ. (Russian Federation); Oleg V. Borshchev, Maxim A. Shcherbina, Institute of Synthetic Polymeric Materials (Russian Federation); Sergey N. Chvalun, Institute of Synthetic Polymeric Materials (Russian Federation); Dmitry Y. Paraschuk, Lomonosov Moscow State Univ. (Russian Federation)

Nowadays development of efficient self-assembled monolayer field-effect transistors (SAMFETs) is a challenge of organic electronics. SAMFETs could provide a significant reduction of rather expensive organic semiconducting materials consumption without the device performance degradation. The known technique for SAMFET fabrication is a self-assembly from solution [E.C.P.Smits, et all, Nature, 2008, 455, 956] that requires highly reactive functional semiconducting molecules and inert atmosphere, it takes at least ten hours and could not be applied in industry.

Herein, we report a novel fast, easily processible and highly reproducible approach to oligothiophene-based SAMFETs fabrication by Langmuir, Langmuir-Blodgett (LB) and Langmuir-Schaefer (LS) techniques. It was shown that LB and LS techniques allow successful fabrication of 2D crystalline semiconducting monolayers based on various organosilicon derivatives of oligothiophenes. An influence of conjugation length and anchor group chemistry of the semiconducting self-assembling molecules on the monolayer structure and electric performance of the SAMFETs was systematically investigated and optimal conditions of SAMFETs fabrication were determined. The efficient SAMFETs with charge carrier mobilities up to 0.01 cm^2/Vs and on/off ratio up to 10^6 based on chlorosilane and disiloxane derivatives of oligothiophenes were fabricated and their functionality in integrated circuits under normal air conditions were demonstrated [Appl. Phys. Lett. 2013, 103, 043310; Langmuir, 2014, 30, 15327]. The performance of the reported SAMFETs is close to those of the SAMFETs prepared by self-assembly from solution. The results obtained demonstrate that the presence of covalent bonds between a semiconducting monolayer and a substrate is not crucial for the monolayer OFETs performance.

9568-135, Session 8

Organic vertical field effect transistors: Achieving high on-off ratio and vertical integration with OLEDs

Hyukyun Kwon, Mincheol Kim, Hyunsu Cho, Seunghyup Yoo, KAIST (Korea, Republic of)

Organic vertical field effect transistors (VFETs) have been explored to enhance the output current level and device operation speed due to the inherent low carrier mobility of organic semiconductors. However, most of VFETs reported to date involve a complex source electrode patterning process owing to their operation mechanism. Here, we investigate on VFETs based on C60 that do not require complex source electrode patterning process by insulting the top surface of a source electrode embedded in C60 layer [1]. In a VFET structure studied in this work, current flow is controlled by the electric field between a gate and a source electrode embedded within an active layer which is called bottom active layer. Based on its operation mechanism, several geometrical parameters such as (i) bottom active layer thickness; (ii) presence of a charge blocking layer and its thickness ensuring insulating properties; and (iii) the width of electrodes are identified as key factors influencing device performance. Through the device optimization with these parameters, the proposed organic VFETs exhibit a large on/off ratio of 6?10^5 and output current that is greater than that of a conventional C60 based OTFT with a similar device dimension. In order to show the benefit of VFETs, a single-pixel organic light-emitting diode (OLED) is integrated vertically with the VFETs under study.

9568-136, Session 8

Sub-threshold charge transport in polymer/organic field-effect transistor *(Invited Paper)*

Seohee Kim, The Univ. of Texas at Austin (United States); Tae-Jun Ha, Kwangwoon Univ. (Korea, Republic of); Prashant M. Sonar, Queensland Univ. of Technology (Australia); Ananth Dodabalapur, The Univ. of Texas at Austin (United States)

Polymer field-effect transistors have been highlighted in the past two decades due to their promising properties and potential for use in large-area electronics and displays. Along with the advance of performance, a detailed understanding on charge carrier transport in polymer field-effect transistors has become more important. In this presentation we provide methods to distinguish between the various modes of conduction and preset a detailed analysis and interpretation of charge transport in the sub-threshold drift-limited regime.

Our experimental results are based on the diketopyrrolopyrrole (DPP) core based polymer transistors which have received a lot of attention especially for their large mobilities exceeding 2 cm2/Vs. Similarly to the other transistors which have a lot of disorder, sub-threshold regime conduction

is critical in polymer field-effect transistors even at high gate voltages and should be analyzed separately from above threshold conduction. In this work, we present the modeling process for the DPP core based co-polymer field-effect transistors. A separate modeling of conduction in the sub-threshold regime provides us a lot of meaningful information. The accurate calculation method for the density of trap states (DOS) in polymer transistors, which is the one of the key methods in describing charge carrier transport phenomena in transistors, will be presented. In addition, a sub-threshold behavior of polymer transistors, such as the separation of sub-threshold regime into two different regimes and the dominant charge carrier transport mechanism in each regime of polymer transistors with varying temperature, will be analyzed in detail.

9569-17, Session PMon

Frequency dependent learning achieved using a type of semiconducting polymer/ electrolyte composite

Wenshuai Dong, Fei Zeng, Tsinghua Univ. (China)

Frequency dependent learning, i.e., the conventional spike-rate-dependent-plasticity learning model (SRDP), has been achieved using semiconducting polymer/electrolyte composite cells of Pt/MEH-PPV/ PEO+Li^+/Pt. These cells responded to depression at low frequency stimulation and to potentiation at high frequency stimulation. This frequency selection displayed a long term memory up to hours and was a unidirectional behavior, which occurred only when applied positive bias but not negative ones. The transition threshold ?m from depression to potentiation varied depending on the previous stimulations. The consumption of this device can be very low compared to other existed artificial synaptic systems, as the current inside it is just tens of nA. Using mixture of semiconducting polymer and electrolytes, i.e., light-emitting electrochemical cells, could simplify fabrication of artificial synapse and related neuromorphic circuits, giving a future that intelligentization of image cognition, photon detection and light emitting could be integrated in a single LEC based circuit. A random channel model was proposed based on the SEM images, to describe ionic kinetics at polymer/electrolyte interface during and after stimulations with various frequencies, and gave a reasonable explanation of our frequency dependent learning behavior.

9569-18, Session PMon

Band-pass filtering phenomenon of a semiconducting polymer/electrolyte composite

Xiaojun Li, Wenshuai Dong, Fei Zeng, Tsinghua Univ. (China)

We reported here a band-pass filtering phenomenon of MEH-PPV/PEO+Cs+ composite, which had been studied as a promise planar light source, i.e., light-emitting electrochemical cells (LECs). Pt/MEH-PPV/PEO+Cs+/Ag cell (Cs-LEC) and Pt/PEO+Cs+/Ag cell (Cs-PEO) were fabricated. Pulse responses were studied by using rectangular pulse with amplitude of 0.5 V, width of 5 ms and varied frequencies. It was found that the charging and discharging peaks varied with input frequency. The weights of responses to various frequencies were calculated by using the responses to 1 Hz as baseline. The responses of Cs-LEC were depressed with a weight modification by 30% between frequency ranges of 50 to 100 Hz, which were irrelative to input sign and types of electrodes. This demonstrated that signal could be transferred bi-directionally. The observed results were repeatable and stable. After exposed under environment of 65% humidity and 25oC for a period of two months, the Cs-LECs displayed moderate degradation. However, the weight of responses of Cs-PEO was found to be potentiated after 50 Hz frequency. The state of Cs ionic pairs in PEO and migration cross polymer/electrolyte interface might play important roles in our observation. Our study gives a strong confidence in uses of LECs for information handling and synaptic computation.

9569-19, Session PMon

Conjugated polymer nanoparticles as nano floating gate electrets for high performance non-volatile organic transistor memory devices

Chien-Chung Shih, Wen-Chang Chen, Wen-Ya Lee, Yu-Cheng Chiu, Jung-Yao Chen, National Taiwan Univ. (Taiwan)

We developed a molecular nano-floating gate of pentacene based transistor memory devices using conjugated polymer nanoparticles (CPN) as the discrete trapping sites embedded in an insulating polymer, Poly (methacrylic acid)(PMAA). The nanoparticles of polyfluorene (PF) and poly(fluorene-alt-benzo[2,1,3]thiadiazole (PFBT) with average diameters of around 50-70 nm were used as a charge-trapping sites, while hydrophilic PMAA served as a matrix and a tunneling layer. By inserting PF nanoparticles as the floating gates, the transistor memory device revealed a controllable threshold voltage shift, indicating effectively electron-trapping by the PF CPN. The electron-storage capability could be further improved using the PFBT-based NFG since their lower LUMO level was beneficial for stabilization of the trapped charges, leading a large memory window (35 V), retention time longer than 104 s with a high ON/OFF ratio of >104. In addition, the memory device performance using conjugated polymer nanoparticle NFG was much higher than that of the corresponding polymer blend thin films of PF/polystyrene (PS). It suggested that the discrete polymer nanoparticles could be effectively covered by tunneling layer, PMAA, to achieve the superior memory characteristics. Besides, the beta phase formation was observed in the conjugated polymer nanoparticles but not in blend system. PF nanoparticles with the beta phase may provide more stable energy state to store electrons than in the PF/PS blend. Our proposed nano-floating conjugated nanoparticles as charge storage sites provides a promising potential route towards the solution-processed organic transistor memories.

9569-20, Session PMon

Oligosaccharide dielectrics towards high performance non-volatile transistor memory devices

Yu-Cheng Chiu, Han-Sheng Sun, Wen-Ya Lee, National Taiwan Univ. (Taiwan); Halila Sami, Redouane Borsali, Ctr. de Recherches sur les Macromolécules Végétales (France); Wen-Chang Chen, National Taiwan Univ. (Taiwan)

Natural-polymers have the potential applications as the substrate or dielectric materials for next-generation green electronics. Herein, we employ the glucose-based oligosaccharides as the gate dielectric to control the threshold voltage of organic field-effect transistor (OFET) based memory devices. The green dielectric, maltoheptaose (MH) and pentacene are employed as the charge-trapping layer and the p-type semiconductor, respectively. The device with the bottom-gate-top-contact configuration exhibits outstanding write-once-read-many (WORM)-type behavior, attributed to the irreversibly electrochemical reaction on the hydroxy groups. The OFET memory device using the MH charge storage layer shows a significant memory window (39.9 V), a high ON/OFF current ratio (>106) and an excellent retention time over 15 days, which is comparable (or even better) to that of the state-of-the-art nano-floating gate memory devices reported in the literature. Moreover, the high-k MH layer can effectively decrease the operation voltage of memory down to the drain voltage of -4 V and maintain the high ON/OFF ratio. The operating mechanism for the dielectric is clarified by an analog device with N-type semiconductor as the active layer and further probed by Kelvin force microscopy. Another two polysaccharides containing the glucose segments are also shown similar results to those of the MH based OFET memory device, revealing the promising application of oligosaccharides for green electronics.

9569-21, Session PMon

Inkjet-printing of non-volatile organic resistive devices and crossbar array structures

Stefan Sax, Sebastian Nau, Alexander Blümel, Karl Popovic,

NanoTecCenter Weiz Forschungsgesellschaft mbH (Austria); Emil J. W. List-Kratochvil, NanoTecCenter Weiz Forschungsgesellschaft mbH (Austria) and Technische Univ. Graz (Austria)

Due to the increasing demand for storage capacity in various electronic gadgets like mobile phones or tablets new types of non-volatile memory devices have gained a lot of attention over the last years. Especially multilevel conductance switching elements based on organic semiconductors are of great interest due to their relatively simple device architecture and their small device feature size. Since organic semiconductors combine the electronic properties of inorganic materials with the mechanical characteristics of polymers, this class of materials are suitable for solution based large area device preparation techniques. Consequently, ink jet based deposition techniques are highly capable to face all preparation related requirements.

In this contribution we present a route towards the first all ink jet printed organic resistive switching memory device. In a detailed study the influence of ink jet printing on the device performance was demonstrated by the stepwise replacement of each functional layer.

A distinct impact to the IV – characteristics was found and analyzed. Along these lines the integration of ink jet printed devices into a fully functional crossbar array structures is reported.

9569-22, Session PMon

Recent progress in printed 2/3D electronic devices

Andreas Klug, Karl Popovic, Alexander Blümel, Stefan Sax, Emil J. W. List-Kratochvil, NanoTecCenter Weiz Forschungsgesellschaft mbH (Austria)

New, energy-saving, efficient and cost-effective processing technologies such as 2D and 3D inkjet printing (IJP) for the production and integration of intelligent components will be opening up very interesting possibilities for industrial applications of molecular materials in the near future. Beyond the use of home and office based printers, “inkjet printing technology” allows for the additive structured deposition of photonic and electronic materials on a wide variety of substrates such as textiles, plastics, wood, stone, tiles or cardboard. Great interest also exists in applying IJP in industrial manufacturing such as the manufacturing of PCBs, of solar cells, printed organic electronics and medical products. In all these cases inkjet printing is a flexible (digital), additive, selective and cost-efficient material deposition method. Due to these advantages, there is the prospect that up to now used standard processes can be replaced through this innovative material deposition technique.

A main issue in this research area is the formulation of novel functional inks or the adaptation of commercially available inks for specific industrial applications and/or processes. In this contribution we report on the design, realization and characterization of novel active and passive inkjet printed electronic and photonic devices such as sensors and memory devices and the heterogeneous integration in printed 3D packages and demonstrators. The main emphasis of this presentation will be on how to convert scientific inkjet knowledge into industrially relevant processes and applications.

9569-23, Session PMon

Optical memory effect in ZnO nanowire based organic bulk heterojunction devices

Arash Takshi, Anand K. Santhanakrishna, Univ. of South Florida (United States)

Due to the required stablished field to separate photogenerated electrons and holes, the current- voltage (I-V) characteristic in almost all photovoltaic devices in dark is an exponential curve. Upon illumination, the shape of the curve remains almost the same, but the current shifts due to the photocurrent. Also, because of the lack of any storage mechanism, the I-V curve returns to the dark characteristic immediately after cessation of the light. Here, we are reporting a photo-electric memory effect in an organic bulk hetrojuction device made of ZnO nanowires as the electron transport layer. The study of the I-V characteristic in dark and light showed a unique change from a rectifying response in dark to a resistive behavior in light. Additionally, after cessation of light, it was observed that the transition from the resistive to rectifying response occurred very slowly, taking about 270 minutes to fully return to the original characteristic in the dark. To our best of the knowledge, such a long opto-electric memory effect has not been observed before in any organic photovoltaic devices. Repeatability of the memory effect was tested by illuminating the cell and measuring the I-V characteristics in several cycles. Also, the impedance study of the device showed a significant change in the dark and light responses. For practical applications as a photo memory device, further experiments are required to gain a better understanding of the mechanism behind the observed memory effect.

9569-24, Session PMon

Flash memory based on solution processed hafnium dioxide charge trapping layer

Jiaqing Zhuang, Su-Ting Han, Ye Zhou, Roy Vellaisamy, City Univ. of Hong Kong (Hong Kong, China)

Hafnium dioxide (HfO2) film prepared by the sol–gel technique has been used as a charge trapping layer in organic flash memory. The thickness, crystallinity and morphology of HfO2 fabricated under various conditions were investigated. X-ray diffraction (XRD) patterns indicated the formation of monoclinic HfO2 crystals with increasing annealing temperature. Atomic force microscopy (AFM) images showed relatively smooth films of HfO2 growth. The annealing temperature-dependent effects on the memory window as well as data retention properties have been discussed. A large memory window and long data retention time have been achieved for the pentacene-based flash memory. The results demonstrate that solution processed HfO2 film could be a promising candidate as a charge trapping layer in printable flash memory.

9569-25, Session PMon

Cellulose-based material as dielectric layer in organic complementary inverters

Barbara Stadlober, Alexander Fian, JOANNEUM RESEARCH Forschungsgesellschaft mbH (Austria); Archim Wolfberger, Thomas Grießer, Montan Univ. Leoben (Austria); Mihai Irimia-Vladu, Andreas Petritz, JOANNEUM RESEARCH Forschungsgesellschaft mbH (Austria)

We report on Trimethylsilylcellulose (TMSC), a natural source based material, as ultrathin dielectric layer for organic thin film transistors and complementary inverters. Dielectric films of about 30 nm are used as gate dielectric on 28 nm thick alumina generated by anodization of the aluminum gate electrode. These thin inorganic/organic bilayer dielectrics exhibit low gate leakage currents of 10-9 A/cm2 at an electric field of 3.0 MV/cm2. Pentacene and C60 based transistors are fabricated using this bilayer dielectric and implemented in organic complementary inverters. The fabricated inverters show excellent performance with respect to high gains up to 1600, high noise margin values of 92.5 % for a supply voltage as low as 4 V.

All measurements within a period of 45 days show noise margin values above 87% for a supply voltage as low as 4 V, indicating a good electrical stability thus making these inverters highly suitable for complex electronic circuits.

9569-1, Session 1

Printed organic nanowire synaptic transistors *(Invited Paper)*

Wentao Xu, Sung-Yong Min, Hyunsang Hwang, Tae-Woo Lee, Pohang Univ. of Science and Technology (Korea, Republic of)

A human brain consumes only as much energy as household light bulb, but can overperform a super computer in many aspects. This ability is realized by a dense network of 1012 neurons and 1015 synapses, where synapses play an important role in human-brain computation and memory. Recently, great efforts have been made to develop synapse-emulating electronic devices, which have reduced energy consumption per synaptic event to picojoules. However, reducing it to the femtojoule level that is comparable to biological synapses is still a challenge. Here, we demonstrated here organic nanowire (ONW) synaptic transistors. The devices emulated functions of a biological synapse, including presynaptic-spike-induced excitatory post-synaptic current (EPSC), inhibitory post-synaptic current (IPSC), short-term plasticity and long-term plasticity. The active channels are composed of highly-aligned ONWs that have a semiconducting polymer inner core in an insulating polymer sheath. These ONW STs consume ~43 fJ per synaptic event, which is so far the lowest among currently available synaptic devices. The ultra-low-energy consuming nanoscale-dimension ONW STs with highly aligned ONW active channels exhibited great promise for realizing intelligent electronics and assembling soft neuromorphic systems with nano-feature size.

9569-2, Session 1

Unraveling the role of space-charge switch mechanism in hybrid non-volatile memory devices

Giovanni Ligorio, Marco Vittorio Nardi, Humboldt-Univ. zu Berlin (Germany); Martin Brinkmann, Institut Charles Sadron (France); Dieter Neher, Univ. Potsdam (Germany); Norbert Koch, Humboldt-Univ. zu Berlin (Germany) and Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany)

The increasing interest in non-volatile memory devices has extended the exploration towards new materials, such as organic-inorganic hybrids. Devices based on organic semiconductors and embedded metal nanoparticles (MNPs) were found to display resistive bistability, suitable for programmable electronic applications.

Different models were developed to explain the resistive switching mechanism occurring in the devices. Charging/de-charging of MNPs and concomitant resistivity changes was mainly proposed as mechanism, despite the lack of solid experimental evidence.

In this contribution we report on the role of the space-charge field due to charged MNPs in two-terminal devices, via electrical characterization. Devices comprise 4,4-bis[N-(1-naphthyl)-N-phenyl-amino]diphenyl (?-NPD) with embedded gold nanoparticles (AuNPs). The electrical characterization (current vs bias) of the devices was conducted with and without illumination during operation. Due to the energy level alignment of the chosen materials, the AuNPs behave as deep charge carrier traps. The induced space-charge spontaneously sets the device to the low conductivity state. The de-charging of the AuNPs can then be dynamically induced through illumination, setting the device to a high conductivity state.

Despite the ability to optically control the charging state of the AuNPs, the devices do not display any bistability. This finding provides evidence that the commonly proposed MNPs charging/de-charging mechanism can be excluded as the cause for electrical bistability in two-terminal devices, and that other mechanisms, such as filament formation, should be evoked.

9569-3, Session 1

Electroforming and resistive switching in alkalihalide - polymer diodes

Stefan C. J. Meskers, Benjamin F. Bory, Technische Univ. Eindhoven (Netherlands); Paulo Rocha, Max-Planck-Institut für Polymerforschung (Germany); Henrique L. Gomes, Univ. do Algarve (Portugal); Dago M. de Leeuw, Max-Planck-Institut für Polymerforschung (Germany)

Organic-Inorganic hybrid diodes containing alkali halide and semiconducting polymer layers, show non-volatile resistive switching after electroforming. The resistive switching is due to voltage-induced changes in the effective work function of the combined alkalihalide and metal contact layer in the diodes . Electroluminescence measurements show that the diodes are electrically bistable and can switch between hole-only and bipolar charge transport configurations.

Before the diodes show non-volatile memory effects, they need to be electroformed. Electroforming involves Frenkel defect formation in the alkalihalide layers of the diodes and results from application of bias voltage exceeding the bandgap of the alkali halide. The electroforming process is completed when the defect density exceeds a critical limit (estimated at 10^25/m^3). The resistive switching after electroforming results from changes in the ionization state of the defects in the alkali halide layers.

9569-4, Session 1

Characterizing filamentary switching in resistive memories *(Invited Paper)*

Yan Busby, Jean-Jacques Pireaux, Univ. of Namur (Belgium)

Characterizing filamentary switching in resistive memories

For many organic, inorganic and hybrid memory devices the resistive switching mechanism is well known to rely on filament formation [1]. This implies that localized conductive paths are established between the two terminal electrodes during the forming step. This filaments sustain the current flow when the memory is in the low conductive state and they can be ruptured and possibly re-formed for more than hundreds of I-V cycles.

The nature and morphology of filaments has been long time debated especially for organic memories. The filament size, density and formation mechanism have been very challenging to be characterized, and need appropriate experimental techniques. However, filaments in organic memories have been recently identified and characterized by cross-section transmission electron microscopy (TEM), conductive-AFM, AFM-tomography and through depth profile analysis combining Time-of-flight secondary ions mass spectrometry (SIMS) and X-ray photoelectron spectroscopy (XPS).

In particular, 3D spectroscopic images obtained with ToF-SIMS give access for the first time to filament formation process and rupture mechanism. From these results, a clear picture of the filament(s) dynamics during memory operation can be drawn.

In this contribution, recent results showing filaments in memories based on different structures and architectures will be discussed. The memories are based on insulating polymers (polystyrene [2] and poly methyl methacrylate [3]), conductive polymers/nanocomposites (polyera N1400 with metal NPs [4]), and small semiconducting molecules (Tris(8-hydroxyquinolinato)aluminium - Alq3 [5]). The results show that resistive switching clearly involves the inhomogeneous metal diffusion in the organic layer taking place during the top electrode deposition and during memory operation. This may be of great relevance in many other organic electronics applications.

Flexible non volatile memory devices based on organic semiconductors *(Invited Paper)*

Piero Cosseddu, Giulia Casula, Stefano Lai, Annalisa Bonfiglio, Univ. degli Studi di Cagliari (Italy)

The possibility of developing fully organic electronic circuits is critically dependent on the ability to realize a full set of electronic functionalities based on organic devices. In order to complete the scene, a fundamental element is still missing, i.e. reliable data storage. Over the past few years, a considerable effort has been spent on the development and optimization of organic polymer based memory elements. Among several possible solutions, transistor-based memories and resistive switching-based memories are attracting a great interest in the scientific community. In this presentation an overview of these two approaches for achieving well performing non volatile memory (NVM) devices will be given.

At first, we will show that inkjet printing can be used for the fabrication of highly flexible Organic Thin Film Transistors, and that they can be eventually employed, by properly engineering their dielectric and/or active layers, as non volatile memory devices with high retention time.

A different interesting solution for the realization of high retention time NVM elements consists in the fabrication of bi-stable resistive devices. Each memory element can be obtained by sandwiching a hybrid organic/inorganic active layer between two metal electrodes. Also in this case, the possibility of employing solution-processable materials and inkjet printing as fabrication process will be addressed.

Moreover, it will be shown, for both cases, that such devices can be easily integrated with electrical sensors enabling the development of a wide range of applications, from artificial skin to smart packaging.

9569-6, Session 2

Ion-dependent frequency selectivity and learning of semiconducting polymer/electrolyte composites

Fei Zeng, Siheng Lu, Wenshuai Dong, Xiaojun Li, Ao Liu, Tsinghua Univ. (China)

Studies on pulse responses have been performed on several semiconducting polymer/electrolyte composites. Frequency selectivity and learning were found and dependent on the types of ions and polymer/electrolyte interfaces. In a Pt/P3HT/PEO+X+ (X=Li, Mg, Nd)/Pt hetero junction, the system response was depressed to low-frequency stimulations (10~50 Hz) but was potentiated to high-frequency stimulations (higher than 80 Hz). Long term memory and learning was realized when the semiconducting polymer was changed to MEH-PPV. Conventional spike-rate-dependent plasticity (SRDP), i.e., BCM learning rule, was realized. The microstructures suitable for frequency selectivity were examined and confirmed by SEM images. Bi-directional signal transportation could be realized by simple connection or using semiconductor/electrolyte mixtures. It was found that input frequency could modulate ionic doping, de-doping and re-doping at the semiconducting polymer/electrolyte interface. Thus, we established a random channel model to describe dynamic processes at the semiconducting polymer/electrolyte interface and explain the observed learning phenomena. We suggest that semiconducting polymer/electrolyte composites will be useful and powerful in mimicking plasticity and learning of bio- synapses, constructing neuromorphic circuits and information computation.

9569-7, Session 2

Non-volatile resistive photo-switches for flexible image detector arrays

Sebastian Nau, Christoph Wolf, Stefan Sax, NanoTecCenter Weiz Forschungsgesellschaft mbH (Austria); Emil J. W. List-Kratochvil, NanoTecCenter Weiz Forschungsgesellschaft mbH (Austria) and Technische Univ. Graz (Austria)

The increasing quest for lightweight, conformable or flexible image detectors for machine vision or medical imaging brings organic electronics into the spotlight for these fields of application. Here were we introduce a unique imaging device concept and its utilization in an organic, flexible detector array with a simple passive matrix wiring.

Along these lines, the origin of unipolar resistive switching in organic electronic devices is unraveled by utilizing the photovoltaic effect: For the first time it is unambiguously possible to rule out most models which are held to be responsible for switching in organic devices. It is shown that the memory behavior is due to the formation and rupture of a localized conductive pathway ('filament') rather than any other claimed effect.

With this knowledge, we present a flexible organic image detector array built up from non-volatile resistive multi-bit photo-switchable elements. This unique realization is based on an organic photodiode combined with an organic resistive memory device wired in a simple crossbar configuration. The presented concept exhibits significant advantages compared to present organic and inorganic detector array technologies, facilitating the detection and simultaneous storage of the image information in one detector pixel, yet also allowing for simple read-out of the information from a simple passive-matrix crossbar wiring. This concept is demonstrated for single photo-switchable pixels as well as for arrays with sizes up to 32 by 32 pixels (1024 bit). The presented results pave the way for a versatile flexible and easy-to-fabricate sensor array technology.

9569-8, Session 2

Design rules and prototype examples for additive printing of organic complementary circuits *(Invited Paper)*

Tse Nga Ng, David E. Schwartz, Ping Mei, Brent S. Krusor, Sivheng Kor, Janos Veres, PARC, A Xerox Co. (United States)

With the recent improvements in printed devices, it is now possible to build integrated circuit systems out of printed devices. The combination of sensor, logic, and rewritable memory will greatly enhance the functionalities of printed electronics. Non-volatile ferroelectric memory in passive or active matrix arrays has been demonstrated (Sekitani, et al., Science, 326 (2009) 1516–1519; Naber, et al., Adv. Mater., 22 (2010) 933–945; Ng, et al., Org. Electron., 12 (2011) 2012–2018). The addition of addressing logic is necessary for these arrays to be scalable (Ng, et al., Sci Rep., doi:10.1038/srep00585): a binary logic decoder allows 2^N rows in an array to be controlled with just N-bit lines. In addition to scaling memory arrays, the decoder logic is also widely applicable to arrayed sensor and display applications.

At Palo Alto Research Center (PARC), we have demonstrated organic complementary circuits by inkjet printing. An example is a printed decoder for handling 3-bit address lines to an array of ferroelectric capacitors. Another example is a temperature sensor tag, in which the control circuit is triggered to generate a pulse to write into the memory when the thermistor temperature exceeds a preset threshold. For these examples, simulation models are developed for the organic transistors to achieve circuit designs that tolerate the variations in printed devices, as well as to determine the minimum performance requirements for reliable digital logic circuits. I will discuss how we tackle the challenges of device variations and in printed transistors and the design rules we learned in the course of developing these circuits.

9569-9, Session 3

Large area formation of self-aligned crystalline domains of organic semiconductors on transistor channels using CONNECT *(Invited Paper)*

Steve Park, Stanford Univ. (United States) and Columbia Univ. (United States)

The electronic properties of solution-processable small molecule organic semiconductors (OSCs) have rapidly improved in recent years, rendering them highly promising for various low-cost large area electronic applications such as active matrix displays, radio frequency identification tags, and integrated logic circuits. However, practical applications of organic electronics requires patterned and precisely registered OSC film within the transistor channel region with uniform electrical properties over a large area, a task that remains a significant challenge. Here we present a novel technique known as CONNECT (Controlled OSC NucleatioN and Extension for CircuiTs), which utilizes differential surface energy and solution shearing to simultaneously generate self-patterned and self-registered OSC film within the channel region and with aligned crystalline domains, resulting in low device-to-device variability. We have fabricated transistor density as high as 840 dpi, with a yield of 99%. We have successfully built various logic gates and a 2-bit half adder circuit, demonstrating the practical applicability of our technique for large-scale circuit fabrication. CONNECT was expanded to use with inkjet printed silver electrodes, showing the versatility of our method to accommodate various solution deposition and fabrication methods.

9569-10, Session 3

High-resolution gravure printed lines: Proximity effects and design rules

Gerd Grau, William J. Scheideler, Vivek Subramanian, Univ. of California, Berkeley (United States)

Gravure printing is a very promising method for printed electronics because it combines high throughput with high resolution. Recently, printed lines with 2μm resolution have been demonstrated at printing speeds on the order of 1m/s. Here we build on these results to study how more complex patterns can be printed that will ultimately lead to printed circuits. We study how the drag-out effect leads to proximity effects in gravure when multiple lines are printed close to each other. Drag-out occurs as the doctor blade passes over the roll surface to remove excess ink from the land areas in between the cells that make up the pattern. In addition to this desirable removal of excess ink, some ink from the cells also wicks up the doctor blade and is removed from the cells. This ink is subsequently deposited on the land area behind the cells leading to characteristic drag-out tails. If multiple lines, oriented perpendicular to the print direction, are printed close to each other, the ink that has wicked up the doctor blade from the first line will affect the drag-out process for subsequent lines. Here we show how this effect can be used to enhance print quality of lines as well as how it can deteriorate print quality. Important variables that will determine the regime for printing optimization are ink viscosity, printing speed, cell size, cell spacing and relative placement of lines. Considering these factors carefully allows one to determine design rules for optimal printing results.

9569-11, Session 3

Inkjet printed carbon nanotubes and zinc tin oxide based thin-film complementary circuits

Bongjun Kim, The Univ. of Texas at Austin (United States); Michael L. Geier, Mark C. Hersam, Northwestern Univ. (United States); Ananth Dodabalapur, The Univ. of Texas at Austin (United States)

Inkjet printing is one of the most promising techniques for low-cost, large-area, and flexible electronics due to its capability for direct patterning. Among many printable semiconducting materials, sorted single-walled carbon nanotubes (SWCNTs) and amorphous zinc tin oxide (ZTO) are some of the most attractive materials for p- and n-type semiconductors, respectively, since they exhibit superior electrical properties. Combination of these two materials makes possible realization of high performance complementary circuits. Such circuits, which are composed of both n- and p-type semiconductors, are essential for low power applications.

In this work, we demonstrate high performance hybrid complementary circuits based on inkjet printed SWCNTs and ZTO semiconductors. These circuits include inverters, ring oscillators, and D flip-flops. Solution processed high-k dielectric layer permits these circuits to operate at low voltages. The complementary inverters show high DC gain and low static power consumption. Five-stage ring oscillators based on these inverters show the highest operating frequencies among previously reported printed-semiconductor based ring oscillators. Positive edge-triggered D flip-flops, which are basic building blocks in sequential logic circuits, operate well at high clock frequencies.

In addition, novel voltage-controlled oscillators are demonstrated by employing double-gate structures. In this structure, an applied gate bias can control transistor threshold voltage and tune oscillation frequencies of the circuit. Such functional block will enable realization of printed analog-to-digital converters.

9569-12, Session 3

Flexible thin film circuitry enabling ubiquitous electronics via post-fabrication customization *(Invited Paper)*

Brian Cobb, Holst Ctr. (Netherlands)

For decades, the electronics industry has been accurately described by Moore's Law, where the march towards increasing density and smaller feature sizes has enabled continuous cost reductions and performance improvements. With flexible electronics, this perpetual scaling is not foreseen to occur. Instead, the industry will be dominated by Wright's Law, first proposed in 1936, where increasing demand for high volumes of product will drive costs down. We have demonstrated thin film based circuitry compatible with flexible substrates with high levels of functionality designed for such a high volume industry. This includes a generic 8-bit microprocessor totaling more than 3.5k TFTs operating at 2.1 kHz. We have also developed a post fabrication programming technique via inkjet printing of conductive spots to form a one-time programmable instruction generator, allowing customization of the processor for a specific task. The combination demonstrates the possibility to achieve the high volume production of identical products necessary to reap the benefits promised by Wright's Law, while still retaining the individualization necessary for application differentiation. This is of particular importance in the area of item level identification via RFID, where low cost and individualized identification are necessary. Remotely powered RFID tags have been fabricated using an oxide semiconductor based TFT process. This process is compatible with the post-fabrication printing process to detail individual identification codes, with the goal of producing low cost, high volume flexible tags. The goal is to produce tags compatible with existing NFC communication protocols in order to communicate with readers that are already ubiquitous in the market.

9569-13, Session 4

Flexible low-voltage organic integrated circuits with megahertz switching frequencies *(Invited Paper)*

Ute Zschieschang, Max-Planck-Institut für Festkörperforschung (Germany); Kazuo Takimiya, RIKEN Ctr. for Emergent Matter Science (Japan); Tarek Zaki, Univ. Stuttgart (Germany); Florian Letzkus, Harald

Richter, Joachim N. Burghartz, Institut für Mikroelektronik Stuttgart (Germany); Hagen Klauk, Max-Planck-Institut für Festkörperforschung (Germany)

A process for the fabrication of integrated circuits based on bottom-gate, top-contact organic thin-film transistors (TFTs) with channel lengths as short as 1 μm on flexible plastic substrates has been developed. In this process, all TFT layers (gate electrodes, organic semiconductors, source/drain contacts) are patterned with the help of high-resolution silicon stencil masks, thus eliminating the need for subtractive patterning and avoiding the exposure of the organic semiconductors to potentially harmful organic solvents or resists. The TFTs employ a low-temperature-processed gate dielectric that is sufficiently thin to allow the TFTs and circuits to operate with voltages of about 3 V. Using the vacuum-deposited small-molecule organic semiconductor 2,9-didecyl-dinaphtho[2,3-b:2',3'-f]thieno[3,2-b] thiophene (C10 DNTT), TFTs with an effective field-effect mobility of 1.2 cm2/Vs, an on/off current ratio of 107, a width-normalized transconductance of 1.2 S/m (with a standard deviation of 6%), and a signal propagation delay (measured in 11-stage ring oscillators) of 420 nsec per stage at a supply voltage of 3 V have been obtained. To our knowledge, this is the first time that megahertz operation has been achieved in flexible organic transistors at supply voltages of less than 10 V. In addition to flexible ring oscillators, we have also demonstrated a 6-bit digital-to-analog converter (DAC) in a binary-weighted current-steering architecture, based on TFTs with a channel length of 4 μm and fabricated on a glass substrate. This DAC has a supply voltage of 3.3 V, a circuit area of 2.6 ? 4.6 mm2, and a maximum sampling rate of 100 kS/s.

9569-14, Session 4

Fully printed 2-bit shift register based on organic electrochemical transistors

Philipp C. Hütter, Thomas Rothländer, Gregor Scheipl, Barbara Stadlober, JOANNEUM RESEARCH Forschungsgesellschaft mbH (Austria)

Organic electrochemical transistors (OECTs) have received considerable attention in recent years due to their numerous advantages. Prominent examples are their simple design allowing for a fabrication by additive printing technique, their low operating voltage, the compatibility with flexible substrates and their possibility to conduct both ionic and electronic charge carriers. Developing circuitry based on organic materials benefiting from those advantages is, in our view, an aim worth pursuing.

We report on entirely screen printed logic gates based on OECTs. The transistors are fabricated from poly(3,4-ethylenedioxithiophene) poly(styrenesulfonate) (PEDOT:PSS), a polymer electrolyte and a conductive carbon screen printing paste. They operate at a voltage of 1.5 V and exhibit an on/off current ratio of 104. The resistors needed to expand the OECTs range of use to logic gates are screen printed PEDOT:PSS resistors. Both, transistors and resistors, show highly reproducible characteristics and are combined to integrated logic gates. In total only five different screen printable materials, including the ones needed for wiring, are utilized to fabricate inverters, NAND gates, flipflops and a 2-bit shift register. The obtained logic gates are characterized by dynamic measurements, revealing a very high reproducibility of the devices' output signals. These very promising results clearly indicate the high uniformity and reproducibility of the screen printed transistors and resistors, emphasizing their applicability for higher integrated circuitry.

9569-15, Session 4

Field-effect memory transistors based on arrays of nanowires of a ferroelectric polymer

Ronggang Cai, Hailu G. Kassa, Univ. Catholique de Louvain (Belgium); Alessio Marrani, Solvay Specialty Polymers Italy S.P.A. (Italy); Albert J. van Breemen, Gerwin H. Gelinck, Holst Ctr. (Netherlands); Bernard L. Nysten, Univ. Catholique de Louvain (Belgium); Zhijun Hu, Soochow Univ. (China); Alain M. Jonas, Univ. Catholique de Louvain (Belgium)

Ferroelectric poly(vinylidene fluoride-co-trifluoroethylene), P(VDF-TrFE), is attracting renewed interest for use in organic non-volatile memory devices, e.g., in ferroelectric field effect transistors (FeFETs). In a FeFET, information is stored in two different permanent polarization states of a ferroelectric film, associated to bits 1 and 0; the reading capability is realized by detecting the source-drain current flowing through a film of a semiconducting material stacked over the ferroelectrics, which is modulated by the permanent polarization state of the ferroelectrics.

Recently, we have developed nanoimprint lithography as a tool to shape ferroelectric P(VDF-TrFE) into arrays of nanowires; as a side benefit of this process, preferential crystal orientation occurs, resulting in improved ferroelectric performance. Here, we report on FeFETs integrating such arrays of ferroelectric polymer nanowires. Two different original architectures are tested, the first one consisting of stacked P(VDF-TrFE) nanowires placed over a continuous semiconducting polymer film; the second one consisting of a nanostriped blend layer wherein the semiconducting and ferroelectric components alternate regularly, leading to lateral electrostatic coupling (as opposed to the usual vertical coupling of standard FeFETs).

Such devices exhibit significant reversible memory effects, with operating voltages reduced compared to their continuous film equivalent. Piezoresponse Force Microscopy (PFM) experiments reveal that the two memory states correspond to a polarized and a depolarized state, with different possible geometries of the channels of free charge carriers accumulating in the semiconductor. The advantages and drawbacks of each coupling geometry will be discussed, as well as their potential for further miniaturization.

9569-16, Session 4

Printed circuits and their applications: Which way forward? *(Invited Paper)*

Eugenio Cantatore, Technische Univ. Eindhoven (Netherlands)

The continuous advancements in Printed Electronics make nowadays feasible the design of printed circuits which enable meaningful applications. Examples include ultra-low cost sensors embedded in food packaging, large-area sensing surfaces and biomedical assays.

This invited paper will offer an overview of state-of-the-art printed electronics circuits, including sensor front-ends and data converters for sensor applications.

Further, the bottlenecks that still hamper a full exploitation of the potential of printed technologies to build circuits will be analyzed. Finally, the most relevant research directions in the field of technology, device modeling, and circuit design for improved performance, yield and robustness will be discussed.

Conference 9570: The Nature of Light: What are Photons? VI

Monday - Thursday 10–13 August 2015
Part of Proceedings of SPIE Vol. 9570 The Nature of Light: What are Photons? VI

9570-1, Session 1

Quantum theory as a description of robust experiments: application to Stern-Gerlach and Einstein-Podolsky-Rosen-Bohm experiments *(Invited Paper)*

Hans De Raedt, Univ. of Groningen (Netherlands); Mikhail I. Katsnelson, Hylke C. Donker, Radboud Univ. Nijmegen (Netherlands); Kristel F. Michielsen, Forschungszentrum Jülich GmbH (Germany)

It is shown that the probability distribution of quantum systems in the singlet state emerges from the requirement that (i) space is isotropic, (ii) the observed events are logically independent, and (iii) the data generated by Einstein-Podolsky-Rosen-Bohm experiments is robust with respect to small changes in the conditions under which the experiment is carried out.

The derivation is based on general principles of logical inference which have been shown to lead to the Schr¨odinger and Pauli equation, without taking recourse to any concept of quantum theory.

This analysis suggests that quantum theory follows from logical inference applied to a well-defined class of experiments, without any commitment to further notions of reality.

It is shown how the mathematical structure of quantum theory follows from the desire to organize experimental data such that it untangles as much as possible, the description of the system under scrutiny from the description of the probes used to acquire the data.

9570-3, Session 1

A convergence: Special relativity, zitterbewegung, and new models for the subcomponent structure of quantum particles

Michael J. Mobley, Grand Canyon Univ. (United States) and The Biodesign Institute, Arizona State Univ. (United States)

Hestenes has presented an integration of Schrödinger's zitterbewegung with the spin matrices of the Dirac equation, suggesting the electron can be modeled by a rapidly rotating dipole moment and a frequency related to the de Broglie frequency. He presents an elegant spacetime algebra that provides a reformulation of the Dirac equation that incorporates these real spin characteristics. A similar model for quantum particles has been derived by this author from a different, quasi-classical premise: That the most fundamental subcomponents of quantum particles all travel at a constant speed of light. Time is equated with the spatial displacement of these subcomponents – the speed of light is the speed of time. This approach suggests a means of integrating special relativity and quantum mechanics with the same concept of time. The relativistic transformation of spinning quantum particles create the appearance of additional, compactified spatial dimensions that can be correlated with the complex phase of the spin matrices as in the Dirac formalism. This paper further examines the convergence on such new models for quantum particles built on this rapid motion of particle subcomponents. The modeling leverages a string-like heuristic for particle subcomponents and a revised description for the wave-like properties of particles. This examination provides useful insights to the real spatial geometries and interactions of electrons and photons.

9570-4, Session 1

Classical explanations of results of quantum mechanics

Albrecht Giese, Consultant (Germany)

In present physics there is a great conviction in favour of the necessity and ability of quantum mechanics to describe our physical world. This is considerably caused by those experimental results which seem to be in clear conflict with classical physics. Topics well known in this sense are the particle-wave paradox and e.g. the quantisation of the spin and of the magnetic moment.

In the view of the particle model presented separately in the meeting, and in the view of Lorentzian relativity as a replacement of Einstein's relativity, several of these observations can in fact be classically explained, at least to a certain extent. Some of these cases are not new but can be traced back to Louis de Broglie and partially also to Albert Einstein.

We will give an overview about the present situation of these phenomena. And we will discuss whether certain restrictions caused by the present understanding of QM can be alleviated.

Points in view:

- Determination of particle mass
- Particle-wave
- Non-emptiness of vacuum
- Virtual particles
- Bohr Magneton + Landé factor
- Quantisation of spin (absolute)
- Quantisation of angular momentum
- Quantisation of magnetic moment (Stern-Gerlach)
- Casimir effect
- Missing radiation in atomic orbits
- Pauli principle
- Unification of strong force and weak force
- Quantum gravity.

9570-5, Session 1

Photons as observer transitions in the event-oriented world view

Wolfgang Baer, Nascent Systems Inc. (United States)

This paper shows how the physical phase of an observing activity cycle can be described as a field of classic systems. When this field exists in a state of dynamic equilibrium, the observable experience of empty space is produced. Small enough oscillations around the dynamic equilibrium are shown to correspond to deBroglie waves, satisfy the Schrödinger equation, and represent the content of space. Larger disturbances can create or destroy the field of systems that underlie the observation of empty space.

This possibility points to the existence of an Event Theory of Reality from which quantum mechanics can be derived as a linear approximation. Such a theory would describes reality as a set of interacting action cycles. Hilbert space would be identified with detector/activator arrays that form the von Neumann cut between physical and observational phases of action cycles. If such arrays are conceived as charge and mass densities then the physical phase is characterized by gravito-inertial influences between the masses and electro-magnetic influences between the charges while the observational phase is characterized by forces that hold charge and mass together. A disturbance in either electromagnetic or gravito-inertial fields would be coupled to each other and therefore light quanta can only transfer from one cycle to another when matched equilibrium eigenstate allow

absorption and emission by mass-charge structures defining the detector/activator arrays. While electromagnetic fields provide a global propensity to transition quasi-random gravito-inertial influences would occasionally satisfy the equilibrium condition that allows quantized amounts of action to actually make the transfer.

9570-6, Session 2

Genesis of quantization of matter and radiation field *(Invited Paper)*

Luis de la Peña, Univ. Nacional Autónoma de México (Mexico); Ana María Cetto, Univ. Nacional Autónoma de Mexico (Mexico)

Are we to accept quantization as a fundamental property of nature, the origin of which does not require or accept further investigation?

To get an insight into this question we consider atomic systems as open systems, since they are by necessity in contact with the electromagnetic radiation field. This includes not only photonic radiation, but, more importantly for our purposes, the random zero-point or nonthermal radiation that pervades the Universe. The Heisenberg inequalities, atomic stability and the existence of discrete solutions are explained as a result of the permanent action of this field upon matter and the balance between absorbed and emitted powers in the equilibrium regime. A detailed study carried out along the years has led to the usual quantum-mechanical formalism as a powerful and revealing statistical description of the behavior of matter in the radiationless approximation, as well as to the radiative corrections of QED. The theory presented gives thus a response to the question posed above, within a local, realist and objective framework: quantization appears as an emergent phenomenon due to the matter-field interaction.

9570-7, Session 2

Urgency of evolution-process congruent thinking in physics

Chandrasekhar Roychoudhuri, Univ. of Connecticut (United States)

The prevailing mode of doing physics can be briefly summarized as establishing some conceptual continuity among inter-related but diverse observations by constructing some postulates to bring some logical congruency between the same observations. The postulates become new ad hoc “knowledge” whose reasonable-ness is first established further through coherent mathematical logics (the constructed theory) and then validated through acquisition of experimental data. This trend has been very successful for over several centuries. This approach can be characterized as the Measurable Data Modeling Epistemology (MDM-E). Unfortunately, MDM-E does not guide us to visualize the invisible interaction processes that are behind the emergence of data. Accordingly, such theories do not provide direct guidance to engineers to become better innovators. So, my proposal is to consciously add Interaction Process Mapping Epistemology (IPM-E) to complement the currently successful MDM-E. Consider the facts that the theories for photoelectric effect and the stimulated emission were proposed by Einstein by the first and the second decade of the twentieth century. But, our engineers did not succeed in establishing the Knowledge Age through Global Internet until the late twentieth century. Let us further, acknowledge that the establishment of the fiber optic network required four engineering processes – generation, modulation, propagation and detection – of two fundamental entities in the universe –electrons and photons. However, no physicists would dare to claim that we really understand what the photons and the electrons really are. But, our technological evolution is continuing un-interrupted. We can now utilize the Global Internet to engage a very large segment of our global smart engineers to start spending a portion of their time to figure out how to slow down the rate of the scary “Sixth Extinction”!

9570-8, Session 2

What is a photon?

A. F. Kracklauer, Consultant (Germany)

The central technical point of this presentation is that EPR-B type experiments preclude a direct, single event, measurement of the intensity of a pulse. In stead, repeated measurements for which the ratio of detections to the total number of possible events is used to determine intensity. This constraint, results in a distortion of the statistics involved. Analysis of the interplay of the consequences of these factors will be presented.

9570-9, Session 2

Did Planck, Einstein, Bose count indivisible photons, or discrete emission/absorption processes in a black-body cavity?

Michael Ambroselli, Chandrasekhar Roychoudhuri, Univ. of Connecticut (United States)

Planck, Einstein and Bose all had to introduce statistics, and thus counting, in order to successfully derive an equation for the energy distribution within the black-body radiation spectrum. The statistical result from this we now call Bose-Einstein statistics. Some of the details involved in the counting procedure may vary while still giving the same result. Similarly, the interpretation of what we count may differ dramatically from one another (as, for example, between Planck and Bose), without impacting the final, mathematical result. We demonstrate here a further alternative, which varies both, in the details of the counting, as well as in the interpretation, while still producing the same well known statistics. This approach puts the “quantumness” back into the radiation emission/absorption process, possibly dispensing with the requirement of quantized light, at least in the context of black-body radiation.

9570-10, Session 3

Spatial photon localization and magnetic monopoles *(Invited Paper)*

Ole Keller, Aalborg Univ. (Denmark)

A wave-packet photon from an atom (or a mesoscopic particle) is born in the so-called rim (Lorenz) zone of matter. This weakly spatial localizability of the photon has enabled us to gain deeper insight in e.g. evanescent fields, photon tunneling, entanglement, and near-field electrodynamics as such. After a brief review of certain aspects of the spatial localization problem, I discuss how magnetic monopoles (so far not observed!) might change the photon mediated interaction between magnetic and electric monopoles in rim-zone contact. Special attention is devoted to the photon wave mechanical picture, and its field-quantized extension.

9570-11, Session 3

Light dispersion in space

Luiz C. Barbosa, Univ. Estadual de Campinas (Brazil)

Abstract Considering an idea of F. Arago in 1853 regarding light dispersion through the light ether in the interstellar space, this paper presents a new idea on an alternative interpretation of the cosmological red shift of the galaxies in the universe. The model is based on an analogy with the temporal material dispersion that occurs with light in the optical fiber core. Since intergalactic space is transparent, according to the model, this phenomenon is related to the gravitational potential existing in the whole space. Thus, it is possible to find a new interpretation to Hubble’s constant. In space, light undergoes a dispersion process in its path, which is interpreted by a special red shift equation, with a constante that is similar with Hubble constant. We observe that this “constant” is governed by three

new parameters. Light traveling the intergalactic space undergoes red shift due to this mechanism, while light amplitude decreases with time, and the wavelength always increases, thus producing the same type of behavior given by Hubble's Law. It can be demonstrated that the dark matter phenomenon is produced by the apparent speed of light of the stars on the periphery of the galaxies, without the existence of dark energy. Based on this new idea, the model of the universe is static, lacking expansion. Other phenomena may be interpreted based on this new model of the universe. We have what we call temporal gravitational dispersion of light in space produced by the variations of the speed of light, due to the presence of the gravitational potential in the whole space

.Keywords: alternative cosmology, alternative red shift.

The photon: EM fields, electrical potentials, and AC charge

Andrew Meulenberg Jr., Hi Pi Consulting (United States); Robert W. Hudgins, Science for Humanity Trust, Inc. (United States); Ralph F. Penland Jr., Science for Humanity Trust, Inc. (India)

Continued analysis of the interference of two converging parallel laser beams and the resultant standing wave has led to further thoughts on the forces and potentials developed in the interaction between photons. A number of papers have raised the issue of oscillating charge as the source of the alternating electric and magnetic fields composing the photon. Since the known (accepted) minimum charge is that of the electron and positron (leptons) with their minimum mass and energy, such a model is untenable. Nevertheless, E- and B-Fields without source charge(s) are not generally accepted today. Since Maxwell did not have that preconceived limitation and his equations still hold, these classical ideas are explored in the attempt to better understand the standing waves that exist within and between photons.

Photons are here considered to be resonant oscillations (solitons) in four dimensions of an undefined 'field' otherwise generally existing at a local energy minimum. The photons' constituent EM fields are modes of this oscillation and result in elevated energy and therefore potentials. It is in the context of the standing waves of photons that the EM fields and potentials lead to a description of alternating (AC) 'currents' (of some form) of unquantized alternating 'charge' (of some sort). The main topic of this paper is the alternating charge.

9570-13, Session 3

Electrons are spin 1/2 charged photons generating the de Broglie wavelength

Richard Gauthier, Santa Rosa Junior College (United States)

A charged photon and its light-speed helical trajectory form a surprising new solution to the relativistic electron's energy-momentum equation E ^2 = p ^2 c ^2 + m^ 2 c ^4 . This charged photon is a new model for the electron, and quantitatively resembles the light-speed electron described by Dirac. His relativistic quantum mechanical equation for the electron was partly derived from the above energy-momentum equation. While the electron's energy is E = gamma mc^ 2 , the charged photon's energy is E = gamma mc ^2 = hf . The electron's relativistic momentum p = gamma mv is the longitudinal component of the charged photon's helically circulating momentum p total = gamma mc . At any electron speed, the charged photon has an internally circulating transverse momentum p trans = mc , which at the helical radius Ro = L Compton / 4pi = 1.93 x 10^-13 m for a slowly-moving electron produces the z-component hbar/ 2 of the electron's spin. The right and left turning directions of the charged photon's helical trajectory correspond to a spin up (sz = +hbar /2) and spin down (sz = -hbar /2) electron. The negative and positive possible charges of the charged photon correspond to the electron and the positron. Using the wave vector k of the circulating charged photon of momentum p=gamma mc, where the wave vector k makes an angle theta given by cos (theta)=v/c with the electron's velocity v, the relativistic de Broglie wavelength of an electron LdeBroglie = h/(gamma mv) is easily derived from the charged photon model. This gives further support for the charged photon model of the electron. The charged photon model for an electron suggests a new interpretation of quantum mechanics where atomic and molecular electrons as well as free electrons are all charged photons. Bound charged photons in an atom have discrete energy levels given by the Schrodinger and Dirac equations, and a charged photon gives off or absorbs an uncharged photon when a bound charged photon moves from one atomic or molecular energy level to another. Wave-particle duality can be understood better with the charged photon model of the electron, since electrons have wave properties because they are charged photons.

9570-14, Session 3

A study of the nature of light by comparing real and digital universes *(Invited Paper)*

Luping Shi, Tsinghua Univ. (China)

The nature of light has been puzzling us for more than a century. The modern theory of quantum mechanics came to picture light as both a particle and a wave. In this talk, the nature of light is studied by comparisons between the real and digital worlds. Together with analysis of theoretical and experiments results, we discuss the possibility that a photon has structure. A possible photon model with internal structure is proposed and discussed. The model can be used to explain not only all of the experiment phenomena, but also the wave particle dualism of light. It can provide clear pictures of both polarization and coherency of light. It can also explain that there are two spin states of 1 and -1. It should be noted that C.N.Yang and R. Mills have generalized electromagnetism, as a U(1) bundle theory, to a very beautiful non-abelian gauge theory as a natural mathematical extension. This theory has not been accepted by the physics community because it requires the existence of massless charged particles. However it might be useful for studying the force within a photon of the proposed photon model. The possible experiments that could be used to prove the model are also addressed.

9570-16, Session 4

Biomimetic antennas for light *(Invited Paper)*

Dmitri V. Voronine, Texas A&M Univ. (United States)

Light-matter interactions play an important role in nature. For example, first steps of photosynthesis involve capture of photons and conversion into useful work. Natural light-harvesting complexes can be described as quantum heat engines and can be used to develop similar bioinspired artificial devices. Processes that are important for optimizing the performance of such biomimetic antennas will be discussed and analyzed from the point of view of recent quantum biology experiments. The nature of light will be considered in order to improve the understanding of these processes.

9570-17, Session 4

Are there photons in fact?

Sergey A. Rashkovskiy, A. Ishlinsky Institute for Problems in Mechanics (Russian Federation)

There are two opposing points of view on the nature of light: the first one manifests the wave-particle duality as a fundamental property of the nature; the second one claims that photons do not exist and the light is a continuous classical wave field, while the so-called "quantum" properties of this field appear only as a result of its interaction with matter.

In this paper we show that many quantum phenomena which are traditionally described by quantum electrodynamics can be described if light is considered within the limits of classical electrodynamics without quantization of the radiation. These include the photoelectric effect, Compton effect, Lamb shift, radiative effects, spontaneous emission, etc. We show that this point of view allows explaining the "quantum" behavior of light in all optical experiments. In particular we give the purely wave description of "the wave-particle duality" of light in the double-slit experiments and in Wiener experiments with standing waves. We show that the Born's rule for light should be replaced by more general rule which follows from wave nature of light from which, the Born's rule can be obtained as an approximation for low intensity of light.

We show that the Heisenberg uncertainty principle for "photons" has a simple classical sense and cannot be considered as a limitation of experimental accuracy. Within the limits of proposed concept we give a purely wave explanation of Hanbury Brown and Twiss experiments and Aspect's experiments with entangled "photons". We show that these experiments demonstrate the purely optical phenomena.

9570-18, Session 4

Electron-positron annihilation and absorption models

Randy T. Dorn, Independent Researcher (United States)

An experimentally verified mathematical model that precisely describes the attraction and motion between an electron and positron does not yet exist. Although there have been no direct experimental measurements of the particle velocity when the distance between the two particles approaches zero, the basic inverse square model used for point charges is thought to be inadequate because it would predict speeds in excess of c, the speed of light. Modifications to this basic model have been made by theorizing a variable velocity dependent relativistic mass or a velocity dependent force. These more complex models predict a particle velocity of approximately c as these particles undergo the particle – antiparticle collisions that result in photon production. This assumption, that the electron and positron both attain a velocity of approximately c during their annihilation collision results in a very compelling model of a photon as an electron and positron in a two body orbital union traveling through space. However, models based on this assumption show that the photon translational velocity must have some dependence on the photon wavelength. Although this dispersion is well known for photons traveling through a medium, it is objectionable to those who insist that in a vacuum every photon travels with a velocity of c regardless of its wavelength. In this paper it is shown that the basic inverse square model of electron - positron attraction actually predicts the basic two body photon model with no wavelength dependent dispersion. Careful measurement and study of two body photon properties may make it possible to develop a more accurate electron-positron annihilation model.

9570-19, Session 4

An epitaph for all photons: thou revealest thyself in thy demise *(Invited Paper)*

Chary Rangacharyulu, Univ. of Saskatchewan (Canada)

Photon interactions with matter, either scattering or absorption processes, involve disappearance of the photon. It is to be stressed that photon scattering is not a process in which a photon changes its direction and momentum etc during the scattering. Here, a secondary photon appears in the final state, necessarily satisfying all the conservation laws. This property of photon interactions, that original photon is always lost leaving no trace of itself except for the partner material entities carrying that information, is very unique to them and not shared by any other subatomic entity. We infer the birth of a photon by experimental arrangements and energy/momentum conservation principles. We may even assign a direction of propagation if an associated particle accompanies the photon. We cannot track a photon as it goes on its endless voyage till it meets its demise. A photon may pass through great distances in vacuum and materials without leaving a trace of its existence. It is only when a photon interacts within a sensitive detector volume, marking the end of its travel, we deduce the photon properties. Thus, a photon is not seen at birth, nor during its long voyage. But, it is "seen" as it ends its life. So, we can only write an epitaph but no birthday songs nor celebrations commemorating its life. This presentation will focus on this peculiarity of photons and its implications to particles and interactions.

9570-20, Session 5

Harnessing infrared photons in optical antenna *(Invited Paper)*

Debashis Chanda, Univ. of Central Florida (United States)

The open scientific question is can we detect infrared radiation in the same way radio frequency (RF) is detected by RF antennas? Such optical antenna will be the ideal solution to address both cooling and color imaging/ detection limitations of present infrared detectors where direct excitation of current on the antenna element avoids cooling requirement and simple dimensional scaling enables frequency tunability. However, all previous efforts based on optical dipole antenna in conjunction with rectifying diode (in combination called "optical rectenna") produced very low IR to electrical conversion efficiencies (~1%) primarily due to very high metal plasma loss at optical frequencies and low antenna IR absorption cross-section. Here we propose a two-element optical antenna array comprised of a perforated metallic (gold) hole array coupled with an underneath disk array which functions as a "light funnel" to trap incident radiation as dipole currents. The sub-wavelength hole-disk antenna array when coupled with a ground plane results in extraordinary transmission through the hole array and zero back reflection. The energy is dissipated as electron plasma loss on the hole-disk system inducing perfect ~100% absorption of the incident radiation captured from a much larger area than the physical dimensions. Further the absorption band is shown to tune over the entire mid-IR band by tuning dipolar coupling between two antenna elements by changing element dimensions or array spacing. Compare to other loss mechanisms electron plasma loss offers the advantage of direct detection via an electronic biasing circuit with high signal to noise ratio.

9570-21, Session 5

Visualizing electrons and photons

Azizul Haque, Independent Researcher (United States); Adam Haque, Univ. of California, Los Angeles (United States)

At the dawn of twentieth century scientists discovered a negatively charged fundamental particle called electron. In addition, particles properties of light were observed in photo-electric effect. Properties that are well established for these light particles (photons), electrons, are their charges, spin magnetic moment and inertia. Nature endows electrons with half-integer spin and photons with integer spin. Positron, an antiparticle of electron, also has half-integer spin, but differ from electron due to its positive charge. At present, all half-integer elementary particles are called fermions and the integer spin particles are called bosons. Unlike fermions, photons are charge neutral. Electrons and positrons are known to annihilate each other on contact. Their annihilation creates photons. Again, high energy photons are found to dissociate into electrons and positrons. Fermions participate in forming atoms and nuclei. Fermions absorb and emit photons. In spite of this, fermions are treated as point particles. Through interference experiments, fermions are found to possess wave property. Our investigation shows that the wave property associated with fermions imply its finite size. However, the existing quantum formulations are based on point particle concept. This is due to the fact that, quantum theories for finite sized charged particles, fail to maintain relativistic invariance. Quantum uncertainty also introduces finite size in all elementary particles. Recently, we have developed a theory to understand the quantum properties of finite sized fermions and bosons that is consistent with special relativity and the quantum uncertainty principle. Using this theory, we are able to demonstrate theoretically the physical appearances of the bosons and fermions. Understanding of the physical structure of photons and electrons will definitely help us advance our technology.

9570-22, Session 5

Wave interference: mechanics of the standing wave component and the illusion of 'which way' information?

Robert W. Hudgins, Science for Humanity Trust, Inc. (United States); Andrew Meulenberg Jr., Hi Pi Consulting (India); Ralph F. Penland Jr., Science for Humanity Trust, Inc. (India)

Two identical, coherent, light beams, 180 degrees out of phase, traveling adjacent parallel paths remain visibly separated by the null (dark) zone produced by their interference. Each part of the interference pattern can be traced to one of the beams. Does such an experiment provide "which way" knowledge in contravention of quantum theory? It is a common and convenient practice, to apply Maxwell's very successful superposition principle to predict the patterns produced by converging wave trains. It uses only the abstract values of wave amplitudes (or even probabilities). As abstractions, waves can pass through each other without interacting and cancel each other without explanation. But waves are not abstractions. They are physical entities. As such, all waves carry energy, momentum, force and mass (effective mass in the case of light), and therefore cannot pass through each other like ghosts or cancel each other without violating conservation laws. Importantly, we have proposed that a standing wave component is intrinsic to the formation of interference phenomenon. Geometric analyses of the mechanical processes that generate standing waves in water, an electric circuit, and in light demonstrated that analogous physical interactions in each type of standing wave create null zones where the equal energies of opposing waves reflect off each other, causing an exchange of momentum. Standing wave analysis of the experimental interference between the two parallel laser beams proved that such a continuous interaction across the null zone between them makes it impossible to provide "which way" knowledge.

9570-23, Session 5

Detection of superposition effects of polarized light by Photo-EMF detectors

Narasimha S. Prasad, NASA Langley Research Ctr. (United States)

We use photo-emf, in contrast to photo-voltaic detection method to analyze the two- beam fringe visibility due to a pair of polarized beams through a Mach-Zehnder interferometer. Measured data and our formulation of the superposition effect demonstrate that the observed effect is carried out by the polarized molecules of the photo-emf detector. The two polarized wave amplitudes do not sum themselves into a new resultant E-vector prior to

stimulating the photo-emf detecting molecules; which are discernible by mathematical models. Our observations conforms to Roychouduri's generalized formulation of Non-Interaction of Waves (or the NIW- property).

Photo-emf detectors based on CdTe single crystals are being used for sensitive vibration measurements. In one configuration, a photo-emf detector is used in a Mach-Zehnder interferometer (MZ) in which two beams from a laser are made to interfere at the detector surface to form fringes. Fringe motion generates electrical current corresponding to vibrations encountered in one its beam paths. In this paper, the role of a photo-emf detector will be explored to underscore that waves by themselves do not interfere. The Mach-Zhender interferometer with variable polarizers withinits beam paths is used to investigate the fringe characteristics. The polarized detecting molecules, physically constrained to oscillate only along the optical axis of the crystal, accept simultaneous stimulations by the two cosine-projected E vector components of the two incident beams along this optical axis. By rotating the two polarizers within the MZ with respect to the detector's optical axis, while keeping the angle between them fixed; one can demonstrate that the detecting molecules actively execute the summation of the stimulations due to the waves; rather than the waves summing themselves. The energy transfer is the square modulus of the sum of the two cosine-projected E-vector stimulations of the detecting molecules. This experiment re-validates the Non-Interaction of Waves (NIW) property.

Using a photo-emf the two- beam fringe visibility due to a pair of polarized beams through a Mach-Zehnder interferometer is demonstrated. Measured data and our formulation of the superposition effect demonstrate that the observed effect is carried out by the polarized molecules of the photo-emf detector. The two polarized wave amplitudes do not sum themselves into a new resultant E-vector prior to stimulating the photo-emf detecting molecules; which are discernible by mathematical models. This experiment re-validates the Non-Interaction of Waves (NIW) property.

9570-24, Session 6

Mysterious quantum Cheshire cat: an illusion resulting from interference *(Invited Paper)*

Kristel F. Michielsen, Forschungszentrum Jülich GmbH (Germany); Hans De Raedt, Univ. of Groningen (Netherlands)

The quantum Cheshire cat was introduced by Aharonov et al. [New J. Phys. 15, 113015 (2013)] in the form of a circularly polarized photon whereby the photon represents the cat and its polarization state the grin, realizing the mysterious behavior of the grinning Cheshire cat in the novel "Alice's Adventures in Wonderland" by Lewis Carroll.

We show that an event-based simulation model [H. De Raedt et al., Quantum Matter 1, 20 - 40 (2012)] reproduces all the reported data of the quantum Cheshire cat interference experiment of Denkmayer et al. [Nature Comm. 5, 4492 (2014)].

As the simulation does not rely on concepts of quantum theory and reproduces all the experimental observations, the latter can be explained without introducing concepts such as particle-wave duality or weak measurements.

Moreover it is explicit that the equivalent of the cat and grin never separate.

In other words, the quantum Cheshire cat is an illusion.

9570-25, Session 6

New experiments call for a continuous absorption alternative to the photon model

Eric S. Reiter, Unquantum Lab. (United States)

A famous beam-split coincidence test of the photon model was performed with gamma-rays instead of visible light. A similar test was performed to split alpha-rays. In both tests, coincidence rates greatly exceed chance, leading to an unquantum effect. Details of these tests are described. In contradiction to quantum theory and the photon model, these new results are strong evidence of the long abandoned accumulation hypothesis, also known as the loading theory. Attention will be drawn to assumptions applied to past key experiments that led to quantum mechanics.

9570-26, Session 6

Quantum physics and the beam splitter mystery

François B. Hénault, Institut de Planétologie et d'Astrophysique de Grenoble (France)

Optical lossless beam splitters are frequently encountered in fundamental physics experiments regarding the nature of light, including "which-way" determination or the EPR paradox. Although they look as common optical components at first glance, their behaviour remains somewhat mysterious. In this communication are examined and discussed some basic properties of these beamssplitters, both from a classical optics and quantum physics

point of view. Herein the most evident contradictions are highlighted, and a new experimental set-up enabling to discriminate the two types of theory is described. Alternative empirical optical models are also proposed.

9570-27, Session 6

Photon diffraction described by momentum exchange theory: what more can edge diffraction tell us?

Michael J. Mobley, Grand Canyon Univ. (United States) and The Biodesign Institute, Arizona State Univ. (United States)

Previous papers have presented an alternative picture for photon diffraction based on a distribution of photon paths through quantized momentum exchange with probabilities defined at the location of scattering, not the point of detection. This contrasted with the picture from classical optical wave theory that describes diffraction in terms of the Huygens-Fresnel principle and sums the phased contributions of electromagnetic waves at the location of detection to determine probabilities. This alternative picture was termed “Momentum Exchange Theory” (MET), replacing the concept of Huygens wavelets with photon scattering (positive and negative dispersions) through momentum exchange with the scattering lattice. MET assumes a momentum representation for diffracted particles and has been applied to several different optical diffraction experimental configurations. Straight edge diffraction has been a particularly revealing experimental configuration as it provides significant clues to the geometric parameters controlling exchange probabilities. Diffraction by an opaque disc is examined to provide further insight to negative (attractive) dispersions. This analysis indicates that the “diffraction force” is an integration of momentum exchange field interactions to derive an exchange probability at interaction points along the photon path – resembling aspects of the QED path integral formulation for particle interactions.

9570-28, Session 6

The photon to electron/positron-pair transition

Andrew Meulenberg Jr., Hi Pi Consulting (United States); Ralph F. Penland Jr., Science for Humanity Trust, Inc. (India); Robert W. Hudgins, Science for Humanity Trust, Inc. (United States)

Our prior work has discussed the solitonic nature and interference of photons and light. This paper addresses the interference of photons with themselves and the conditions under which a specific resonance creates the entangled electron/positron pair. Analysis of the forces and potentials in the interaction between photons has raised the issue of oscillating charge as the source of the alternating electric and magnetic fields comprising the photon. Since the photon is net neutral yet is composed of electric fields, the object of this paper is to explore the physical mechanism(s) describing how the alternating fields of the photon can be ‘rectified’ to produce the separated opposite charges of the electron and positron pair.

Physics spent more than 50 years deciding that the electron mass is entirely electromagnetic. Nevertheless, the concept of the electron being a self-bound photon has never been acceptable. Since photons are here considered to be resonant oscillations (solitons) of an undefined ‘field’ in four dimensions, we must also look to the 4th dimension to resolve the charge separation. The photons’ constituent EM fields are modes of this oscillation. It is in the context of the standing waves of photons that the EM fields and potentials lead to a description of alternating (AC) ‘currents’ (of some form) of unquantized alternating ‘charge’ (of some sort) that can be rectified (twisted) into two coupled (at least initially) resonant bodies with opposite charge and, now, with restmass.

9570-29, Session 6

Matter in the form of toroidal electromagnetic vortices

Wilhelm F. Hagen, Consultant (Germany)

The creation of charged elementary particles e± from neutral photons g is explained as a conversion process of electromagnetic energy from linear to circular motion at the speed of light into two localized, toroidal shaped vortices of trapped electromagnetic energy with opposite charges (EM-vortices or Energiewirbel). The photon can be represented as a superposition of left and right circular polarized transverse electric fields of opposite polarity. If these components are separated by interaction with a strong field (nucleon) they would curl up into two electromagnetic vortices (EMV) due to longitudinal magnetic field components forming toroids. These vortices resist change of motion, perceptible as particles with inertia and hence mass. The opposite electrical fields of the photon can be envisioned as originating from a common zero potential axis, the optical axis of the photon. This leads to opposite potentials at the surface of the toroids perceptible as opposite charged elementary particles e± from neutral photons g. These spinning toroids generate extended oscillating fields that interact with stationary field oscillations. The velocity-dependent frequency differences cause beat signals equivalent to matter waves, leading to interference. The extended fields entangled with every particle explain wave particle duality issues. Spin and magnetic moment are the natural outcome of these gyrating particles. As the energy and hence mass of the electron increases with acceleration so does its size shrink proportional to its reduced wavelength. The mysteries about the weak and strong nuclear forces can be easily explained as different manifestations of the intermediate electromagnetic forces. The unstable neutron consists of a proton surrounded by a contracted and captured electron. The associated radial electromagnetic forces are the source of the weak nuclear force. The deuteron consists of two axially separated protons held together by a centrally captured electron. The axial electromagnetic forces are the source of the strong nuclear force, providing stability for “neutrons” only within nucleons.

The same principles were applied to determine the geometries of force-balanced nuclei. The alpha particle emerges as a very compact symmetric cuboid that provides a unique building block to assemble the isotopic chart. Exotic neutron-4 appears viable which may explain dark matter. The recognition that all heavy particles, including the protons, are related to electrons via muons and pions explains the identity of all charges to within 10–36. Greater deviations would overpower gravitation and may explain the accelerating inflation of the universe based on mismatched charges. Such explanations would render the invention of dark energy obsolete. Gravitation is envisioned as residual force of standing electromagnetic (SEM) waves generated by interacting particles that experience SEM quantum jumps as observed with slow neutrons. Correlating gravity to microscopic quantities leads to the age of the universe of 13.5 b-years. There is no need to invent complex quarks, gluons, strings, virtual particles or multiverses. Reality is simple and beautiful.

9570-101,

The photon: From Newton and Maxwell to Einstein and Schwinger *(Keynote Presentation)*

Marlan O. Scully, Texas A&M Univ. (United States) and Princeton Univ. (United States) and Baylor Univ. (United States)

The photon concept has a strange history. From the beginning there has been debate whether light is particle-like as Newton suggested or wave-like as Young showed. This debate continued up to modern times and was in particular illuminated by Einstein’s discussion the fluctuations and entropy of electromagnetic radiation. Based on thermodynamic reasoning he came to the conclusion that light has both a particle and a wave side. In the mid ’20’s quantum mechanics in the Heisenberg-Schrödinger form came into being and the first papers on quantum electrodynamics (which really blends

both the particle and the wave nature of light) were put forth by people like Born, Heisenberg, and Jordan in the famous dreimaennerarbeit and Dirac's quantization of the electromagnetic field. It was however later in the early '30's that Fermi wrote his famous Reviews of Modern Physics paper and put the quantum theory of radiation on solid footing. Simultaneously, the electron was being investigated both from the point of view of quantum field theory and the Schrödinger wave equation and it was shown that the Schrödinger equation is in a real sense the wave rendition of the quantum field theoretic description of the electron.

One then naturally asks and the great minds like Kramers (think WKB, that Kramers), asks the question "how far and how exactly can we consistently compare the radiation field with an ensemble of independent particles?" He goes on to note that wave phenomena are now being applied to the electron, e.g., and says "now that wave mechanics has become a consistent formalism one could ask whether it is possible to consider the Maxwell equations to be a kind of Schrödinger equation for light particles instead of considering them up to now to be classical equations of motion which formally look like a wave equation and which are quantized only later. In our book on quantum optics, Zubairy and I show that it is possible to develop a theory in which the photon and the neutrino are very analogous; and show that the photon wave function obeys Maxwell's equations which can be written as a Dirac equation for the photon much like the Dirac equation for the neutrino. Both are massless particles and we are talking in the single photon and single neutrino limit. In this way, we see that the photon wave function has many points in common with the matter wave function. It is however important to note that there are differences associated with for example, the fact that the electromagnetic field, i.e., the photon is transverse in the present study and this is one example of how the photon wave function is different from a nonrelativistic massless particle. In general, there is much to be said for taking the literal point of view that a photon is what a photon detector detects. Following this philosophy we arrive at the wave function for a photon coming from the perspective of quantum field theory.

9570-30, Session 7

Could space be considered as the inertial rest frame?

Chandrasekhar Roychoudhuri, Michael Ambroselli, Univ. of Connecticut (United States)

Separability of Doppler Effect: Analysis of spontaneous and stimulated emissions by excited Ne-atoms with different velocities inside a He-Ne laser tube help us appreciate that emitter and detector velocities are separately identifiable with separate Doppler effects accommodated by quantum mechanics. Optical Doppler Effect should not be explained as due to a single relative velocity between the source and the detector. When this understanding is applied to distant stellar spectra; we can start separating out various components of spectral frequency shifts. The line broadening taking place within the stellar atmosphere is due to Maxwell's velocity distribution of hot molecules. The physical line-center frequency shift happens separately due to the vectorial velocity of the entire star (collectively, the same vectorial velocity of all the gas molecules). Then the detecting star's velocity (the Sun holding our earth-based detector) introduces another apparent Doppler shift. Clever experiments would be able to discern these Doppler shifts and hence the different velocities in the inertial space.

Ether drag experiments: We will present arguments to explain the three key ether-drag experiments viz., (i) Fresnel Drag results (positive and negative from two-way and one-way interferometers), (ii) Bradley (always positive) telescope aberration and (iii) Michelson-Morley (essentially) negative results. We will present our arguments by positing space as a Complex Tension Field (CTF). EM waves are linear excitations of this CTF and hence must always propagate away from the generating source. The stable particles are localized resonant complex non-linear excitations of the same stationary CTF; hence their movement will always require some potential gradients (forces) produced around the particles due to their complex oscillations.

Running time is not a measurable physical parameter of any object. Both classical and quantum physics have modeled and analyzed diverse types of classical and quantized oscillators and under what conditions the characteristic frequencies can be altered. Thus, frequency has the status as a primary physical parameter that can be altered by altering the physical condition of the oscillator. We can derive a secondary parameter, one period or a time interval, by inverting the primary parameter, the frequency. We assign the measurability to our conceptually derived running time by multiplying the period (inverse of the frequency) by counting larger and larger number of oscillation frequency or the period. This conceptually defined mathematical tertiary parameter, the running time, cannot undergo any physical changes, except through physical changes imposed on the frequency of the primary physical oscillator; which may represent the experimental clock.

Is the natural linewidth due to spontaneous emission life-times or due to time-finite envelopes of the emitted-wave packets?

Negussie Tirfessa, Manchester Community College (United States); Chandrasekhar Roychoudhuri, Michael Ambroselli, Univ. of Connecticut (United States)

We have achieved a great success with the standard model of elementary particles but we also understand that it does not give us a complete picture of our universe. The photon concept is more than a century old but both classical and quantum theories of radiation do not provide us with a prescription for modeling the shape and structure of an EM radiation emitted or absorbed by atoms and dipoles. The quantum theory of interaction between matter and field, Quantum Electrodynamics (QED), has been successfully applied to matter and field interactions. Despite the great success of QED in predicting matter field interactions outcomes, QED does not provide us with the nature and structure of a photon. QED does not also give us guidelines for localizing photons. Semi-classical radiation theory has also been successfully used in predicting experimental results but there are disagreements in some of the experimental results. Our experimental data are guided and dictated by the interaction process between atoms, dipoles and fields. Atoms and dipoles as detectors guide our observation of emission and absorption processes. Developing a model of the emission process requires visualization of the invisible interaction process during emission.

Most of the measured spontaneous emission life times are ?t ~ ns. Conventional method gives a natural linewidth of 1/ ?t ~ GHz by using Fourier Transform. This is in agreement with experimental results of linewidth. Some metastable atomic emission life times are longer ?t ~ ?s which gives a natural linewidth of 1/?t ~ MHz. Fourier transform techniques is a great mathematical tool that gives results that coincides with experiments but it gives us guidance on the representation of the emission process or on how to model the emitted photon.

In a previous papers and book, we have proposed that photons are diffractively evolving classical wave packet as a propagating undulation of the Complex Cosmic Tension Field (C2TF) after the excess energies are released by atomic or molecular dipoles as perturbations of the C2TF. The carrier frequency of the pulse exactly matches the quantum condition ?Emn= h?mn and the temporal envelope function creates the Lorentzian broadening of the measured spectral lines. In this paper we will use our photon model to match experimentally measured spectral lines of atoms and use it to compute linewidth .

9570-32, Session 7

Phase shift between Michelson two beam due to propagation in an optical waveguide

Octavio N. Sanchez, Manuel Fernández-Guasti, Univ. Autónoma Metropolitana-Unidad Iztapalapa (Mexico)

The electromagnetic energy within the interference fringes of two crossing coherent light beams poses important conceptual problems. In the standard electromagnetic description, the energy is redistributed from the dark to the bright fringes. No clear mechanism has been stated regarding this energy redistribution. However, if the two beams no longer overlap, each beam should regain their initial features. Efforts to measure the two beams after the interference region have been elusive due to diffraction.

An alternative indirect measurement explored here, is to feed the interfering fields into an optical fibre. Due to the different incidence angle of each beam, they can propagate in different waveguide modes. Since modes have different velocities, the relative phase between the two fields should change. A relative phase retardation of the two interfering beams, will produce a displacement of the interference maxima and minima at the fibre output with respect to these extrema at the input.

To this end, a Michelson interferometer was set up and a small portion of a fringe was selected. This wave front was subsequently split, one beam focused into an optical fibre while the other was used as reference. The interferometer mirror was scanned so that fringes were displaced at the output. The two intensities, before and after the fibre, were registered as a function of scanning. A phase shift of 29 mrad was obtained between the two signals. These results indicate that there are two fields propagating in the fibre in different modes. Thus the two fields are still present after their interference at the interferometer output.

9570-33, Session 7

Light and harmonicity: the golden section

Dionysios G. Raftopoulos, Independent Researcher (Greece)

Adhering to Werner Heisenberg's and the school of Copenhagen's natural philosophy we introduce the localized observer as an absolutely necessary element of a consistent physical description of nature. Thus we have synthesized the theory of the harmonicity of the field of light, which attempts to present a new approach to the events in the human perceptible space. It is an axiomatic theory based on the selection of the projective space as the geometrical space of choice and its first fundamental hypothesis is none other than special relativity theory's second hypothesis properly modified. The result is that all our observations and measurements of physical entities always refer not to their present state but rather to a previous one, a conclusion evocative of the "shadows" paradigm in Plato's cave allegory. In the kinematics of a material point this previous state we call "conjugate position", which has been called the "retarded position" by Richard Feynman. We prove that the relation of the present position with its conjugate is ruled by a harmonic tetrad. Thus the relation of the elements of the geometrical (noetic) and the perceptible space is harmonic. In this work we show a consequence of this harmonic relation: the golden section.

Keywords: Perceptible and geometrical projective space, theory of the harmonicity of the field of light, golden section.

9570-34, Session 8

Can the photon be described by a general particle model?

Albrecht Giese, Consultant (Germany)

Particle physics deal with a few basic particle types: Leptons, Quarks, Photons.

Most of the particles we know are either leptons or are built by quarks (as e.g. mesons and nucleons). A special place occupies the photon which seems to be independent. And, among other aspects, it has twice the spin of leptons and quarks.

Using the properties of particles such as their mass, spin, and magnetic moment, and from the relativistic behaviour of matter – which can be derived from the 'zitterbewegung' of the electron – we can draw up a model, in which a particle is composed of a pair of sub-particles which orbit each other. This model conforms largely to the quantum mechanical concepts of Louis de Broglie. It replaces the idea of particle-wave-duality as manifested by the Copenhagen interpretation of QM. And this model allows for a description of particle properties with high precision on the basic of classical physics.

This particle model, which was developed for leptons and quarks, is also a candidate for the description of the photon. The consequences for an understanding of the photon are an essential topic of this talk. Most of the properties of the photon can be explained by the model, some aspects need further evaluation.

This model explains for the first time the famous relation E=h*?. It has also the capability to explain open issues like cosmological inflation, dark energy, and dark matter. And in contrast to the way as Albert Einstein has done it, relativity has not to be founded on 'principles' but follows from the structure of fields and particles and gets in this way a real physical basis.

9570-35, Session 8

Quantum mechanical probability current as electromagnetic 4-current from topological EM fields

Martin B. van der Mark, Philips Research Nederland B.V. (Netherlands)

Starting from a complex 4-potential A=?d? we show that the 4-current density in electromagnetism and the probability current density in relativistic quantum mechanics are of identical form. With the Dirac-Clifford algebra Cl(1,3) as mathematical basis, the given 4-potential allows topological solutions of the fields, quite similar to Bateman's approach, but with a double field solution that was overlooked previously. A more general null-vector condition is found and wave-functions of charged and neutral particles appear as topological configurations of the electromagnetic fields. The description of electron-positron annihilation into two photons requires a seamless integration of the Maxwell and Dirac equations, which may be shown as an example.

9570-36, Session 8

On a heuristic framework for modeling the fundamental particles and interactions

Ted Silverman, IIAS (United States)

A quasi-constructive model of the vacuum is presented in a 3-space plus 1-time dimensional framework. Space is represented as a continuum with a dynamical density. Particles are localized, harmonic oscillations of spatial density, which interact via their extended scalar fields. Density gradients manifest in the space surrounding particles, as well as in the ambient space of scalar fields generally, and these gradients comprise, collectively, the metric field. Newton's constant is deduced from first principles and is given by a simple expression in terms of the Planck and fine structure constants, in a form analogous to that in which the electric charge is represented in quantum electrodynamics. In particular, the photon emerges as a kinematic effect - relativistic modulation of the electron's extended scalar field.

9570-37, Session 8

Quantum mechanics beyond Gaussians: from coarse graining to tower of scales

Antonina N. Fedorova, Michael G. Zeitlin, Institute of Problems of Mechanical Engineering (Russian Federation)

We construct some universal picture for re-consideration of base states and generic phenomena, like entanglement, in Quantum Mechanical set-up.

Our main goal is related to the analytical continuation of the standard zoo of solutions/base states from trivial ones, like plane waves or gaussians to novel states, possibly realizable, which permit more realistic (re) interpretation of the base folklore of Quantum Mechanics as well as more proper analytical/numerical modeling on the whole qualitative scale from entanglement to decoherence. Definitely, there is a set of experimental features as well as theoretical prerequisites demanding the appearance of new usefulness images.

We start from some simple categorification procedure allowing to consider generic states as sheaves but not functions, after that we look for internal hidden symmetries on the level of the underlying "categorified" Hilbert space of extended states. The orbits of these symmetries create the arena where we can model the novel features of our generalization of Quantum Mechanics. The analytical instruments allowing us to model both qualitative and quantitative aspects are Nonlinear Local Harmonic

Analysis on the representations of orbits of hidden symmetries of underlying generalized Hilbertian spaces and variational principles which permit the algebraization of the subsequent control of the type of behaviour.

It seems that reasonable extension of the zoo of possible (realizable) states can simplify the search of prototypes for realizable quantum devices as well as provide the more realistic (re)interpretation of the long-living standard "quantum folklore".

9570-38, Session 9

The fine structure constant alpha: relevant for a model of a self-propelling photon and for particle masses *(Invited Paper)*

Karl Otto Greulich, Fritz Lipmann Institute (Germany)

A model for a self propelling (i.e. massless) photon (K.O. Greulich Proc SPIE 8832-43) is based on oscillations of a charge amounting to elementary charge / SQRT alpha, where alpha is the fine structure (Sommerfeld) constant (1/ 137, 036). When one assumes a similar model for particles which do have rest mass (i.e. non- self propelling), alpha plays also a role in elementary particles.

Indeed all fundamental elementary particles can be described by the alpha / beta rule --? m(particle) = alpha power to – n * beta power to m* 27.2 eV / c2 ?-- where beta is the proton to electron mass ratio 1836.12 and n= 0....14, m= -1,0 or 1 (K.O. Greulich, Spring meeting 2014 German Physical Society T 99.4). Thus, photons and particle masses are intimately related to the fine structure constant. If the latter would not have been strictly constant throughout all times, this would have had consequences for the nature of light and for all masses including those of elementary particles.

9570-39, Session 9

The electron as a confined photon

Charles G. Akins, Akins Enterprises LLC (United States)

A new topological study is presented of a semi classical quantized model for the electron, consisting of a circularly bound monochromatic photon. This model for the electron includes a topologically created elementary charge, point-like behavior in high-energy scattering events, half-integral spin, and the magnetic moment of the electron. We will also present evidence for the causes of: 1) the fine structure constant, 2) the magnetic moment anomaly of the electron, 3) the elementary charge, 4) a binding force which allows a photon to be confined to become and electron, 5) the property of inherent inertial mass in the electron, and 6) Relativity. Within this context we propose that all matter is composed of EM waves, and that Relativity and Quantum Mechanics are the simple result of the behavior of those EM waves. For the most part we will use simple scalar mathematics to support this premise, because most of the problems have relatively simple solutions. However we will also submit that new formulations are needed for field equations. The following is a "thought experiment" intended to explore the architecture and topology of the electron.

9570-40, Session 9

The nature of the photon and the electron *(Invited Paper)*

John G. Williamson, Univ. of Glasgow (United Kingdom)

A linear, first order, extension of the classical theory of electromagnetism has been developed. A wave-function has been derived which is a solution to the first order, free-space Maxwell equation. Allowed propagating field only solutions are in some respects quantised in that they come in "lumps" and are associated with an integral angular momentum. The new solutions encompass all the fields of the photon, just and no more, properly describe the components in each and every Lorentz frame, and hence embody the relativistic transformations. These are photon-like solutions of the classical Maxwell equations.

Including a dynamical rest-mass term gives a mechanism for the self-confinement of the elements of the extended electromagnetism into qualitatively new kinds of solutions. Though charge is not introduced, the confinement mechanism forces the new solutions into a re-configuration of the fields, exhibiting a quantised charge. For the simplest configuration, this may be readily estimated and is found to be close to the elementary charge. The spin may also be calculated and is found to be half-integral. Just as is the case with the, related but simpler, Dirac equation, there are four and only four such solutions. These are identified with the spin up and spin down electron and positron. Experimental tests of the new theory lie in high energy laser experiments, spin-polarised scattering experiments and in cosmology.

The new theory, because it describes light and matter on the same footing, may be expected to offer unprecedented opportunities in developing new materials, devices and technologies.

9570-41, Session 9

Absolute relativity and the quantisation of light

John G. Williamson, Univ. of Glasgow (United Kingdom)

A new theory has been developed to describe both light and material particles. A surprising consequence is that field only solutions –light – are necessarily quantised.

A principle, called here absolute relativity, is implemented using a physical mathematics based only on the proper relativistic properties of the four dimensions of space-time.

Processes corresponding to multiplication, division and differentiation are defined. In addition to the 4 unit vector quantities this leads to twelve further unit elements, each encapsulating precisely a proper relativistic form: a Lorentz invariant unit point, six unit planes transforming as the elements of the electromagnetic field, four volumes, transforming like an angular momentum density, and a unit hyper-volume which squares to negative unity.

A set of coupled linear differential equations have been derived. These simplify to the free-space Maxwell equations in the pure-field case. A new, relativistic, field-only wave-function is proposed describing packets of energy of any magnitude but all with the same angular momentum: photons. It is concluded that the "quantisation" of light arises as a result of the rigorous consideration of the properties of space and time in special relativity. The new theory predicts that the "quantisation" is not intrinsic,

but arises from the nature of the emitter and absorber. The near-field should remain continuous. It predicts a series of "photons" with relative energies of the squares of the natural numbers. Phat photons. It is predicted that, in the fractional Quantum Hall regime, fractionally quantised "photons" may be possible.

9570-42, Session 9

A meta-analyzer for circular polarization resolved spectroscopy *(Invited Paper)*

Din Ping Tsai, Academia Sinica (Taiwan) and National Taiwan Univ. (Taiwan); Wei-Yi Tsai, Chun Yen Liao, Wei Ting Chen, Pei Ru Wu, National Taiwan Univ. (Taiwan); Greg Sun, Univ. of Massachusetts Boston (United States); Peter Török, Imperial College London (United Kingdom)

Distinguishing from a right-handed (RCP) or left-handed circularly polarized (LCP) wave in both spatial and spectral domain by a conventional method is less efficient since the most materials in nature exhibit similar optical properties under a RCP or LCP illumination. The metasurfaces, an array of sub-wavelength antenna with varying sizes, shapes and orientations enable us to design the devices with tailored optical properties [1, 2]. Here, we present a multifunctional metasurface working in visible region, which integrating the functionalities of grating, mirror and circular polarization splitter into a single micro-device. Using gold nano-rods with varying orientations as building blocks to construct our device with ~?/4 thickness, different wavelengths and handed circular polarizations of incident wave can be distinguished through diffraction angles. The spatial resolution of angular dispersion is about 0.025 degree per unit wavelength. This work paves the road to a wide range of applications such as polarization analyser and plasmon-enhanced circular dichroism spectroscopy.

9570-44, Session 10

Discovery of dynamical space: experiments and theory *(Invited Paper)*

Reginald T. Cahill, Flinders Univ. (Australia)

Recently the existence of space as a complex dynamical system was discovered, based on various experiments going back to 1887. The early experiments by Michelson and Morley 1887, and Miller 1925, used light speed anisotropy detected with interferometers. Only in 2002 was the calibration theory first derived. More recently there have been other experimental techniques, including Doppler shift effects detected by NASA using spacecraft earth flybys. The most recent technique uses current fluctuations through the nanotechnology reverse biased Zener diode barrier potential, by using two detectors and measuring the time delay in correlations to determine speed and direction of the space flow. Physics has never had a knowledge of this dynamical space, and the theory is well developed, and is now known to explain the origin of gravity, quantum fluctuations, bore hole g anomalies, galactic rotations, galactic lensing of light, universe dynamics, laboratory G measurements, GPS, and more. This dynamical space supports a coordinate system, and it was this that was originally thought to be space itself.

9570-45, Session 10

Energetic spacetime: the new aether

John A. Macken, Macken Instruments Inc. (United States)

This work builds on the spacetime-based photon model initially presented at The Nature of Light V conference. Previously it was shown that a proposed "charge conversion constant" with units of meters/Coulomb was capable of converting charge, electric field and the impedance of free space into quantifiable properties of spacetime. Since the impedance of free space (Zo ≈ 377 ohms) converts to the impedance of spacetime (c^3/G), the implication is that photons are a quantized wave propagation in the "spacetime field" which was also described.

Now this model is expanded further to show that it meets several other properties required of a photon model. First, this wave-based model is shown to explain Compton scattering better than the particle models of a photon. Second, the proposed model satisfies the Feynman path integral formulation. Rather than a photon having a single trajectory between the emission and absorption points, the model produces a sum over an infinity of trajectories to achieve a quantum amplitude determining the probability of absorption. Third, the model explains the wave-particle duality of photons. A photon does not have quantized energy because a photon can lose energy in Compton scattering or redshift and the phopton continues to exist. The photon's particle-like properties are shown to be the result of angular momentum being quantized. Finally, the angular momentum of a linearly polarized photon is examined and found to possess predictable angular momentum which is hard to detect. An experiment is suggested to test this contention

9570-46, Session 10

Modelling superposition of many polarized beams on an isotropic photo detector

Chandrasekhar Roychoudhuri, Michael Ambroselli, Univ. of Connecticut (United States)

In a previous paper [SPIE Proc.Vol.7063, paper #4 (2008)], we have modeled possible modes of excitations that detecting dipoles carry out before absorbing a quantum cupful of energy out of two simultaneously stimulating EM waves along with experimental validation; basically corroborating Malus' law. For the two beam case, the cos? factor, ? being the angle between the two polarization vectors, is too simple a case to directly extrapolate the model to possible complex behavior of quantum dipoles stimulated simultaneously by N-polarized beams. This paper presents possible models for simultaneous stimulation by N-polarized beams and the follow-on energy absorption. We then propose experiments for the particular case of three polarized beams. Comparison with literature will be presented. We will also compare the behaviors of energy absorbed by an anisotropic photo detector with that of the energy transmitted by a transparent polarized crystal. The comparison should be interesting because photo detection is a quantum process; but transmission by a crystal is a classical bulk process. We will also discuss helicity of "photons" in the context of "chirality" of materials (molecules) while interacting with polarized beams.

9570-47, Session 10

Tabletop demonstration of non-Interaction of photons and non-interference of waves

Narasimha S. Prasad, NASA Langley Research Ctr. (United States); Chandra Roychoudhuri, Univ. of Connecticut (United States)

Recently, Non- Interaction of Waves or the NIW property has been proposed as a generic property of all propagating electromagnetic waves by one of the authors (CR). In other words, optical beams do not interact with each other to modify or distribute their field energy distribution in the

absence of interacting materials. This paper plans to re-create CR's original demonstration of the NIW-property as an on-site table-top experiment. We will use a tilted Fabry-Perot etalon to generate a set of spatially separate parallel beams out of an incident laser beam; which will then be focused on a one-sided ground glass, the flat side being towards the etalon. This flat side reflects back all the incident beams as fanning out independent laser beams, remaining unperturbed even though they are reflecting out of a common superposed spot. It is clear that there are neither "interference between different photons", nor "a photon interferes with itself", even within a region of superposed beams. In contrast, the ground glass surface (same silica molecules but granular or lumpy) generates a set of spatial fringes on its surface. Clearly, granulated individual silica lumps are responding simultaneously to the local resultant E-vectors due to all the superposed beams and are scattering energy proportional to the square modulus of the sum of all the simultaneous dipolar amplitude stimulations. The dark fringe locations imply zero resultant amplitude stimulation and hence no scattering. Are the fundamental physics behind the generation of superposition fringes by photo detectors different from those due to aground glass? We will discuss our views.

9570-48, Session 11

Clock time is absolute and universal *(Invited Paper)*

Xinhang Shen, NAC Geographic Products Inc. (Canada)

A physical clock can never directly measure time, but can only record the result of a physical process during a period of time such as the number of cycles of oscillation which is the multiplication of time and the frequency of oscillation. After Lorentz Transformation, time expands by a factor gamma, but the frequency decreases by the same factor gamma, and the resulting multiplication i.e. the displayed time of a moving clock remains unchanged. That is, the displayed time of any physical clock is an invariant of Lorentz Transformation. The Lorentz invariance of the displayed times of clocks can further prove within the framework of Special Relativity our earth based standard physical time is absolute, universal and independent of inertial reference frames as confirmed by the universal synchronization of clocks on the GPS satellites and clocks on the earth.

9570-49, Session 11

Special relativity from observer's mathematics point of view

Boris Khots, Dmitriy Khots, Compressor Controls Corp. (United States)

When we create mathematical models for quantum theory of light we assume that the mathematical apparatus used in modeling, at least the simplest mathematical apparatus, is infallible. In particular, this relates to the use of "infinitely small" and "infinitely large" quantities in arithmetic and the use of Newton – Cauchy definitions of a limit and derivative in analysis. We believe that is where the main problem lies in contemporary study of nature. We have introduced a new concept of Observer's Mathematics (see www.mathrelativity.com). Observer's Mathematics creates new arithmetic, algebra, geometry, topology, analysis and logic which do not contain the concept of continuum, but locally coincide with the standard fields.

We use Einstein special relativity principles and get the analogue of classical Lorentz transformation. This work considers this transformation from Observer's Mathematics point of view.

Keywords: Observer, arithmetic, derivative, probability, quantum mechanics, quantum theory of light

9570-52, Session 11

Quantum mechanics via sheaves and schemes: on the route to categorification

Michael G. Zeitlin, Antonina N. Fedorova, Institute of Problems of Mechanical Engineering (Russian Federation)

Sheafification together with microlocalization and the subsequent analysis of quantum dynamics on orbits with special, so-called MRA-filtrations (generating a full tower of the underlying internal hidden scales), considered in the companion paper, are the starting points of our attempt of Categorification Program for Quantum Mechanics and/or General Local Quantum Field Theory.

In some sense, we may hope on the same breakthrough as in the golden era of Algebraic Topology and Algebraic Geometry in the 50s and 60s of the 20th Century, which was concluded by Grothendieck's approach and provided the universal description for a variety of long standing problems. Roughly speaking, in (Quantum) Physics such an approach provides useful, constructive and universal methods to glue the complex local data into the general picture by power machinery taking into account the topological and (algebraical) geometrical data of the underlying hidden internal structures.

Definitely, the simple linear algebra of structureless Hilbert spaces cannot describe the whole rich world of quantum phenomena. Our approach introduces (Grothendieck's) Schemes instead of varieties/manifolds as generic quantum objects, naturally encoded the full zoo of phenomenological things discussed in Quantum Mechanics. The key ingredient of such an approach is the bridge between the von Neumann description of measurement together with the Gelfand ideal of the state and GNS (Gelfand-Naimark-Segal)-construction on one side of the river and locally ringed space, structure scheaf and (affine) scheme on the opposite (categorificated) side.

9570-53, Session 11

On the nature of "stuff" and the hierarchy of forces

Martin B. van der Mark, Philips Research Nederland B.V. (Netherlands)

From super clusters of galaxies down to the quarks in the proton, at all length scales the structure of matter is the result of a balance of forces. In this paper it is argued that with decreasing size there must necessarily be an increase of the fraction of kinetic and binding energy with respect to the total energy. Smaller sizes require stronger forces which represent more of the energy available. The smallest possible size of granularity is found to be where the internal kinetic energy and total energy become comparable, which occurs at the size of the proton. We infer that the proton is the smallest stable particle, being a light speed circulation of energy.

9570-54, Session 11

The electrostatic to gravitational force ratio within the electro-gravi-magnetic (EGM) construct

Riccardo C. Storti, Delta Group Engineering, P/L (Australia)

The Electro-Gravi-Magnetic (EGM) construct is a derived methodology based upon the Polarizable Vacuum (PV) model of gravity and Buckingham Pi Theory (BPT). Their union has produced impressive experimentally verified results consistent with the Standard Models of Particle-Physics and Cosmology. The body of research in this paper is based on the fundamental EGM prediction that Photons are quantized massive propagating units of matter such that, when standard engineering scaling and similarity techniques are applied, the "Many Orders of Magnitude" problem between

ElectroStatic and Gravitational Forces is reconciled as a function of Cosmological Expansion.

9570-100,

Are electrons oscillating photons; or, oscillating “vacuum”; or, something else? - The 2015 Panel discussion

Chandrasekhar Roychoudhuri, Univ. of Connecticut (United States) and Femto Macro Continuum (United States); Charles G. Akins, Akins Enterprises LLC (United States); John G. Williamson, Univ. of Glasgow (United Kingdom); John A. Macken, Macken Instruments Inc. (United States); David Mathes, Parsec (United States); Richard Gauthier, Santa Rosa Junior College (United States); Martin B. van der Mark, Philips Research Nederland B.V. (Netherlands)

What physical attributes separate EM waves, of the enormous band of radio to visible to x-ray, from the high energy narrow band of gamma-ray? From radio to visible to x-ray, telescopes are designed based upon the optical imaging theory; which is an extension of the Huygens-Fresnel diffraction integral. Do we understand the physical properties of gamma rays that defy us to manipulate them similarly? One demonstrated unique property of gamma rays is that they can be converted to elementary particles (electron and positron pair); or a particle-antiparticle pair can be converted into gamma rays. Thus, EM waves and elementary particles, being inter-convertible; we cannot expect to understand the deeper nature of light without succeeding to find structural inter-relationship between photons and particles. This topic is directly relevant to develop a deeper understanding of the nature of light; which will, in turn, help our engineers to invent better optical instruments.

Conference 9571: Fourteenth International Conference on Solid State Lighting and LED-based Illumination Systems

SPIE. OPTICS+ PHOTONICS OPTICAL ENGINEERING+ APPLICATIONS

Wednesday - Thursday 12–13 August 2015

Part of Proceedings of SPIE Vol. 9571 Fourteenth International Conference on Solid State Lighting and LED-based Illumination Systems

9571-1, Session 1

Semiconductor lasers (VCSEL, laser diode, and LEDs) characterization

Mahmoud Gadalla, Tanta Univ. (Egypt)

This paper includes some experimental results and theoretical explanation about VCSEL, Laser Diode (LD) and LEDs. It explains the power-current (P-I) relation with temperature effect, and then goes briefly to discuss VCSEL and LD emission pattern and their spectrum temperature dependence. Finally a number of LEDs will be examined from the point of view of emission pattern and spectrum analysis.

9571-2, Session 1

Next-generation glass-base phosphor-converted laser light engine

Jin-Kai Chang, National Sun Yat-Sen Univ. (Taiwan); Wei-Chih Cheng, Taiwan Color Optics, Inc. (Taiwan); Yi-Yin Kuo, National Sun Yat-Sen Univ. (Taiwan); Chun-Chin Tsai, Far East Univ. (Taiwan); Yung-Peng Chang, Taiwan Color Optics, Inc. (Taiwan); Yi-Chung Huang, Brogent Technologies, Inc. (Taiwan); Li-Yin Chen, National Sun Yat-Sen Univ. (Taiwan); Wood-Hi Cheng, National Chung Hsing Univ. (Taiwan)

We report the first experimental demonstrating a novel high-reliable laser light engine (LLE) employing employing Ce:YAG and Ce:LAG-doped glass. The LLE module consisted of a color wheel and a 10 W blue light laser array. The color wheel included two color conversion layers and a micro motor. The conversion layers of the yellow and green phosphors were bonded on an aluminum substrate and placed on a micro-motor. The laser array source was used to excite the color wheel which would create yellow and green lights. The combination of blue, yellow, and green lights will produce high-purity white light for use in laser light engines.

A common type of phosphor-converted color wheel consisted of a GaN-based semiconductor chip and phosphor-doped silicone as a phosphor-converted layer. The silicone is a key component in conventional LLEs. However, the high heat flux radiating from the laser focus point may make the silicone yellow and decreasing the transmittance. In recent years, glass-based phosphors have been discussed as the solution of carrier material for high-power white LEDs due to much higher thermal stability than silicone-based phosphors.

In this study, we present a novel LLE employing glass-based phosphor. The luminance and chromaticity measurements of the LLEs including luminous efficacy, quantum efficiency, color purity, correlated color temperature, and chromaticity coordinates will be presented. A better thermal stability of glass-based phosphor-converted color wheel may be beneficial to the many applications where the LLE modules with high power and high reliability are demanded for use in the next-generation LLEs.

9571-3, Session 1

Extraction efficiency enhancement in ultra-violet LEDs based on spin on glass microlenses

Chi-min Liu, National Taiwan University (Taiwan); Guo-Dung J. Su, National Taiwan Univ. (Taiwan)

Currently, light emitting diodes (LEDs) technology is widely applied to many aspects in daily life. We developed a new method to enhance the ultra-violet LEDs efficiency. A new fabrication method of a microlens is proposed that can be easily applied to ultraviolet light-emitting diodes (UV LEDs) and microlens system. We demonstrated a self-assembled microlens on top of UV LEDs based on self-surface tension and hydrophilic confinement effect to improve extraction efficiency. The microlens was made of transparent negative photoresist SU-8 and self-surface tension. This approach is cost effective and low time-consuming. Integrated with UV LEDs , microlens can improve extraction efficiency 5% in total power.

9571-4, Session 1

Standardization of UV LED measurements

George P. Eppeldauer, Thomas C. Larason, Howard W. Yoon, National Institute of Standards and Technology (United States)

Traditionally used source spectral-distribution or detector spectral-response based standards cannot be applied for accurate UV LED measurements. The most popular LEDs in the UV range have peaks at 405 nm, 395 nm, 385 nm, and 365 nm. These LEDs produce broadband radiation and their peaks can change about +/- 5 nm. The spectral bandwidths of the LEDs can be different as well. The detectors used for the measurement of these LEDs also have different spectral bandwidths. The CIE standardized square-shape spectral response function for UV measurements cannot be realized with small spectral mismatch when using filtered detectors. E.g., for the measurement of 365 nm peak LEDs, the realized UV-A meters have different response functions producing large measurement errors even if the same LED is measured. In these broadband UV measurements, the signal is equal to the spectral product of the source distribution and the spectral response of the LED-measuring detector/meter. In order to perform uniform LED measurements, instead of the traditional source and detector standards, the signal measurement procedure is standardized here. In the present example, LEDs with 365 nm peak are applied for fluorescent crack-recognition using liquid penetrant (non-destructive) inspection. Using the traditional standards and measurement methods, the broadband UV measurement errors can be several times ten percent or larger. The requirement from the standard signal-measurement procedure is to obtain invariance in the measured output signal for variations in both the peak and the spectral width of the source. The spectral-shape of the meter response has to be chosen broad and flat enough to obtain the same signal for the different LEDs or LED groups with the required low measurement uncertainty. As a first step of the new standard procedure, the UV source is standardized. Instead of traditionally used Hg lamps, environment friendly UV LED sources are used. The peak changes and the spectrum-half-width can be maximized according to the spectral flatness of the detector in the spectral range determined by the LED sources to be measured. The UV LED source can be calibrated against an FEL lamp standard to determine its spectral irradiance. In a second step, the measurement procedure is standardized. The spectral irradiance responsivity of a reference UV detector/meter is calibrated. The output signal of the reference UV meter is calculated from the calibrated spectral function of the UV source and the calibrated spectral response of the reference UV meter. The maximum allowed peak wavelength changes of the source (using the measured response function of the reference meter) can be calculated from the expected uncertainty of the output signal measurement. From the output signal, both the integrated irradiance (in the reference plane of the reference meter) and the integrated responsivity of the reference meter can be determined. Test UV meters can be substituted for the reference UV meter in the same irradiance, and the ratio of the output signals can be used as the calibration factor for the test meter. From the calibration factor and the integrated response of the reference

meter, the integrated response of the test meter can be determined. When the calibrated test meter measures the signal from a field UV source, the integrated irradiance from the field source can be determined. In the given LED-365 nm example, this irradiance level is standardized by the ASTM-E1417 and it shall be at least 1 mW/cm2 at a distance of 40 cm from the source. UV damage-free nitrided Si detectors were used in the here developed reference UV irradiance meters with fluorescence-free band-pass filters attached to the front. The realized spectral response function was broad and flat (constant) enough, compared to the source distributions, to obtain small enough output signal variations as a result of using the standard procedure. When the measurements are extended for a wider wavelength range (using more different UV LEDs) pyroelectric detectors with low noise-equivalent-power (NEP) can be used as reference detectors. The low-NEP is needed to calibrate the detector for spectral response at the output of a monochromator. The scale transfer to field UV LED measurements can be made with filtered UV quantum detectors. The measurement uncertainty obtained using the LED-365 source standard and the standard broadband UV measurement procedure, was 5 % (k=2), significantly lower than the measurement errors obtained using traditional standards. Improving the spectral flatness of the reference meter, the uncertainty of the reference UV LED measurements can be decreased to the couple of percent (k=2) level.

9571-5, Session 2

Thermoresponsive scattering coating for smart white LEDs

Hugo J. Cornelissen, Joan Yu, Giovanni Cennini, Philips Research (Netherlands); Jurica Bauer, Paul P. C. Verbunt, Cees W. M. Bastiaansen, Dick J. Broer, Technische Univ. Eindhoven (Netherlands)

In this paper we present a novel smart LED system, based on single white emitting LEDs, able to adjust the CCT of the emitted light in response to electrical current. The smart LEDs are based on a thermoresponsive material, coated on top of LEDs, that uses the heat generated by the LED to switch between a scattering and a transparent state, in turn causing a change in the CCT of the light emitted by the device. Furthermore, by tuning the design of the LED we were able to develop an LED system that automatically changes the CCT of the emitted light in the range between 2900 and 4150 K upon changing the current applied to the LED. Due to the presence of two different phosphors in the LED package, the chromaticity of the light emitted by the LED system remains within the 5-steps MacAdam ellipses from the black body line at all currents and CCTs, rendering this LED system applicable in the lighting industry.

9571-6, Session 2

High efficient packaging structure with high concentration phosphor matrix

Yu-Yu Chang, Hsin-Ying Lin, Zi-Yan Ting, Tsung-Hsun Yang, Ching-Cherng Sun, National Central Univ. (Taiwan)

In this paper, we propose and demonstrate a high efficient packaging structure of pcW-LED. In the packaging structure, a high reflective cup is used for a higher photon recycling and phosphor matrix is used for a higher light extraction for blue light without scattering effect. Accordingly, to minimize the loss blue light and to maximize the white light efficiency can be fulfilled at the same time. With a high concentration phosphor optical model, phosphor which is coated on a transparent substrate can be simulated to optimize the coating area and spacing. In simulation, a full coated phosphor substrate is analyzed first, and a specific thickness of phosphor layer will be chosen for a maximum light output of yellow light. Therefore, the spacing of phosphor matrix can be analyzed and optimized to extract more blue light for a certain correlated color temperature which is fixed at 6500K in this paper. In simulation, the best result is 71.6% in packaging efficiency with the phosphor particle size is center at 6 ?m in the radius. The result shows a 4% enhancement compared with a remote hemisphere packaging structure which is the best result of the previous simulation. In experiment, when the CCT is 6590K, the best packaging efficiency of the phosphor matrix structure can be 68% which is much higher than 62.4% of the remote hemisphere package. Therefore, with the same spectrum, the luminous efficacy could be 18 lm/W more. This packaging structure can be realized and closer to the boundary of 75% in packaging efficiency at 6500K which can be a breakthrough for a high efficient package in pcW-LED.

9571-7, Session 2

Direct growth and controlled coalescence of thick AlN template on circle patterned-Si substrate

Tinh Binh Tran, Hideki Hirayama, Shiro Toyoda, Noritoshi Maeda, RIKEN (Japan)

AlGaN-based deep ultraviolet light emitting diodes (UV-LEDs) have attracted considerable attention due to their wide range of applications in air, water purification, disinfection, non-line-of-sight communication, etc. AlGaN-based deep UV-LEDs on sapphire substrates have been already commercialization. However, the growth of AlGaN/AlN on silicon substrates for deep UV-LED applications have been extensively studied due to lots of challenges such as a large lattice mismatch between AlN and Si (111) (~19%) will lead to high-dislocation density and crack initiating stress, the presence of an oxide on the Si substrate also leads to low coherence between AlN template and the Si substrate, or the low growth rate, etc. Thus, conventional bulk AlN grows on Si is troublesome for researchers.

In this work, we report on the fabrication and investigation of thick AlN templates grown directly on circle patterned-Si(111) substrates using NH3 pulse-flow multilayer with epitaxial lateral overgrowth (ELO) for further use in AlGaN-based deep UV-LED applications. The effect V/III ratio on the growth rate and the growth temperature on the crystalline quality of thick AlN templates were mainly studied. A ~8 μm-thick AlN template with XRD FWHM of about ~840 arcsec and 1350 aresec for (002) and (102) reflection planes were obtained, respectively. Low roughness surface and dislocation density were also confirmed by using AFM (atomic force microscope) and TEM (transmission electron microscopy) techniques. The achievement of high quality and crack free with a uniform thickness of AlN film on 2-inch Si(111) substrate is of great interest for AlN-based deep UV-LED applications.

9571-9, Session 3

Selecting “pleasing” correlated color temperature for illumination of outdoor environments

Andrius Petrulis, Pranci?kus Vitta, Rimantas Vaicekauskas, Arturas ?ukauskas, Vilnius Univ. (Lithuania)

Commonly, subjects prefer higher illuminances irrespectively of the correlated color temperature (CCT). However in outdoor environments, energy saving, light pollution, and circadian disruption issues require limiting the illuminance to particular levels. To that end, finding the most appropriate lighting conditions can be performed by the selection of the most “pleasing” CCT. In this work, subjective judgments on the most “pleasing” CCT were investigated in outdoor environments using a tetrachromatic solid-state light engine with tunable CCT and high-fidelity color rendition. Using a

remote control (smart phone with application software), subjects were asked to adjust CCT within the 1850-10,000 K range in several outdoor environments (medieval courtyard, park area, and modern city). Typically, the normal distributions of the widely scattered selections were observed on the reciprocal CCT scale. Despite a wide scatter of individual judgments, the mean selected CCT of 3000±200 K and 3500±250 K was established for constant illuminances of 5 lx and 50 lx, respectively, almost independently of the viewed scene. In addition, when instantaneous dimming was applied in order to maintain constant circadian irradiance with increasing CCT, subjects selected even lower CCTs at low illuminances in order to maintain visibility and sacrificed a part of high illuminance in order to maintain the preferred CCT. Our results prove the existence of the ranges of "pleasing" CCT for outdoor environments with limited illuminance and resolve the ambiguity of the Kruithof rule in that it is not invariant in respect of adjustable variables (illuminance and CCT).

9571-10, Session 3

A color management system for multi-colored LED lighting

Maumita Chakrabarti, Anders Thorseth, Jørgen Jepsen, Dennis D. Corell, Carsten Dam-Hansen, DTU Fotonik (Denmark)

The LED color mixing systems, widely used in different lighting applications, often suffer from poor color rendering and color instability. In order to overcome these problems without sacrificing efficiency, we present an approach to obtain controlled chromaticity and stability over short and long term from a set of initially optimized settings.

A new color control system is described and implemented for a five–color LED light engine, covering a wide white gamut. The system provides intelligent control of the individual LED color arrays to produce high quality white light ranging in correlated color temperatures (CCT) between 3000 K and 5800 K. A feed-back control system combines a new way of using pre-calibrated look-up tables and a rule-based optimization of chromaticity distance from the Planckian locus (Duv) for each CCT with a calibrated color sensor for chromaticity control. A pre-calibrated look-up table is generated using a new algorithm, called Ideal White Light Radiator-guided search algorithm (IWLiR) which can provide spectral mixtures characterized by a high general color rendering index (CRI) Ra > 85 and specific CRI R9 > 40 for rendering the strong red objects e.g. skin tones. The calibrated color sensor monitors the chromaticity of the mixed light and also provides the correction factor for the current driver by using the look-up table. The long term stability and accuracy of the system will be experimentally investigated with a target tolerance within a circle radius 0.0011 in the uniform chromaticity diagram (CIE 1976).

9571-11, Session 3

The stability of spectrum reproduction by LEDs

Hua Yang, Jing Li, Ran Yao, Pengzhi Lu, Yanrong Pei, Institute of Semiconductors (China)

Reconstruction natural light spectrum by reasonable method is an important branch when fabricating LED-based products for general illumination, especially to the needs of health lighting. But as is well-known, although mixed LED sources have a higher theoretical maximum efficiency and allow for dynamic control, it generally have less color consistency both initially and over time because of different LEDs are not stable by operating conditions and operating temperature. So while there are many methods to realize the spectrum simulation, the complexity of manufacture progress and color quality of products is key consideration when evaluating these methods.

In order to find some method for evaluating the quality of spectral reconstruction, this article fabricate the white-light LED systems that simulated the natural light and analyze the methods that the basics spectral power distribution simulation and mainly color issues that related to such as color consistency and constancy that is inherent in the design and manufacturing process. The model with 3, 4, 6 and more primary LEDs based on the real measured spectrum and theoretical spectrum are analyzed. The spectral power sensitivity relation between the LEDs with different wavelength and color characteristic is analyzed. The degree of fitting is over 0.99, and color constancy is acceptable. These researches simplified the method of visible spectrum reconstruction and make it possible for the light simulators used in general lighting in a cost effective way.

9571-12, Session 3

Experimental investigation of analog and digital dimming techniques on photometric performance of an indoor Visible Light Communication (VLC) system

Fahad Zafar, Vineetha Kalavally, Monash Univ. Malaysia (Malaysia); Masuduzzaman Bakaul, Monash University Malaysia (Malaysia); Rajendran Parthiban, Monash Univ. Malaysia (Malaysia)

For making commercial implementation of light emitting diode (LED) based visible light communication (VLC) systems feasible, it is necessary to incorporate it with dimming schemes which will provide energy savings, moods and increase the aesthetic value of the places using this technology. There are two general methods which are used to dim LEDs commonly categorized as analog and digital dimming. Incorporating fast data transmission with these techniques is a key challenge in VLC. In this paper, digital and analog dimming for a 10 Mb/s non return to zero on-off keying (NRZ-OOK) based VLC system is experimentally investigated considering both photometric and communicative parameters. A spectrophotometer was used for photometric analysis and a line of sight (LOS) configuration in the presence of ambient light was used for analyzing communication parameters. Based on the experimental results, it was determined that digital dimming scheme is preferable for use in indoor VLC systems requiring high dimming precision and data transmission at lower brightness levels. On the other hand, analog dimming scheme is a cost effective solution for high speed systems where dimming precision is insignificant.

9571-13, Session 4

Necessity of mixed-level simulations for optical modeling of light-emitting diodes with patterned substrates

Mayank Bahl, Synopsys, Inc. (United States); Alexander Linkov, OSRAM Opto Semiconductors GmbH (Germany); Evan Heller, Synopsys, Inc. (United States); Georg Rossbach, OSRAM Opto Semiconductors GmbH (Germany); William Cassarly, Robert Scarmozzino, Synopsys, Inc. (United States)

Extensive research has been conducted to improve the design of light-emitting diodes (LEDs) so as to enhance the light extraction efficiency, and improve beam shaping, through techniques such as the use of photonic crystal gratings, patterned substrates, surface textures and back reflectors. Increasingly complex designs have necessitated the use of computational simulations which have provided numerous insights for improving LED performance. Ray optics based techniques such as Monte Carlo ray-tracing or rigorous electromagnetic (EM) wave optics based techniques such as finite-difference time-domain (FDTD) and rigorous coupled wave analysis (RCWA) are commonly applied for optical modeling of LEDs. Whether ray-optic or wave-optic techniques are used for the numerical simulation is usually based on the focus of the design and the geometric scale of the structures involved in the problem. This paper compares the optical responses of prototypical periodically-patterned substrate examples with varying lateral periods and dimensions computed with both methods. It

is shown that these results may differ even when the grating periods are much larger than the wavelength, especially when the considered surface is in a realistic LED chip environment. Such results indicate that to accurately model LEDs involving periodically-patterned features a standalone ray-optics approach may be insufficient even at large structure sizes. We have recently proposed a mixed-level simulation approach combining rigorous EM wave based tools (RCWA and/or FDTD) and ray-optic tools. Here, we demonstrate cases where this approach is necessary to comprehensively model the light extraction in modern LED designs.

9571-14, Session 4

A novel design for high-performance dental lamp based on white-LEDs

Jhih-You Cai, National Central Univ. (Taiwan); Hsin-Yang Ho, Witslight Technology Group (Taiwan); Wei-Ting Chien, National Central Univ. (Taiwan) and Witslight Technology Group (Taiwan); Ching-Cherng Sun, National Central Univ. (Taiwan)

In our research, we propose a novel design for the dental lamp based on white-light LEDs. In general, the uniform illumination, low glare, high color-rendering index, and shadowless performance are needed consideration in the design of dental lamp. Traditionally, the halogen is used in the dental light, the light source is wasted energy caused by the low efficacy. Furthermore, the patient is in danger and uncomfortableness caused by the UV and IR radiation, respectively. LEDs can solve the problems, which we talk above. In our design, the concept is easy. The LEDs with high color-rendering index are used in our design. To avoid the glare happening, the LEDs are put in the center with a tilt angle, and the light is emitted in the opposite direction of dental lamp. The secondary optical elements, such as reflector, are used in our design. The reflector can reflect the light toward the oral cavity of the patient. We optimize the surface of the reflector, and make uniform illumination with high illuminance. Finally, we make a prototype to verify our design. The prototype produces high performance lighting in dental light.

9571-16, Session 4

LED streetlight analysis from outer space

Ivan Moreno, José Samuel Pérez Huerta, Tonatiuh Saucedo Anaya, Univ. Autónoma de Zacatecas (Mexico); Daniel Luis, Univ Autonoma de Zacatecas (Mexico)

Photographs of the Earth at night are a valuable source of freely available online information of streetlights. And since 2012 two new spaceborne imaging detectors may be used for city lighting photometry because they have higher spatial resolution and radiometric precision. Data from these detectors have sufficient resolution to identify and measure sources of waste light, such as streetlights, airports, harbors, leisure, stadiums and city centers. We retrieve data from imagery of these new instruments to analyze LED street lighting. In particular we propose a method to measure and analyze light pollution. Also, color image processing is used for approximate identification or discrimination of lighting technology types: high intensity discharge (HID), fluorescent, and LED lamps.

9571-17, Session 4

Freeform TIR lens design by sampling LED's intensity distribution in multiple Cartesian coordinate systems: A composite ray mapping method

Donglin Ma, College of Optical Sciences, The Univ. of Arizona (United States); Zexin Feng, The Univ. of Arizona (United States); Rongguang Liang, College of Optical Sciences, The Univ. of Arizona (United States)

A composite ray mapping method by combining uv ray mapping and ?? ray mapping method has been proposed to design a freefrom TIR lens for rectangular illumination, where the source's intensity distribution is tailored in hybrid coordinate system consisting of uv spherical coordinate system and ?? spherical coordinate system. In this paper, we are going to extend the composite ray mapping method to multiple xy coordinate systems. In the method, we sample the ray's intensity distribution into plenty of rectangular grids, which have the best topological match to those rectangular grids on the target surface. With the multiple-to-one corresponding relationships between the source's intensity distribution and target's irradiance distribution, we can finally construct the freeform TIR surfaces and freeform refractive surface using Snell's law. Compared to our previous design using uv- ?? composite ray mapping method, this design approach is expected to have much less surface error and improve the illumination uniformity in a further step due to the better topological match. Moreover, this design method can only have flat surfaces to work as the flux acceptance surface inside and all of freeform surfaces are located outside. As a result, it can greatly reduce the difficulties of fabrication. In addition, due to the overlapping mechanism by multiple-to-one ray mapping, the method could lead to a more robust freeform optics compared to traditional freeform optics designs.

9571-18, Session 4

LEDs-based multiwavelength photoreactor for photocatalysis applications

Luis Armando Díaz-Torres, Ctr. de Investigaciones en Óptica, A.C. (Mexico); Daniel Berrones, Carlos R. García, Univ. Autonoma de Coahuila (Mexico); Jorge Roberto Oliva-Uc, Ctr. de Investigaciones en Óptica, A.C. (Mexico); Raul Ochoa-Valiente, Univ. Autonoma de Coahuila (Mexico)

In this work, a low cost photoreactor based on LEDs technology was designed, constructed and characterized for photocatalysis applications. The photoreactor was designed with cylindrical configuration; its dimensions were 15.3 cm and 26 cm for diameter and height respectively. The maximum volume of solution for controlled photocatalysis experiments using this reactor is 600 ml. Arrangements of three low-cost LEDs (365nm, 395 nm and 420 nm) were placed in triangular configuration in order to optimize the density of energy at the center of the photoreactor. The different LEDs´ arrangements were connected with independent and tunable electronic circuits. In addition, a cooling system (low-cost fan) was installed on top of the photoreactor to keep constant the temperature during the photocatalysis experiments. The temperature inside of photoreactor was monitored by measuring the temperature of 600 ml. of deionized water into the reactor and under the UV light during 180 min, which simulates a photocatalysis experiment. The maximum temperatures obtained inside the reactor when the LEDs of 365 nm, 395 nm and 420 nm are operating were 26°±2°C, 17.2°±1C, 18±0.5°C, respectively. Finally, the spectral radiance and the optical power were characterized at the center of the photoreactor for the different LEDs systems for optimization purposes. Due to the good stability of temperature as a function of time and the high optical power emitted by the LEDs at the center of the photoreactor, this design can be very suitable for controlled photocatalysis experiments.

9571-27, Session PWed

High performance near-ultraviolet flip-chip light-emitting diodes with distributed Bragg reflector

Il-Gyun Choi, Geun-Mo Jin, Jun-Cheon Park, Soo-Kun Jeon, Eun-Hyun Park, Semicon Light Co., Ltd. (Korea, Republic of)

Ultraviolet (UV) light-emitting diodes (LEDs) usually have very low external quantum efficiency (EQE) and high forward voltage due to poor light extraction efficiency and high contact resistance. Thus, to enhance the performance of UV flip-chip LEDs, p-type electrodes should be good reflectors having high reflectance, low contact resistance and thermal stability. For GaN-based flip-chip LEDs, metal-based reflectors, such as Ag- and Al-based schemes, have been widely used so as to increase the light extraction. Unlike Al reflector, however, Ag is subject to thermal degradation, such as agglomeration and the formation of voids. In addition, the reflectance of Ag contact drop rapidly in the near-UV region. On the other hand, reflectance of Al is also kept in the UV region but, Al has a small work function and so serves as an electrode for n-type GaN. Therefore, in this work, we have fabricated the near-UV flip-chip LEDs with the high EQE using distributed Bragg reflectors (DBRs). A DBR is a highly reflective mirror which consists of alternating layers of high- and low-index materials, each having a quarter-wavelength thickness to generate constructive interference. In conventional DBR structures are composed of two different materials which have high-index contrast, such as TiO2 and SiO2. However, to achieve high-performance near-UV flip-chip LEDs, we used Ta2O5 instead of TiO2 that absorbs lights of UV region. Thus, we have designed a DBR composed of twenty pairs of Ta2O5 and SiO2 using optical coating design software. The DBR designed by our group achieves a reflectance of ~100 % in the near-UV region, which is much better than reflectance of Ag and Al. The difference of reflectance between DBR and metals will be more increased in the real device due to above mentioned issues.

9571-28, Session PWed

High performance GaN based blue flip-chip light-emitting diodes

Geun Mo Jin, IL-Gyun Choi, Jun-Cheon Park, Soo-Kun Jeon, Eun-Hyun Park, Semicon Light Co., Ltd. (Korea, Republic of)

In this study, high performance nitride-based flip-chip (FC)l ight-emitting diodes (LEDs) were investigated and fabricated. The availability of high brightness, high power, and large area of GaN-based light-emitting diodes (LEDs) has enabled their applications in exterior automotive lightings, outdoor displays, backlights for liquid crystal display (LCD) TV. Recently ,the FC LEDs has been used to contain such high-performance products. In general, the use of silver as a p ohmic contact metal and a highly reflective material of the flip chip. However, silver has a problem in the manufacturing process and the reliability due to agglomeration or migration. Therefore, to solve this problem, was used instead of Ag reflector Distributed Bragg Reflectors(DBR) to improve the EQE. Further, ITO was used as a p ohmic layer in order to stabilize the voltage. A DBR is a highly reflective mirror which consists of alternating layers of high- and low-index materials, each having a quarter-wavelength thickness to generate constructive interference. In conventional DBR structures are composed of two different materials which have high-index contrast, such as TiO2 and SiO2. DBR is designed 99% or more reflectivity for normal incidence in the visible region of 400nm ~ 700nm, in consideration of the oblique angle of incidence. FC LEDs fabricated of a reflector having a better reflectance than the silver will have a high-performance, high-reliability.

White LED motorcycle headlamp design

Wen-Shing Sun, National Central Univ. (Taiwan)

The motorcycle headlamp is composed of a white LED module, an elliptical reflector, a parabolic reflector and a toric lens. We use non-sequential ray to improve the optical efficiency of the compound reflectors. Using the toric lens can meet ECE_113 regulation and obtain a good uniformity.

9571-31, Session PWed

Trap-assisted tunneling contributions to subthreshold forward current in InGaN/GaN light-emitting diodes

Marco Mandurrino, Michele Goano, Stefano Dominici, Marco Vallone, Francesco Bertazzi, Giovanni Ghione, Politecnico di Torino (Italy); Mario Bernabei, Luigi Rovati, Giovanni Verzellesi, Univ. degli Studi di Modena e Reggio Emilia (Italy); Matteo Meneghini, Gaudenzio Meneghesso, Enrico Zanoni, Univ. degli Studi di Padova (Italy)

Improving the physical understanding of the subthreshold forward current in GaN-based LED is important for LED technology optimization purposes. This current is actually a sensitive marker of device growth qualit. Its increase is a signature of device degradation induced by accelerated stresses. Moreover, it is governed by trap-assisted tunneling mechanisms, that may also play a role in the efficiency droop phenomenon at high driving currents.

In this work, we presents results from a simulation-based investigation of the subthreshold forward current in blue InGaN/GaN single-quantum-well LEDs. We specifically show that the excess forward leakage currents in InGaN/GaN LEDs grown on different substrate materials (SiC, Si) can be explained by the combined effect of trap-assisted, electron and hole tunneling “under the quantum well”, i.e. electron tunneling from the n-doped LED region into traps located in the spacer and EBL regions and hole tunneling from the p-doped EBL into traps located in the n-doped GaN region. Non-local tunneling-to-trap currents and attendant recombination with free carriers are accounted for in the adopted simulation code self-consistently with Poisson’s and charge transport equations, so that their impact on subthreshold IV curves can be assessed quantitatively for LED structures realistically described at both material and technology level. The sensitivity of the electron and hole tunneling currents to trap parameters (energy, donor/acceptor type) is analyzed in detail for the possible correlations with trap characterization data available in the literature and the information it can provide on the role played by extended or point defects.

9571-32, Session PWed

RGB color sensor implemented with LEDs

José David Filoteo, Julián Móises Estudillo-Ayala, Univ. de Guanajuato (Mexico); Juan Carlos Hernández-Garcia, Consejo Nacional de Ciencia y Tecnología (Mexico); Mónica Trejo-Durán, Alberto Muñoz Lopez, Daniel Jauregui-Vázquez, Roberto Rojas-Laguna, Univ. de Guanajuato (Mexico)

In this paper is present the design and implementation of an optical sensor to detect color changes in objects through reflection of incident light from a white light source, with the purpose of use it in measuring the ripeness of fruit and applications in industrial and / or agriculture. The system is constituted by an RGB LED array, a photodetector, a current source and a plastic optical fiber. The multimode optical fiber has the characteristics of a numerical aperture of 0.51, a diameter of 1mm, an interval of transmission in the visible. Using a graphical interface designed in Labview ®, it is possible control the power of the diodes in a digital form mixing colors using different intensities achieving a white light source that will serve as a source for the color sensor. We use a microcontroller ATmega2560 as data acquisition device to monitor the colors obtained using Matlab® and showing the result with the RGB color model of 8 bits. We show tests with guava fruits with two different maturity stages. Observing the evolution of color change of the skin of the fruit to conditions to over-maturity. The results obtained with instrument show a precision error of 3% average to detect changes color when compared to samples of digital images by 11 days test.

Numerical and experimental study on the evaluation of light collecting performance of the bio-fluorescence sensor

Bonghyun Jo, YiSeul Jo, Sun-Seok Byeon, Hee Won Shin, Tae Kyu Ahn, Sungkyunkwan Univ. (Korea, Republic of); Jong-Chul Lee, Gangneung-Wonju National Univ. (Korea, Republic of); Youn-Jea Kim, Sungkyunkwan Univ. (Korea, Republic of)

Bio-fluorescence sensor using deep UV LED (Light Emitting Diode) has been explored and developed to detect tactical biological agent against biological aerosol attacks. The LED as excitation source adopted in bio-fluorescence sensor introduces lightweight, low cost, low electrical power consumption. However, LED is generally difficult to be focused in small area and to induce fluorescence that distinguishes between bioparticles and non-bioparticles (i.e. abiotics) because emitted at a large divergence angle. In order to enhance the detection efficiency in bio-fluorescence sensor capitalized on LED, light collecting is an important problem. We have performed several numerical studies on three types of optical lens such as aspheric, ball, and bi-objective lens using the commercial software, LightTools (Synopsys Inc.), which is used to analyze illumination characteristics from LED. The estimated losses are reported to be 20%, 25%, and 17% for aspheric, ball, and bi-objectice lens, respectively. The values and distributions of irradiance were compared with various types of optical lens to evaluate light collecting performance in detection area.

Design of high power LED-based UVA emission system and a photosensitive substance for clinical application in corneal radiation

Alessandro D. Mota, André M. Cestari, Opto Eletrônica S.A. (Brazil); André Orlandi, Univ. de São Paulo (Brazil); Anselmo G. Oliveira, Cristina H. B. Terruggi, Univ. Estadual Paulista “Júlio de Mesquita Filho” (Brazil); Giuliano Rossi, Opto Eletrônica S.A. (Brazil); Jarbas C. Castro Neto, Univ. de São Paulo (Brazil); João P. B. Ligabô, Opto Eletrônica S.A. (Brazil); Tiago A. Ortega, Univ. de São Paulo (Brazil); Tiago Rosa, Opto Eletrônica S.A. (Brazil)

An alternative treatment to keratoconus disease is a procedure called cross-linking. This disease weakens the corneal cell structure, leading the corneal to a conical shape, and the consequence is the lost of visual acuity. The standard technique consists of administration of a photosensitive substance called riboflavin in corneal tissue, which penetration is possible by removing corneal epithelium, and a dose of 5.4 J/cm2 of homogeneous UV light is fired on corneal surface for 30 minutes. The UV light exposure leads to a modification of corneal collagen fibers, becoming it more rigid and dense, which will contain the advance of the disease. This work presents an opto-electronic equipment that permit the reduction of treatment duration in up to 2 minutes by increasing UV power up to 45mw/cm2, and keeping the total well established accumulated energy of 5.4J/cm2. It consists of one UV LED source (365nm), one projection optical system to patient’s cornea on a circular area of 11mm diameter, and a microcontrolled electronic system for controlling output power by using a system based on PID (proportional, integrative, and derivative controller in a closed loop) in software. This system results in constant output power and in uniform power distribution, with less than 10% of variation in both cases. Additionally, the main advantages of the system presented are: fast treatment procedure, low risk of infection (no epithelium remove), painless procedure, and reduction of treatment costs because there is no demand to controlled operating room.

9571-35, Session PWed

Process research of LED full-color display matrix with small pixel

Jing Li, Hua Yang, Ran Yao, Institute of Semiconductors (China)

Besides lighting, Light-emitting diode (LED) is offer a wide range of potential applications including display. In contrast with LCD, LEDs display has better contrast ratio, higher response rate etc which makes LEDs along with other self-illumination technologies an ideal candidate in making display panel. Due to the popularization of HD and Ultra HD standard, display panel with better image quality is needed which means the number of pixels of the panel needs to be increased while the size of each pixel needs to be minimized. In this paper, we demonstrated a LED full-color display panel based on a 32?32 LED matrix with typical pixel size of 0.5mm. Benefit from the application of flip-chip bonding, LED full-color display array with small pixel was obtained by mounting red LEDs, green LEDs and blue LEDs directly onto an isolating substrate. The isolation layer consists of a SiO2 layer of 800nm and polyimide layer of 2700nm. Polyimide as an important electrical insulating layer, we study some properties of it, such as :PI amination rate as a function of the curing temperature, PI resistivity as a function of the curing temperature and the punction electric field intensity of PI as a function of the film thickness of PI.In addition, the substrate has metalized pads and connection before the matrix was connected to control unit. Comparable brightness of the LED matrix emitting at different color was achieved by adjusting the input current.

Inline arrayed beam spot lighting in agriculture based on a guided-wave beam splitter

Hong-Shik Lee, Jin Hwan Lee, Jae Hyoung Ryu, Korea Institute of Lighting Technology (Korea, Republic of)

With the increasing attention towards the fusion of green-IT and agriculture in the recent days, the light-emitting-diode (LED) plant factory has been receiving tremendous attention. Miniaturization of such LED based illumination products will enable them to be used in relatively small space. In addition to that, due to their low power consumption and low heat dissipation, those products can be used for a long period of time. However, For the economic efficiency of the photosynthetic efficiency of the LED lighting facilities may be required to increase the specific light distribution technology light irradiation efficiency of the plant. In this paper, we propose and implemented an inline arrayed beam spot lighting in agriculture based on a guided-wave beam splitter, in order to achieve a particular light distribution. We primarily endeavored to create an inline arrayed beam spot lighting based on an integrated optic guided wave beam splitter drawing upon silica waveguides, where the guided beam emerge from the corresponding 5 ports with a power ratio determined by the design configuration. The beam splitter is constituted of an integrated-optic 1 ? 5 beam splitter and a beam forming lens configuration. The splitter is designed with a tree-shaped geometry in which one straight waveguide at the input end branches out into 5 waveguides at the output end using Y-junctions. The ratio of power distributed among the 5 output waveguides was calculated to be 0.17:0.22:1:0.22:0.17, with the power normalized to the output of central waveguide.

9571-19, Session 5

Carrier-distribution studies in GaN-based light-emitting-diodes

Dinh Chuong Nguyen, David Vaufrey, CEA Grenoble (France); Mathieu Leroux, Ctr. de Recherche sur l’Hétéro-Epitaxie et ses Applications (France)

Carrier injection in GaN-based light-emitting-diodes (LEDs) is studied by means of simulation. Initially, two LED structures were optically and electrically characterized: the first one has a single-stripe-like cathode (SC) and the second one has multiple-stripe-like cathodes (MC). The experiments revealed an internal-quantum-efficiency (IQE) improvement in the MC structure: its IQE's peak value and the related current-density are both higher than their counterparts in the SC structure. Based on these results, those multiple-quantum-well LEDs were modeled with the carrier leakage and the Auger recombination being specifically focused. The simulations show a similar IQE enhancement in the MC structure and an unbalanced distribution of electrons and holes at the edges of the active region in both models. The disparity is even more pronounced in the SC structure. Furthermore, several parameters at the MC structure's active-region-p-side interface, such as the injected-hole concentration, can be up to as seven times higher as that in the SC structure. Meanwhile, the difference is smaller for the corresponding parameters at the active-region-n-side interface, such as the injected-electron concentration. This may suggest that the p-type layer play an important role in carrier-concentration balancing and further studies on the p-GaN properties are then needed.

The simulation results imply that the disparity between electron and hole injections may be related to the LED efficiency-loss. The injection ratio between these two types of carrier is currently being studied by the ongoing pulsed-electroluminescence experiments. Its results will be communicated later.

9571-20, Session 5

Design analysis of InGaN-GaNAs active region for long wavelength visible emission

Chee-Keong Tan, Nelson Tansu, Lehigh Univ. (United States)

Charge separation issue in III-Nitride InGaN light-emitting diodes (LEDs) becomes more severe with higher In-content due to polarization field in the QW, hampering the development of high efficiency long-wavelength InGaN LEDs. Critical implementation of approaches such as semipolar/nonpolar QW and staggered QW have been successfully adopted to address the charge separation issue in the blue and green LEDs. Nonetheless realizing a high In-content InGaN QW active region for long wavelength emission especially in the red spectral regime remains a fundamental barrier for current approaches, primarily due to the difficulty in high quality crystal growth of the InGaN QW. The strategy of probing the high In-content use and charge separation issue through active region design is thus essential for future development in high efficiency GaN-based long wavelength LEDs.

In this work we present a GaN-based active region through the formation of InGaN / GaNAs QW to achieve long wavelength emission from green to red spectral regime in the LEDs. Dilute-As GaNAs alloy has been recognized as a potential candidate for GaN-based LEDs in long wavelength spectral regime. The characteristics of InGaN / GaNAs QW active region are analyzed as follow: (a) transition energy, (b) wavefunction overlap and (c) spontaneous emission rate. Our finding demonstrates significant enhancement of electron-hole wavefunction overlap and thus improved spontaneous emission rate by the use of InGaN / GaNAs QW as compared to the conventional InGaN QW. The comparison of the characteristics between the conventional InGaN QW and InGaN / GaNAs QW will be discussed.

9571-21, Session 5

Effect of barrier materials on the polarization field in the active region of blue InGaN LED using Sentaurus

Karunavani Sarukunaselan, Vithyacharan Retnasamy, Zaliman Sauli, Mukhzeer Mohamad Shahimin, Steven Taniselass, Sarveshvaran Suppiah, Kamarudin Hussin, Univ. Malaysia Perlis (Malaysia)

This paper addresses the barrier material of the structural design of a blue InGaN light emitting diode (LED) in order to analyze the polarization effect occurred in the active region by carrying out a simulation using Sentaurus Synopsys. It was observed that the traditional GaN barrier had the highest polarization field due to high lattice mismatch between the wells and barriers. When InGaN or AlInGaN were employed as barrier, the band diagram showed a lower polarization effect. This was attributed to the overlapping of electrons and holes wave functions.

9571-22, Session 5

Quantum well thickness variation investigation on optical and thermal performances of GaN LEDs

Karunavani Sarukunaselan, Vithyacharan Retnasamy, Zaliman Sauli, Mukhzeer Mohamad Shahimin, Steven Taniselass, Sarveshvaran Suppiah, Kamarudin Hussin, Univ. Malaysia Perlis (Malaysia)

Blue InGaN LED suffers from a severe efficiency droop at high current density and electron leakage is believed to be one of the primary cause of it. In this study, InGaN LED was simulated using Sentaurus TCAD. The effects of thickness of the quantum wells on the device performances when were examined through simulation. Results of the simulations suggested that to achieve a low efficiency droop, the wells have to be thick.

9571-23, Session 6

Understanding the dopant activation for improved manufacturing yield in InGaN based light emitting diodes

Nicholas A. Lacroce, Guangyu Liu, Chee-Keong Tan, Lehigh Univ. (United States); Ronald A. Arif, Soo Min Lee, Veeco Instruments Inc. (United States); Nelson Tansu, Lehigh Univ. (United States)

Manufacturing efficiency of InGaN-based light-emitting diodes (LEDs) depends heavily on growth uniformity and control of dopant levels. Effectively controlling dopant activation and the variables which affect it are critical for large scale manufacturing. Without a controlled manufacturing environment, device characteristics vary greatly with position on the fabricated wafer. Specifically, the post-growth annealing used for activating the Mg+ acceptor dopant in the p-type AlGaN and p-GaN layers of the LEDs is very sensitive to the annealing environment of the wafer. Within the reaction chamber however, annealing temperature varies with position causing large non-uniformity in dopant activation and device characteristics. Thus, understanding how the Mg acceptor activation of the p-GaN and AlGaN layers alters the device properties is a critical step in understanding the way these temperature changes affect the device quality of commercially produced LEDs.

In this work we examine both numerically and experimentally the effect of varying p-type doping levels in the p-GaN layers as well as the AlGaN electron blocking layers of the LED devices. Specifically, the device properties of the LEDs are investigated which include the internal quantum efficiency, output power, band profile, and carrier concentration as functions of current density. In addition, the contribution of the dopant activation in the individual p-GaN and AlGaN layers to the variation of device characteristics is discussed. The temperature-dependent dopant activation issues will be clarified by better understanding the effect of the p-type GaN doping levels on the relevant device characteristics.

9571-24, Session 6

Efficiency improvement of the light-emitting diodes by the lateral overgrowth GaN on an ALN nanorod template

Wen-Yi Lan, Yu-Feng Yin, Chen-Hung Tsai, National Taiwan Univ. (Taiwan); Mu-Xin Ma, National Cheng Kung Univ. (Taiwan); Hsiang-Wei Li, National Taiwan Univ. (Taiwan); Wei-Chi Lai, National Cheng Kung Univ. (Taiwan); Jian-Jang Huang, National Taiwan Univ. (Taiwan)

In recent years, light-emitting diodes (LEDs) have played a critical role in the areas of backlights for flat panel displays, optical communications and general lightings. Despite their superior light emitting efficiency, there is still demand for better performance so that LEDs can achieve a higher penetration rate to general lighting market. In the past, GaN epi-layers were grown directly on the planar sapphire substrate by metal-organic chemical vapor deposition (MOCVD). However, the quality of GaN epi-layers suffers from a high threading dislocation density due to the large lattice mismatch (13%) and thermal expansion coefficient misfit (62%). In this work, we propose an AlN nanostructure template on the sapphire substrate to decrease the defect density in GaN epi-layers. The AlN naonstructure was synthesized by vapor-liquid-solid (VLS) mechanism. VLS is considered as a cost-effective and fast growth way to fabricate high quality nanostructures. We characterize the GaN LED epi-structure by its luminescence efficiency along with the extraction of internal quantum efficiency (IQE) of the InGaN/GaN quantum wells. The corresponding material quality is investigated by Raman spectra and transmission electron microscopy (TEM) images near the voids of the AlN rods. As a result, IQE of the device with the proposed AlN nanorod template increases by 12.2% as compared with the reference sample without AlN rod.

9571-25, Session 6

Optoelectronic and structural properties of InGaN nanostructures grown by plasma-assisted MOCVD

Daniel Seidlitz, Matara K. I. Senevirathna, Yohannes Abate, Nikolaus Dietz, Georgia State Univ. (United States); Axel Hoffmann, Technische Univ. Berlin (Germany)

This contribution reports on the optoelectronic and structural layer characteristics of InN and InGaN epilayers grown on sapphire templates with an AlN buffer layer by Plasma Assisted Metal Organic Chemical Vapor Deposition (PA-MOCVD).

In-situ characterization during the PA-MOCVD enables essential insight of the remote plasma composition and the epitaxial growth process. Analyzed Plasma Emission Spectroscopy (PES) and UV Absorption Spectroscopy (UVAS) provide detection and concentrations of plasma generated active species (N*/NH*/NHx*). Nitrogen (N2) as well as hydrogen (H2) or ammonia (NH3) precursors have been used to assess the nitrogen-active fragments that are directed from the hollow cathode plasma tube to the growth surface. Normal Incidence Reflection Spectroscopy (NI-RS) is utilized to obtain real-time information about be nucleation and overgrowth process as well as the growth evolution and film thickness of InGaN layers deposited on sapphire substrates with various high-/low temperature AlN buffer layers.

The in-situ diagnostics results are supplemented with ex-situ materials structures investigation results of nanoscale structures using Scanning Near-field Optical Microscopy (SNOM). The structural properties have been analyzed by Raman spectroscopy and Fourier Transform Infrared Reflectance (FTIR). The Optoelectronic and optical properties were extracted by modeling the FTIR reflectance (e.g. free carrier concentration, high frequency dielectric constant, mobility) and optical absorption spectroscopy. The correlation and comparison between the in-situ metrology results with the ex-situ nano-structural and optoelectronic layer properties provide insight into the growth mechanism on how plasma-activated nitrogen-fragments can be utilized as nitrogen precursor in group III-nitride MOCVD. The here assessed growth process parameter focus on the reactor pressure, substrate temperature and composition of plasma generated reactive species.

9571-26, Session 6

Quantum barrier thickness study on blue InGaN LED optical performance using Sentaurus

Karunavani Sarukunaselan, Vithyacharan Retnasamy, Zaliman Sauli, Mukhzeer Mohamad Shahimin, Steven Taniselass, Sarveshvaran Suppiah, Kamarudin Hussin, Univ. Malaysia Perlis (Malaysia)

Blue InGaN LEDs have a drawback whereby it suffers from efficiency droop at high current injection levels. One of the major factors of this droop behaviour is contributed by electron leakage. The aim of this study is to suppress electron leakage in the device by understanding how barrier thickness affects the carrier distribution in the device as well as the device performances. Simulation results obtained showed that thinner barrier increased the device's efficiency since there was better electron confinement and tunnelling effect.

Conference 9572: Nonimaging Optics: Efficient Design for Illumination and Solar Concentration XII

SPIE. OPTICS+ PHOTONICS OPTICAL ENGINEERING+ APPLICATIONS

Sunday - Monday 9 –10 August 2015

Part of Proceedings of SPIE Vol. 9572 Nonimaging Optics: Efficient Design for Illumination and Solar Concentration XII

9572-1, Session 1

String method of nonimaging optics from a radiation theory perspective

Benaz Colabewala, Roland Winston, Lun Jiang, Univ. of California, Merced (United States)

String method of Nonimaging Optics from a Radiation Theory Perspective

9572-2, Session 1

Asymmetric design for compound elliptical concentrators (CEC)

Lun Jiang, Roland Winston, Univ. of California, Merced (United States)

It has been known that asymmetric design for nonimaging concentrators can be realized by the string method for infinitely far away source. In this paper we present and prove that the string method can also be used for a finite source and any convex absorber even when it is positioned asymmetrically. This prompts the question of whether there exists an ideal concentrator for any source-absorber pair naturally. This also produces the curious question of whether the SMS method can be implemented for asymmetric cases.

9572-3, Session 1

All fiber actively mode-locked fiber laser emitting cylindrical vector beam

Yong Zhou, An-Ting Wang, Chun Gu, Lixin Xu, Hai Ming, Univ. of Science and Technology of China (China)

We demonstrated an all fiber actively mode-locked pulse laser emitting cylindrical vector beam. A few-mode fiber Bragg grating is adopted to achieve mode selecting and spectrum filtering. An offset splicing of single mode fiber with four mode fiber is utilized as a mode coupler in the laser cavity. A LiNbO3 Mach-Zehnder modulator , which is controlled by an electric signal, is utilized to achieve active mode locking in the laser cavity. The laser emits mode-locked pulses with 1-ns duration and 12.06 MHz repetition and operates at 1547nm with 30 dB spectrum width of 0.3nm. We built a mechanical polarization controller in the laser cavity to adjust the polarization in the laser cavity, both radially and azimuthally polarized beams have been obtained with with very good modal symmetry. An optical circulator is utilized in the ring fiber laser to connect with the few-mode fiber Bragg grating and ensure unidirectional propagation of the light.

9572-4, Session 1

Improved and customized secondary optics for solar concentrators

Daniel Vázquez, Antonio A. Fernandez-Balbuena, Univ. Complutense de Madrid (Spain); Angel Garcia-Botella, Univ. Politécnica de Madrid (Spain); Javier Alda, Univ. Complutense de Madrid (Spain)

In this contribution the line flow method is applied to an optimized secondary optics in a photovoltaic concentration system where the primary optics is already defined and characterized. This method is a particular application of photic field theory. This method uses the parameterization of a given primary optics, including actual tolerances of the manufacturing process. The design of the secondary optics is constrained by the selection of primary optics and maximizes the concentration at a previously specified collection area. The geometry of the secondary element is calculated by using a virtual source, which sends light in a first concentration step. This allows us to calculate the line flow for this specific case. This concept allows designing more compact and efficient secondary optics of photovoltaic systems.

9572-5, Session 2

Dielectric totally internally reflecting concentrator structure for vertical bifacial photovoltaic receivers

Elizabeth Thomsen, Matthew Stocks, Andrew W. Blakers, The Australian National Univ. (Australia)

A new dielectric total internal reflective concentrator (DTIRC) design has been developed for use with bifacial photovoltaic cells. The structure incorporates the bifacial cell standing vertically at the base of the structure, immersed in dielectric.

DTIRC structures have several advantages including having no losses at the sidewalls (unlike mirrors), being able to manufacture the entire structure from one material, and being shorter and more compact than comparable compound parabolic concentrator (CPC) structures.

DTIRC structures with single-sided photovoltaic receivers, like CPC structures, are designed using the paths of the edge rays to calculate the sidewalls. If these rays successfully hit the receiver then all rays at lower angles will also hit the receiver.

In a vertical DTIRC structure, it is not just the edge rays which need to be taken into account in designing the structure. Around the bifacial receiver, rays at normal and close to normal incidence are the hardest to totally internally reflect onto the receiver. Once outside the area closest to the receiver, a modification of the maximum concentration method can be used to design the remainder of the sidewalls.

Ray tracing has been performed to confirm that the vertical DTIRC structure concentrates light as expected. The structure gives a lower concentration than a CPC with vertical bifacial receiver, however it is also a shorter structure with more uniform flux distribution over the receiver (leading to lower losses in the photovoltaic receiver).

9572-6, Session 2

Advances in luminescent and microtracking solar concentration *(Invited Paper)*

Noel C. Giebink, The Pennsylvania State Univ. (United States)

Sunlight is a diffuse energy resource and thus all methods of solar energy conversion and use by society share one feature in common – concentration. Optical concentration offers a route to lower the cost of high efficiency photovoltaics, but this typically requires bulky mechanical tracking that is incompatible with rooftop installation and on geometric optics that cannot harvest the diffuse solar component. This talk will focus on recent developments in quasi-static microtracking and luminescent solar

concentration that address these respective challenges.

Whereas étendue conservation limits geometric concentration of diffuse light in a dielectric slab depending on its refractive index to ~5x, luminescent concentration has the potential to reach higher concentration ratio >100x. We are exploring a new opportunity to boost luminescent concentrator performance by photonically controlling the luminescent étendue, leveraging highly directional emission within the framework of nonimaging optics to demonstrate >3x secondary geometric gain that has applications ranging from photovoltaics to scintillator-based radiation detection.

Recent efforts in high efficiency concentrating photovoltaics (CPV) will also be discussed, focusing on a new paradigm that combines microscale solar cells with wide-angle microtracking to enable >200x concentration ratio CPV panels < 1 cm thick that accomplish full-day tracking with < 1 cm lateral translation at fixed latitude tilt. This approach is experimentally validated outdoors for a small-scale panel prototype featuring 3D-printed plastic lenslet arrays and GaAs microcell photovoltaics, representing a step toward the goal of embedded CPV systems that can be integrated on building rooftops in the form factor of standard fixed panel PV.

9572-7, Session 3

Hybrid solar collector using nonimaging optics and photovoltaic components *(Invited Paper)*

Eli Yablonovitch, Gregg Scranton, Univ. of California, Berkeley (United States); Roland Winston, Lun Jiang, Bennett K. Widyolar, Univ. of California, Merced (United States); David Cygan, Alexandr Kozlov, Gas Technology Institute (United States)

The project team of Gas Technology Institute, University of California at Merced (UC-M) and Dr. Eli Yablonovitch of University of California at Berkeley are developing a hybrid solar collector using non-imaging optics and photovoltaic components integrated with particle laden gas as thermal transfer and storage media, to simultaneously generate electricity and high temperature dispatchable heat. The collector uses the spectral selectivity property of Gallium arsenide (GaAs) cells to maximize the exergy output of the system, resulting in an estimated exergy efficiency of 48%. The thermal media is composed of fine particles of high melting point material in an inert gas that increases heat transfer and effectively stores excess heat in hot particles for later on-demand use.

9572-8, Session 3

A new optical concentrator design and analysis for rooftop solar applications

Cheng Zheng, Qiyuan Li, Evatt Hawkes, The Univ. of New South Wales (Australia); Gary Rosengarten, RMIT Univ. (Australia); Robert A. Taylor, The Univ. of New South Wales (Australia)

Nearly one half of our global energy consumption is associated with meeting thermal requirements for buildings and industrial processes. This is a huge market for thermal energy – a market which is currently powered by natural gas. Alternatively, solar energy technology can potentially provide a cleaner and more sustainable way to deliver some of that thermal energy. We propose that compact, roof-integrated solar thermal systems are critically underdeveloped since they represent a viable alternative for providing industrial heat in a diversified energy portfolio. In order to produce high quality thermal energy for industrial processes (e.g. > 200 oC), concentration of sunlight is needed. In order to avoid wind loading issues, low-profile collectors are desirable. In this paper, a linear focus, linear tracking, catadioptric concentrator system is proposed and indoor optical experiments are conducted to validate this design. The performance is analyzed using both optical simulation software (Zemax) and indoor laser experiments. The developed concentrator proposed has a focal distance of < 10cm and relatively high concentration ratio (4.5 ~ 5.9 X). The concentrator is capable of achieving up to 75% optical efficiency (at normal incidence) and operates effectively during the middle 6 hours of a sunny day (e.g. under a global irradiance of 1,000W/m2). Overall, we hope this paper will catalyze dialogue on rooftop solar thermal concentrators with form factors similar to PV panels.

9572-9, Session 3

Self-tracking concentrator based on switchable transparency and rejected-ray recycling

Harry N. Apostoleris, Matteo Chiesa, Masdar Institute of Science & Technology (United Arab Emirates); Marco Stefancich, National Research Council (Italy)

We present a solar concentrator with a reactive tracking mechanism based on light-activated transparency switching. The system is composed of a CPC whose exit aperture contains a solar cell and whose entrance aperture is covered by a transparency switching material (TSM). A lens focuses incident light onto the entrance surface, inducing a localized transparency switch in the TSM, a phenomenon which has been demonstrated in paraffin-silicone composites. The localized switching produces a moving aperture that follows the position of the focal spot, which changes with the variation in the solar angle. Because the entrance surface is mostly reflective, rays rejected by the by the concentrator on first incidence have a high probability of being trapped by a second reflection at the entrance. In this way rejected rays are recycled multiple times through the concentrator, increasing the probability of absorption. This tracking-trapping mechanism essentially rotates the acceptance cone of the concentrator to follow the sun, increasing the effective acceptance angle of the concentrator without the corresponding decrease in concentration required by thermodynamics for a fully static concentrator. By theorectical analysis based on statistical ray optics and rigorous ray-tracing simulation we demonstrate the capabilities and limits of the system in terms of flux concentration and acceptance angle. Preliminary experimental results including proof-of-concept demonstrations of the concentrator and the moving aperture component will be presented.

9572-10, Session 3

Design of a solar collector system formed by a Fresnel lens and a CEC coupled to plastic fibers

Perla M. Viera-Gonzalez, Guillermo E. Sánchez-Guerrero, Daniel E. Ceballos-Herrera, Romeo J. Selvas-Aguilar, Univ. Autónoma de Nuevo León (Mexico)

One of the main challenges for systems based in solar concentrators and plastic optical fibers (POF) is the accuracy needed for the solar tracking. One approach to overcome these requirements is increasing tolerances to angular misalignments by using systems composed by Fresnel lens and compound elliptical concentrators (CEC), however this technique is effective for photovoltaic applications, it is not clear for systems coupled to POF for indoor illumination. On this subject, it is presented a numerical analysis of a solar collector formed by a Fresnel lens combined with a CEC coupled to POF in order to compare its performance under angular misalignments and also to show a trade-off analysis for different Fresnel lens shapes used in the collector system. The description of the Fresnel lenses and its designs are included, in addition to the focal point areas with space and angular distribution profiles considering the optimal alignment with the source and maximum permissible misalignments for each case. For the two systems the coupling between the optical components is analyzed and the total performance is calculated, having as result a comparison between an Imaging and a Nonimaging system for building illumination.

9572-11, Session 4

Experimental flux mapping for linear solar concentrators

Cameron C. Stanley, Ahmad Mojiri, Gary Rosengarten, RMIT Univ. (Australia)

Silicon photovoltaic cells typically convert 15-20% of the incident solar energy into electrical power, with the majority of the remaining energy dissipated as heat. Photovoltaic-thermal (PV/T) solar receivers attempt to utilise this wasted energy and are capable of simultaneously producing both thermal energy and electricity. A fluid flowing adjacent to the photovoltaic cells is used to capture the wasted heat and also actively cool the photovoltaic cells. However, in practice the maximum temperature of the fluid is limited to around 70°C by the direct thermal coupling between the PV cells and the thermal channel, and the dependence of the cells performance on temperature.

We have developed a hybrid PVT receiver for linear concentrating systems, such as parabolic troughs or linear Fresnel mirrors, which utilises spectral beam splitting to thermally decouple the PV cells from the thermal absorber. Incident solar energy is decomposed into different wavelength bands, with wavelengths above 1100nm and less than 700nm absorbed directly as heat whilst the remaining wavelengths are directed to the silicon PV cells. By doing so, we have effectively decoupled the thermal absorber from the PV cells and achieved thermal output temperatures up to 150°C concurrently with electrical conversion efficiency of around 9%.

This work reports on experimental flux mapping performed for the hybrid PVT receiver to determine the optimal receiver design. This was done using a close range radiometry technique together with a swept point-source measurement technique. Radiant flux distribution across the thermal absorber and the photovoltaic cells were measured and are discussed.

9572-12, Session 4

Fundamentally new classes of aplanatic lenses *(Invited Paper)*

Heylal Mashaal, Daniel Feuermann, Jeffrey M. Gordon, Ben-Gurion Univ. of the Negev (Israel)

We identify fundamentally new classes of aplanatic lenses where the focus resides inside the lens. These new aplanatic designs comprise a primary contoured dielectric entry and a secondary contoured profile where the secondary surface can, in general, be mirrored, but, in these pure-dielectric devices, are required to satisfy total internal reflection. We show that, in analogy to their dual-mirror counterparts, these aplanatic lenses engender 8 basic, distinct design categories. Only a minority of categories is found to have the potential to yield viable lenses from realistic materials. Flux concentration of far-field small-angle sources such as the sun and, conversely, narrow-field collimation of wide-angle emitting light sources can approach the thermodynamic limit. Losses due to chromatic aberration are smaller than in conventional lenses of comparable f-number, primarily due to the focus being embedded in the lens. By the same token, exit numerical aperture can be increased by a factor of n (the dielectric's refractive index) - and hence flux concentration can be increased by a factor of n^2 - relative to common lenses where the focus resides outside the lens.

9572-13, Session 4

Design and optical analysis of solar dish and linear secondary concentrator for photovoltaics

Nicholas W. Fette, Arizona State Univ. (United States); Herb Hayden, Tyler Beeney, Chao-han Lin, Southwest Solar Technology, LLC (United States); Zihan Zhang, Exa Corp. (United States)

A high efficiency, commercial scale (54 m2) concentrating solar energy system using high flux photovoltaic cells and a unique concentrator design has been developed, analyzed, and tested. The development for a dish primary concentrator and linear secondary optic was previously reported. In continued technical development, the team has applied new materials for thermal, optical, and mechanical performance; new optical design of primary concentrator for increased flux uniformity under optical aberration; and new workflow and tools for computer aided design, engineering analysis, and manufacture of the dish and secondary optical components. For the secondary optic and cell encapsulant, materials selection is driven by need for thermal stability. As a result, fused silica components with high clarity and low thermal expansion have been manufactured via two processes for comparison: molding and negative machining from off-the-shelf rods. A more stable encapsulant has also been applied to reduce effects of off-gassing that damage TIR surfaces. For the primary concentrator dish, a novel overlay design has been developed, including software to automatically generate a massive number of surfaces for direct import into CAD models. In this approach, multiple mirrors panels attached to a single mirror facet fill the same target area with light, similar to a heliostat system. This overlay design shows potential for reducing flux non-uniformity due to manufacture tolerances, and the implemented design matches the incoming flux in position and angle space to the acceptance profile of the secondary optical array. Operation of the system is ongoing.

9572-14, Session 5

Six-primary laser-phosphor illuminator for cinema projector

Junejei Huang, Yuchang Wang, Delta Electronics, Inc. (Taiwan)

To meet the high performance requirement of cinema projector, a laser-phosphor illuminator with 6 primary colors is proposed. The six primary colors are divided into two groups and include colors of R1, R2, G1, G2, B1 and B2. Colors of B1, B2 and R2 come from lasers of wavelengths 440 nm, 465 nm and 639 nm. A second B1 laser alternately pumps G-phosphor to get G1 and pumps Y-phosphor to get G2 and R1. The illuminator comprises collimating and condensing lenses, green and yellow reflectors, phosphor-wheel and integration rod. The G-phosphor and Y-phosphor are deposited on two rings of the phosphor-wheel. For each phosphor, half ring is occupied and the other half is mirror or transparent. A taper rod is used as integration rod and connected to the illumination path of the projector. Two groups of colors are sequentially switched by the rotation of the phosphor-wheel. Two sequences of three colors are sent to the 3-chip cinema projector and synchronized with frame rate of 120Hz. In 2D mode, six primary colors get a wide color gamut. In 3D mode, two groups of three primary colors provide two groups of images that received by left and right eyes. All lasers in a refrigerator are connected to the lamp module by optical fibers. The lamp module is compact and suitable for retro-fit market. By replacing the conventional UHP lamp in the existing 0.95" DMD 3-chip engine with this lamp module, an equivalent brightness can be achieved both in 3D and 2D mode.

9572-15, Session 5

Efficient color mixing through etendue conservation using freeform optics

Simone Sorgato, Light Prescriptions Innovators Europe, S. L. (Spain) and Vrije Univ. Brussel (Belgium); Julio C. P. Chaves, Rubén Mohedano, Aleksandra Cvetkovic, Maikel Hernandez, Light Prescriptions Innovators Europe, S. L. (Spain); Juan Carlos Miñano, Pablo Benitez, Light Prescriptions Innovators Europe, S. L. (United States); Hugo Thienpont, Brussels Photonics Team, Vrije Univ. Brussel (Belgium); Fabian Duerr, Vrije Univ. Brussel (Belgium)

Today's SSL illumination market shows a clear trend to high flux packages with higher efficiency and higher CRI, realized by means of multiple color chips and phosphors. Such light sources require the optics to provide both near- and far-field color mixing. This design problem is particularly challenging for collimated luminaries, since traditional diffusers cannot be employed without enlarging the exit aperture and reducing brightness. Furthermore, diffusers compromise the light output ratio (efficiency) of the lamps to which they are applied.

A solution, based on Köhler integration, consisting of a spherical cap comprising spherical microlenses on both its interior and exterior sides was presented in 2012. The diameter of this so-called Shell-Mixer was 3 times that of the chip-array footprint, which makes it not fully compatible with luminaires with tight geometrical/mechanical constraints. A new version of the Shell-Mixer, based on Nonimaging Optics principles, where neither the outer shape of the cap nor the surfaces of the lenses are constrained to spheres or 2D Cartesian ovals will be shown in this work. The new shell is free-form, only twice as large as the original chip-array and equals the original model in terms of uniformity and brightness.

9572-16, Session 5

Illumination system design with random optimization

Simon Magarill, William Cassarly, Synopsys, Inc. (United States)

Automatic optimization algorithms can be used when designing illumination systems. Illumination system optimization using merit functions that are adjusted to match a given design setup can provide improved system performance. For systems with many design variables, we present a multi-step optimization process method. At each step, different variables and/or merit functions are used. We have found that this approach can sometimes leads to more efficient solutions. In this paper we illustrate the effectiveness of a multi-step approach using several different examples.

9572-17, Session 5

Light extraction method for mixing rods based in grooves with elliptical shape

Guillermo E. Sánchez-Guerrero, Perla M. Viera-González, Daniel E. Ceballos-Herrera, Romeo J. Selvas-Aguilar, Univ. Autónoma de Nuevo León (Mexico)

Homogenize light is the principal purpose of mixing rods. Light extraction from mixing rods is proposed by changing the shape of the face, the rod or a combination of both for many applications. Light extraction also can be done by its lateral face by cutting the Mixing rod. In this work a simulation of square and hexagonal poly(methyl methacrylate) (PMMA) mixing rods were made in Zemax® OpticStudio designed with an elliptical transversal cut to extract light from a lateral face. The cut is specular for rays that fulfill the total internal reflection condition, the reflected rays are deviated and the Total Internal Reflection (TIR) condition broken, then, extracted. An advantage of this cut is that it can be controlled in depth to extract the amount of light required and the remaining light used for other purposes. Also it can reduce the size of the mixing rods and optical components. For the simulation an LED light were used as source, the light were homogenized by the mixing rod and due to it, the light extracted is also homogenous. The candela map, radiant intensity and color of the light extracted are presented and compared in both mixing rods.

9572-18, Session 5

Etendue-squeezing light injector

Julio C. Chaves, Simone Sorgato, Light Prescriptions Innovators Europe, S. L. (Spain); Pablo Benitez, Juan Carlos Miñano, Light Prescriptions Innovators, LLC (United States) and Univ. Politécnica de Madrid (Spain); Waqidi Falicoff, Light Prescriptions Innovators, LLC (United States); Ruben Mohedano, Light Prescriptions Innovators Europe, S. L. (Spain)

There is a need to make portable devices, such as smartphones or tablets, thin and light weight. All components in these devices need to be small and closely packed, and this is also true of backlights, one of the largest components in these devices. Very thin backlights, however, may lead to situations in which the backlight is thinner than the LED illuminating it, leading to a need to inject light from a relatively large LED into a thin light guide. This cannot be done by simply placing the LED next to the light guide, as a considerable amount of light would be lost. There is, therefore, the need for a coupling optic between LED and light guide.

For a horizontal light guide, one possible way to achieve a good coupling is by dividing the LED emitter horizontally into several sections, each of which is the same height as the thickness of the light guide. Then, an optic is designed to bring the light emitted from these different LED sections to the same height as the light guide. This is achieved in a two-step process in which the light from each LED section is first shifted sideways and then shifted up or down to bring it to the same level as the light guide. This process is called etendue squeezing and it transforms a tall LED light source into a wide but thin light source, whose height matches the thickness of the light guide, making the optical coupling possible.

9572-19, Session 6

Design of diffractive optical surfaces within the SMS design method *(Invited Paper)*

João Mendes-Lopes, Pablo Benítez, Juan Carlos Miñano, Univ. Politécnica de Madrid (Spain)

The Simultaneous Multiple Surfaces (SMS) was developed as a design method in Nonimaging Optics during the 90s. Later, the method was extended for designing Imaging Optics. The SMS method involves the simultaneous calculation of N optical surfaces (refractive or reflective) using N one-parameter wavefronts for which specific conditions are imposed. The relationship between degrees of freedom (N optical surfaces) and constrains (N wavefronts) is not exactly one to one. For simplicity in our explanation we will consider that it is so. When designing an nonimaging optical system, these conditions comprise coupling of every one of these N wavefronts to other wavefronts with prescribed conditons.

This paper shows an extension of the SMS method to diffractive surfaces. Using this method, diffractive kinoform surfaces are calculated simultaneously and through a direct method, i. e. it is not based in multi-parametric optimization techniques. Using the phase-shift properties of diffractive surfaces as an extra degree of freedom, only N/2 surfaces are needed to perfectly couple N one parameter wavefronts. Wavefronts of different wavelengths can also be coupled, hence chromatic aberration can be corrected in SMS-based systems. This method can be used by combining and calculating simultaneously both reflective, refractive and diffractive surfaces, through direct calculation of phase and refractive/reflective profiles. Representative diffractive systems designed by the SMS method are presented.

9572-20, Session 6

Exact wavefront surface refracted by a smooth arbitrary surface considering a plane wavefront incident

Maximino M. Avendaño-Alejo, Univ. Nacional Autónoma de México (Mexico)

We study the formation of wavefront produced by smooth arbitrary surfaces with symmetry of revolution considering a plane wavefront propagating parallel to the optical axis and impinging on the refracting surface. The

wavefronts are obtained by using the Huygens' principle; we have already seen that the shape of the caustic and wavefront surfaces are related through Malus-Dupin theorem and they represent the monochromatic aberrations which can be called image errors, furthermore their shapes could be modified by changing the parameters of the lens in such a way that if a caustic surface is vanished the optical system produces a perfect image, on the other hand for a caustic possessing a large area it could be applied to design no-imaging optical systems. The shape of the wavefront depends only on the indices of refraction and geometrical properties of the refracting surface such as the first and second derivatives. This analytic formula has potential applications in the microscopy field, illumination or corrector plates.

9572-21, Session 6

Freeform aplanatic concentrators

Bharathwaj Narasimhan, Pablo Benitez, Dejan Grabovickic, Juan Carlos Miñano, Milena I. Nikolic, Jose M. Infante Herrero, Univ. Politécnica de Madrid (Spain)

Axisymmetric aplanatic concentrators have been used in the past for solar concentrators and condensers (Gordon et. al, 2004; Winston et. al, 2012). It is well know that such a system must be stigmatic and satisfy the Abbe sine condition. This problem is well known (Schwartlitz, 1906) to be solvable with two aspherics when the system has rotational symmetry.

However, some of those axisymmetric solution have intrinsically shading losses when using mirrors, which can be prevented if freeform optical surfaces are used (Benitez, 2007).

In this paper, we explore the design of freeform surfaces to obtain full aplanatic systems. Here we prove that a rigorous solution to the general non-symmetric problem needs at least three free form surfaces, which are solutions of a system of partial differential equations (PDE). We present here that the solutions of the said system of PDE can be found using optimization. The merit function for such an optimization includes the spatial and angular deviation of the rays from the target rays according to the aplanatic condition. Therefore, the value of the merit function at the "exact" solution will be zero. The examples considered have one plane of symmetry, where a consistent 2D solution is used as a boundary condition for the 3D problem. We have used the x-y polynomial representations for all the surfaces, and the optimization has shown very fast convergence. As an example, an aplanatic freeform concentrator compose by two mirrors and a single-sided lens is shown.

9572-22, Session 6

Freeform reflector construction by ray mapping method in modified double pole coordinate system

Donglin Ma, Zexin Feng, Rongguang Liang, College of Optical Sciences, The Univ. of Arizona (United States)

With the broad application of freeform optics in the field of LED illumination engineering, people have developed various kinds of methods to design freeform reflectors. These methodologies include supporting ellipsoids, trial and error approaches, simultaneous multiple surfaces (SMS) method solving corresponding Monge-Ampere equation, and geometrical ray mapping method and so on. The main drawback for the trial and error method is too much computing time required due to the costly ray tracing techniques. The method of supporting ellipsoids also requires of a number of optimization steps and iterations for the generation of each ellipsoid, which is also very time consuming. The SMS method usually requires at least one pair of surfaces and is not suitable to design the reflector with only one single surface. For the Monge-Ampere method, the derivation and solving of the partial differential equation is very tedious and time consuming. In a word, among all of these methods the geometrical ray mapping method is the most efficient in freeform optics design. However, this method cannot guarantee that the derived freeform surface can satisfy the integrability condition. Therefore, the key task is to find a diffeomorphism ("ray mapping") so that the transformed irradiance distribution matches the design target and the constructed surface satisfies the so called integrability condition. In this presentation, we will introduce a new ray mapping method to sample the source's intensity distribution in the modified double pole coordinate system to realize the "perfect" match between the source and target.

9572-23, Session 6

Diffraction effects in freeform optics

Melissa N. Ricketts, Roland Winston, Univ. of California, Merced (United States); Vladimir I. Oliker, Emory Univ. (United States)

Freeform optics is a relatively new field that addresses the methods necessary to describe surfaces lacking symmetry, and/or surfaces that create non-symmetrical irradiance distributions. The Supporting Quadrics Method (SQM) developed by Oliker uses envelopes of quadrics to create prescribed irradiance distributions. These optical systems are tested in ray trace software, which does not take into account diffraction effects. It is important to understand what diffraction effects are present when moving from the ray trace stage to the prototype stage. Here we study the diffraction effects of Supporting Quadrics Method.

9572-24, Session PMon

Development of daylighting systems with non-imaging concentrator

Seoyong Shin, Myongji Univ. (Korea, Republic of)

Recently, it is found that more consideration has been given to the interaction between energy, buildings, and the environment. As buildings are the main source of energy use and greenhouse gas emissions, daylighting serves for both to improve indoor environment as well as to save energy utilization in buildings. Fiber-based daylighting systems have been shown to be a promising and e?ective way to transmit sunlight in the interior space. To increase efficiency, the current need is to illuminate optical fibers with uniform light flux so that uniform light can be delivered in the interior of the building. We propose a method for achieving uniform illumination over the fiber-bundle and distributing uniform light in the interior. Light is collected through a concentrator and focused toward a collimating device, which inserts the light over the trough compound parabolic concentrator to illuminate array of optical fibers with uniform light flux. An optics diffusing structure, which includes a combination of lenses to achieve high average illuminance and illuminance uniformity, is utilized to spread the light in the interior. The results clearly reveal that the efficiency in terms of uniform illumination, which also reduces the heat problem for optical fibers, is improved. Furthermore, a comparison study is conducted between current and previous approaches. Finally, the proposed daylighting system turns out convenient in terms of energy saving and reduction in greenhouse gas emissions.

9572-25, Session PMon

Day lightening system with fibre optics using non imaging concentrator

Shivaji B. Sadale, Pratika G. Patil, Sanskruti J. Powar, Madhavi N. Nikam, Shivaji Univ. (India)

Energy crisis is one of the biggest challenges before mankind. The electric lightening for domestic and industrial use is a major portion of the total energy demand. On a normal bright day usually there is excess intensity of light outdoors but in large building still there is a need of lightening. We have investigated the indoor day lightening with solar light using fiber optics. The outdoor sunlight can be used to provide light inside the building during daytime. Day light is always in superior to artificial light for everyday tasks. We have developed an effective day lighting device comprising a concentrator and optical fiber with a view to harness maximum solar lighting, eliminate the dark area lighting problem in various domestic as well as commercial building. The concentrator has been designed using non imaging techniques particularly edge ray principle. We have studied the concentration of light outdoor with our device and transport of light from outdoor to the interiors of the building through optical fiber cable. The rays falling on the device are reflected and then focused at one end of optical fiber. The intensity of light is measured for visibility, and losses.

9573-4, Session PMon

Aligning and measuring the curvature and thickness of high-precision lens

Kun-Huan Wu, Shenq-Tsong Chang, Ming-Ying Hsu, Ting-Ming Huang, Wei-Yao Hsu, Shih-Feng Tseng, Instrument Technology Research Ctr. (Taiwan)

The radius of curvature is one of the most important specifications for spherical optics. There are several methods and devices currently on the market that can be used to measure it, including optical level, non-contact laser interferometer (Interferometer), a probe-contact profiler (Profilometer), the centering machine and three-point contact ball diameter meter (Spherometer). The amount that can be measured with a radius of curvature of the lens aperture range depends on the interferometer standard lens f / number and lens of R / number (radius of curvature divided by the clear aperture of the spherical surface ratio between them). Unfortunately, for lens with diameter greater than 300 mm, the device is limited by the size of the holding fixture lenses or space. This paper aims to provide a novel surface contour detection method and machine, named "CMM spherometry by probe compensation," to measure the radius and thickness of the curvature of the optical surface by a coordinate measurement machine (CMM). In order to obtain more accurate optimization results, we used probe and temperature compensation to discuss the effect. The trace samples and the measurement results of CMM and the centering machine, which has top and bottom autocollimators, are compared.

9573-30, Session PMon

Analysis investigation of supporting and restraint conditions on the surface deformation of a collimator primary mirror

Chia-Yen Chan, Instrument Technology Research Ctr. (Taiwan); Zhen-Ting You, Bo-Kai Huang, Yi-Cheng Chen, National Central Univ. (Taiwan); Ting-Ming Huang, Instrument Technology Research Ctr. (Taiwan)

For meeting the requirements of the high-precision telescopes, the design of collimator is essential. The diameter of the collimator should be larger than that of the target for the using of alignment. Special supporting structures are demanded to reduce the deformation of gravity and to control the surface deformation induced by the mounting force when inspecting large-aperture primary mirrors.

9573-31, Session PMon

Development of 1-m primary mirror for a spaceborne camera

Hagyong Kihm, Korea Research Institute of Standards and Science (Korea, Republic of)

We present the development of a 1-m lightweight mirror system for a spaceborne electro-optical camera. The mirror design was optimized to satisfy the performance requirements under launch loads and space environment. The mirror made of Zerodur® has pockets at the back surface and three square bosses at the rim. Metallic bipod flexures support the mirror at the bosses and adjust the mirror's surface distortion due to gravity. We also show an analytical formulation of the bipod flexure, where compliance and stiffness matrices of the bipod flexure are derived to estimate theoretical performance and to make initial design guidelines. Optomechanical performaces such as surface distortions due to gravity, assembly, isothermal loads, and moisture absorption are explained. Environmental verification of the mirror is achieved by vibration and thermal vacuum tests.

9573-1, Session 1

ICESat-2 ATLAS telescope testing and integration

Tyler C. Evans, SGT, Inc. (United States)

Many lessons were learned in the comprehensive testing of the one meter Beryllium flight telescope for the ICESat-2 mission. This paper will focus on testing areas of encircled energy analysis and boresight alignment of fiber optic cables. Several tests were able to be performed on the telescope itself, helping drive down risk, cost, and schedule during the integration phase of the telescope onto the instrument and box structure. The main ICESat-2 instrument is the Advanced Topographic Laser Altimeter System (ATLAS). It measures ice elevation by transmitting laser pulses, and collecting the reflection in a telescope. Because so few photons return from each pulse, the alignment of each receiver channel fiber is critical as well as minimizing the distortion.

A one meter parabola collimator system with a point source fiber-coupled 532nm laser and a CCD detector was used to feed collimated light into the telescope that was recorded with a CCD detector in the telescope focal plane. Fiber optic cables were also used to back-illuminate the telescope and image in the collimator focal plane. The telescope was mounted in a gimbal that allowed for three degrees of rotational freedom allowing the telescope to be steered to each respective science field point. The setup worked well for accomplishing the testing. Through well written procedures and prior experience, the testing was carried out according to plan and on schedule despite obstacles along the way such as late ground support equipment and tests that needed to be repeated.

9573-2, Session 1

In-situ mitigation of radiation-induced attenuation in optical fiber used for sensing at nuclear facilities

Reinhold Povilaitis, Keith E. Holbert, Arizona State Univ. (United States)

Modern high-bandwidth fiber optics are good candidates for use in sensing applications at nuclear waste facilities and generating stations. Though many exhibit good radiation hardness, radiation-induced attenuation may represent a significant challenge in maintaining signal quality over the operational lifetime of such sensing systems. Use of higher power light sources at operational wavelengths has been shown to reduce transmission loss caused by radiation.

Tests by Holbert et al. to determine radiation-induced attenuation (RIA) of fiber optics at 850 nm subjected to 0.8 and 7 Mrad of gamma radiation have been extended to assess the extent to which the RIA may be mitigated. Cable sections approximately 85 m in length are irradiated up to a total dose of 2-3 Mrad at room temperature. Optical power measurements are logged by a fiber optic sensor module by way of a 1 ?W LED light source. After absorbing the desired dose the cables are removed from the radiation environment and allowed to anneal at room temperature for >24 hours. Photobleaching is accomplished using the same 850 nm light source used for measuring attenuation. The intensity of the LED light source is incrementally increased to a max output of 1 mW while transmission loss recovery is recorded. We seek to determine the optimum light intensity and treatment interval for in-situ healing as well as the periodicity for ensuring that attenuation remains manageable without intolerable degradation of the fiber optic cable due to the episodic application of this RIA mitigation strategy.

9573-3, Session 1

ZERODUR(R): new stress corrosion data improve strength fatigue prediction

Peter Hartmann, SCHOTT AG (Germany); Günter Kleer, Fraunhofer-Institut für Werkstoffmechanik (Germany)

The extremely low thermal expansion glass ceramic ZERODUR® finds more and more applications as sophisticated light weight structures with thin ribs or as thin shells. Quite often they will be subject to higher mechanical loads such as rocket launches or modulating wobbling vibrations. Designing such structures requires calculation methods and data taking into account their long term fatigue. With brittle materials fatigue is not only given by the material itself but to a high extent also by its surface condition and the environmental media especially humidity. This work extends the new data and information gathered on the bending strength of ZERODUR® with new results concerning its long term behavior under tensile stress.

The parameter needed for prediction calculations which combines the influences of time and environmental media is the stress corrosion constant n. Results from the past differ significantly from each other. In order to obtain more reliable data the stress corrosion constant has been measured with the method comparing the breakage statistical distributions at different stress increase rates. For better significance the stress increase rate was varied over four orders of magnitude from 0.004 MPa/s to 40 MPa/s. Experiments were performed under normal humidity for long term earth bound applications and under nitrogen atmosphere as equivalent to dry environment occurring for example with telescopes in deserts and also equivalent to vacuum for space applications.

As shown earlier diamond ground surfaces of ZERODUR® can be represented with a three parameter Weibull distribution. Predictions on the long term strength change of ZERODUR® structures under tensile stress are possible with reduced uncertainty if Weibull threshold strength values are considered and better reliable stress corrosion constant data are applied.

9573-5, Session 1

Effect of major factors on damage threshold of optical rectification crystals

Qinglong Meng, Zhuolin Su, Junli Yu, Bin Zhang, Sichuan Univ. (China)

The crystal material would be damaged under the high-power femtosecond laser radiation during the generation of terahertz in optical rectification, limiting the further increase of the generation efficiency of terahertz radiation. It remains a big challenge to theoretically predict the material removal mechanism in femtosecond laser damage. In this paper, the prediction model of crystal damage threshold under femtosecond laser based on the two-temperature model has been built up. On the basis, the influence of the major parameters of the femtosecond laser on the damage threshold has been analyzed quantitatively. For comparison, the experimental results have also been presented. The results show that, for the given peak power density of femtosecond laser, the damage threshold of the optical rectification crystal increases with the increasing of pulses duration for the case of the relatively small pulse duration, whereas decreases for the case of the relatively large pulse duration. The experimental results are consistent quite well with the theoretical results.

9573-6, Session 2

Optomechanical performance of 3D-printed mirrors with embedded cooling channels and substructures

Joni Mici, Paul Zorabedian, Saatyan S. Zalawadia, David M. Stubbs, Lockheed Martin Space Systems Co. (United States)

Advances in additive manufacturing increasingly allow for manufacture of topologically complex parts not otherwise feasible through conventional manufacturing methods. Maturing metal and ceramic additive manufacturing technologies are becoming more adept at printing topologically complex mirror substrates. Reflective optics used in high energy laser (HEL) systems require materials with low coefficient of thermal expansion (CTE), high specific stiffness, and most importantly high thermal conductivity to effectively dissipate heat from the optical surface. Currently, the limits of conventional manufacturing dictate the topology of HEL optics to be monolithic structures which rely on passive cooling mechanisms and high reflectivity coatings to withstand laser damage. Additive manufacturing enables the printing of embedded cooling channels in metallic mirror substrates to allow for (1) active cooling and (2) tunable cooling. This paper analyzes the performance improvement possibilities of HEL mirrors with embedded cooling channels using finite element methods and analytical approximations.

9573-7, Session 2

Extended volume and surface scatterometer for characterization of 3D-printed optical elements

Florian Dannenberg, Cornelius F. Hahlweg, bbw Hochschule (Germany)

The use of 3d printing technology seems to be a promising way for low cost prototyping of optical components or systems. It is especially useful in applications where customized equipment repeatedly is subject to immediate destruction, as in experimental detonics and the like. Due to the nature of the 3d printing process, there is a certain inner texture and therefore inhomogeneous optical behaviour to be taken into account. Recent investigations are dedicated to quantification of optical properties of such printed bodies and derivation of corresponding optimization strategies for the prinitng process. Beside mounting and alignment means, also refractive and reflective elements are subject to investigation. The measurements are based on an imaging nearfield scatterometer for combined volume and surface scatter measurements as proposed in previous papers. The device has been extended for observation of photoelasticity effects and therefore homogeneity of polarization behaviour. Such optical properties are of interest not only for light guiding elements, but also for mounts and other supporting parts, which have to be characterized regarding to their absorption and scatter behaviour. Practical examples from current research studies are included.

9573-8, Session 2

Fabrication of light-weighted 3D-printed mirrors

Harrison Herzog, Richard Bates, Alyssa De La Torre, Jacob Calis, Jacob Segal, Jeremy Smith, The Univ. of Arizona (United States)

Direct Metal Laser Sintering (DMLS) and Electron Beam Melting (EBM) 3D printing technologies are being utilized to create lightweight, optical grade mirrors out of AlSi10Mg aluminum and Ti6Al4V titanium alloys at the University of Arizona. The mirror prototypes are polished to meet the ?/20 RMS and ?/4 P-V visible optical requirements.

The senior interdisciplinary design team is comprised of six University of Arizona engineering students that within three different major disciplines. The students are tasked to design a mirror that is fully optimized for low mass and maximum stiffness, using topological optimization algorithms. The mirror must endure the polishing process with the necessary stiffness to eliminate print-through. The challenge for the team is to reduce porosity within the 3D printed mirror and determine the best polishing methods to meet the optical requirements. The prototypes will undergo hot isostatic press (HIP) and heat treatment to improve density, eliminate porosity, and relieve stress.

Metal 3D printing allows for nearly unlimited constraints on design and eliminates the need for a machine shop when creating an optical mirror. This research can lead to an increase in mirror mounting support complexity in the manufacturing of lightweight mirrors and improve specific properties of the mirror substrate. Additionally, the project aspires to have many future applications of light-weighted 3D printed mirrors, such as spaceflight.

This paper covers the design/fab/polish/test of the 3D printed mirrors, the thermal/structural finite element analysis, and the results.

9573-9, Session 2

3D-additive manufactured optical mount

Paul V. Mammini, Lockheed Martin Space Systems Co. (United States); David Ciscel, John Wooten, CalRAM Inc. (United States)

The Area Defense Anti-Munitions (ADAM) is a low cost and effective high power laser weapon system. It's designed to address and negate important threats such as short-range rockets, UAVs, and small boats. Many critical optical components operate in the system. The optics and mounts must accommodate thermal and mechanical stresses, plus maintain an exceptional wavefront during operation.

Lockheed Martin Space Systems Company (LMSSC) developed, designed, and currently operates ADAM.

This paper covers the design and development of a key monolithic, flexured titanium mirror mount that was manufactured by CalRAM using additive processes.

9573-10, Session 3

Leveraging semiconductor lithography technology for projection lens applications *(Invited Paper)*

Brian M. McMaster, Corning Tropel Corp. (United States)

The materials, tooling and processing developed for lithograph lenses is now being applied to commercial high power projection lenses after decades of technology development. These technologies include lens suspensions, adhesives and alignments. Lens suspension techniques for low stress & large temperature ranges will be presented as well as the unique adhesives used. A discussion of different methods of individual lens alignments of individual components, lens stacks and the technology selection for positioning of multiple moving lens groups motion will be reviewed. Finally, an overview how some of these technologies were selected by using DFMA.

9573-11, Session 3

Elliptically framed tip-tilt mirror optimized for stellar tracking

James H. Clark III, U.S. Naval Research Lab. (United States); F. Ernesto Penado, Jeremy Petak, Northern Arizona Univ. (United States)

We compare a design innovation of an elliptically framed tip-tilt optical tracker with an existing circularly framed tracker for the Navy Precision Optical Interferometer. The tracker stabilizes a 12.5 cm stellar beam on a target hundreds of meters away and requires an increase in operational frequency. We reduced mass and size by integrating an elliptical mirror as one of the rotating components, which eliminated a rotating frame. We used the same materials as the existing tracker; however, light-weighted both the aluminum frame and Zerodur® mirror. We generated a computer-aided design, converted it into a finite element model, and performed modal analysis on two load cases. In load case 1, we tied down three points on the bottom surface of the tracker that correspond to the tie-down points of the comparison tracker. This reveals a first mode of frequency of 140 Hz, a factor of two over the current tracker's first mode of frequency of 67 Hz. In load case 2, we tied down the four corners of the tracker base in addition to the three tie-down points, simulating a firmly bolted and secured mount. The first mode of vibration for this case is 203 Hz, an increase over load case 1 by a factor of 1.45 and more than three times the fundamental frequency of the existing tracker. We conclude that these geometrical changes with the additional tie-down bolts are a viable solution path forward to improve steering speed and recommend a continuation with this effort.

9573-12, Session 3

Contamination and UV lasers: lessons learned

John G. Daly, Vector Engineering (United States)

Laser Induced damage to optical elements has been a subject of significant research, development, and improvement, since the first lasers were built over the last 50 years. Better materials, with less absorption, impurities, and defects are available, as well as surface coatings with higher laser damage resistance. However, the presence of contamination (particles, surface deposition films, or airborne) can reduce the threshold for damage by several orders of magnitude. A brief review of the anticipated laser energy levels for damage free operation is presented as a lead into the problems associated with contamination for ultraviolet (UV) laser systems. As UV lasers become more common in applications especially in areas such as lithography, these problems have been costly. This has been characterized as Airborne Molecular Contamination (AMC) in many published reports. Normal engineering guidelines such as screening materials within the optical compartment for low outgassing levels is the first step. The use of the NASA outgassing database (or similar test methods) with low Total Mass Loss (TML) and Collected Volatile Condensable Materials (CVCM) is a good baseline. Energetic UV photons are capable of chemical bond scission and interaction with surface contaminant or airborne materials results in deposition of obscuring film laser footprints that continue to degrade laser system performance. Laser systems with average powers less than 5 mW exhibit aggressive degradation. Lessons learned over the past 15 years with UV laser contamination and steps to reduce risk will be presented.

9573-13, Session 4

Criteria to asses production readiness of complex optical systems *(Keynote Presentation)*

Anees Ahmad, Nathan Tenney, Raytheon Missile Systems (United States)

The product development cycle consists of many phases with increasing levels of design and production maturity. These days there is a much greater emphasis on affordability and producibility of complex space and military systems because of the reduced budgets. Therefore, it is important to evaluate the production readiness of complex systems to ensure smooth transition to the production phase. NASA and Department of Defense commonly use the Technology Readiness Levels (TRLs) and the Engineering Manufacturing Readiness Levels (EMRLs) to determine the technical maturity and production readiness of complex systems at various stages of development.

The EMRL assessment is a good method of concisely and effectively assessing and communicating the degree to which a product is producible, reliable, and affordable. It is objective measure of product or program maturity and progress during design, development, and production phases. The EMRLs capture the knowledge required to successfully transition from technology development phase to the engineering manufacturing development and into production phase with minimal risk. The EMRLs consist of six levels (0-5) and twenty criteria and metrics including such items as technology, engineering, manufacturing, quality, reliability, test, logistics, safety, contracts, funding, and cost. Each EMRL is matched to an established product development milestone or gate and provides a concise, easy to use metric of product maturity against the maturity required for

the desired milestone. The EMRLs have proven to be effective and efficient in measuring product maturity and readiness for transition from one phase to the next. A system must be able to satisfy EMRL-4 criteria before it is deemed to be ready for full rate production. This presentation will describe the level of system's maturity required for each of the 20 EMRL-4 criteria before it is deemed ready for full rate production.

9573-14, Session 5

Cost-optimized methods extending the solution space of lightweight spaceborne monolithic ZERODUR(R) mirrors to larger sizes

Antoine Leys, SCHOTT AG (Germany); Tony B. Hull, The Univ. of New Mexico (United States); Thomas Westerhoff, SCHOTT AG (Germany)

We address the problem that larger spaceborne mirrors require greater sectional thickness to achieve a sufficient first eigenfrequency that is resilient to launch loads, and to be stable during optical telescope assembly integration and test, this added thickness results in unacceptable added mass if we simply scale up solutions for smaller mirrors. Special features, like cathedral ribs, arch, chamfers, and back-side following the contour of the mirror face have been considered for these studies. For computational efficiency, we have conducted detailed analysis on various configurations of a 800 mm hexagonal segment and of a 1.2-m mirror, in a manner that they can be constrained by manufacturing parameters as would be a 4-m mirror. Furthermore each model considered also has been constrained by cost-effective machining practice as defined in the SCHOTT Mainz factory. Analysis on variants of this 1.2-m mirror has shown an optimal configuration. We have then scaled this optimal configuration to 4-m aperture. We discuss resulting parameters of cost-optimized 4-m mirrors. We also discuss the advantages and disadvantages this analysis reveals of going to cathedral rib architecture on 1-m class mirror substrates.

9573-15, Session 5

Selection considerations between ZERODUR and silicon carbide for dimensionally-stable spaceborne optical telescopes in low-earth-orbit

Tony B. Hull, The Univ. of New Mexico (United States); Antoine Leys, Thomas Westerhoff, SCHOTT AG (Germany)

A principal consideration for spaceborne optical telescope assemblies is material dimensional stability under realistic varying thermal boundary conditions. Candidate materials for spaceborne mirrors fall into two groups, those with low coefficient of thermal expansion and low thermal diffusivity, and those with high coefficient of thermal expansion and high thermal diffusivity. An example of the former is ZERODUR® and of the latter is Silicon Carbide (SiC). Cases are analyzed comparing how examples of ZERODUR® based systems and SiC based systems will distort as each system is exposed to thermal stimuli varying in both direction and amplitude. Such time domain thermal variation is typical of low-earth-orbit surveillance platforms, where not only view factors relative to the sun and earth change considerably in short time intervals, but also the location-specific thermal attributes of the earth below may enter the optical telescope assembly. The thermal figures-of-merit are minimal distortion of the optics, and minimal perturbations of the six-degree-of-freedom solid body alignments between mirrors, focal plane and pointing systems. Factors of selection other than thermal are considered, including optical finishing, heritage, stiffness and mass, ground testing, driven complexity of the system, cost and schedule.

9573-16, Session 5

Evolving design criteria for very large aperture space-based telescopes and their influence on the need for intergrated tools in the optimization process

William R. Arnold Sr., NASA Marshall Space Flight Ctr. (United States)

NASA's Advanced Mirror Technology Development (AMTD) program has been developing the means to design and build the future generations of space based telescopes. With the nearing completion of the James Webb Space Telescope (JWST), the astrophysics community is already starting to define the requirements for follow on observatories. The restrictions of available launch vehicles and the possibilities of planned future vehicles have fueled the competition between monolithic primaries (with better optical quality) and segmented primaries (with larger apertures, but with diffraction, costs and figure control issues). Regardless of the current shroud sizes and lift capacities, these competing architectures share the need for rapid design tools. As part of the AMTD program a number of tools have been developed and tested to speed up the design process. Starting with the Arnold Mirror Modeler (which creates Finite Element Models (FEM) for structural analysis) and now also feeds these models into thermal stability analyses. They share common file formats and interchangeable results. During the development of the program, numerous trade studies were created for 4 meter and 8 meter monolithic primaries, complete with support systems. Evaluation of these results has led to a better understanding of how the specification drives the results. This paper will show some of the early trade studies for typical specification requirements such as lowest mirror bending frequency and suspension system lowest frequency. The results use representative allowable stress values for each mirror substrate material and construction method and generic material properties. These studies lead to some interesting relationships between feasible designs and the realities of actually trying to build these mirrors. Much of the traditional specifications were developed for much smaller systems, where the mass and volume of the primary where a small portion of the overall satellite. JWST shows us that as the aperture grows, the primary takes up the majority of the mass and volume and the established rules need to be adjusted. For example, a small change in lowest frequency requirement can change the cost by millions of dollars.

The paper uses numerous trade studies created during the software development phase of the Arnold Mirror Modeler to illustrate the influences of system specifications on the design space. The future telescopes will require better performance, stability and documented feasibility to meet the hurdles of today's budget and schedules realities. AMTD is developing the tools, but the basic system planning mentality also has to adopt to the requirements of these very large and complex physical structures.

9573-17, Session 5

Recent updates to the Arnold Mirror Modeler and integration into the evolving NASA overall design system for large space-based optical systems

William R. Arnold Sr., NASA Marshall Space Flight Ctr. (United States)

Since last year, a number of expanded capabilities have been added to the modeler. The support the integration with thermal modeling, the program can now produce simplified thermal models with the same geometric parameters as the more detailed dynamic and even more refined stress models. The local mesh refinement and mesh improvement tools have been expanded and more user friendly.

The goal is to provide a means of evaluating both monolithic and segmented mirrors to the same level of fidelity and loading conditions at reasonable man-power efforts. The paper will demonstrate most of these new capabilities.

9573-18, Session 6

Novel applications of active mirror analysis

Victor L. Genberg, Gregory J. Michels, Sigmadyne, Inc. (United States)

Active and adaptive mirrors are commonly used to improve the performance of telescopes and other high performance optical systems. This paper will address the use of this analysis capability to solve a variety of other optomechanical problems. Examples will include:

1) Finding best coating thickness to minimize surface error

2) Understanding perplexing test results

3) Correlation of test and analysis results

4) Determining CTE variation within an optic

9573-19, Session 6

Shear stresses in cemented and bonded optics due to temperature changes

Paul R. Yoder Jr., Consultant (United States); Daniel Vukobratovich, Raytheon Missile Systems (United States)

This paper applies analytical means previously published by Chen and Nelson (1979) to estimate the shear stresses developed within the joints between typical cemented optical components and within opto-mechanical subassemblies made of materials with significantly different coefficients of thermal expansion (CTEs) when exposed to extreme ambient temperatures. Two cemented doublet examples, one involving glasses with a large CTE mismatch and another with more equal CTEs, are analyzed. An example involving a prism made of fused silica bonded with epoxy to a titanium base also is considered.

9573-20, Session 6

Unified optomechanical modeling: Thermo-elastic stability of a fiber optic diffractive encoding system

Alson E. Hatheway, Alson E. Hatheway Inc. (United States)

A challenge for optomechanical engineers is to make the structure sufficiently stiff to support the optical elements and stabilize the image on the detector. A complementary challenge, in an existing design, is to determine which elements need more stiffness and which others are satisfactory.

When presented with evidence (either empirical or analytical) that the image is unstable it is often not obvious which optical elements are the prime offenders. The uncertainty arises because both the elements' motions and their optical properties contribute the image motions. Since both the motions and the properties may vary by orders of magnitude in a particular design, neither one is a reliable guide for identifying major contributors to the problem.

Unified optomechanical modeling provides a vehicle for tracing offending image motions to particular optical elements and their supporting structure. The unified modeling method imports the optical elements' properties into a finite element structural model of optical system. It convolves the elements' motions and their optical properties in a single optomechanical modeling medium. This provides the engineer with a tool that discloses each element's contribution to the offending motions of the image on the detector.

This paper describes the use of the unified modeling technique to optimize the structure of an infrared imaging system.

9573-21, Session 6

Light source heat absorption analysis of a Dyson type lithography lens

Ming-Ying Hsu, Cheng-Fong Ho, Shenq-Tsong Chang, Ting-Ming Huang, Instrument Technology Research Ctr. (Taiwan)

The lithography system in high energy light source, the system refractive lens is absorption the heat from light source. The light source power is uniform distribution in mask side. The incident rays power density is calculated by radiometry in each lens surface. The lens heat absorption ratio is depending on optical glass species, quality and wave length. The optical glass higher internal transmittance means less heat absorption. Meanwhile, the optical glass in different temperature condition, the lens refractive index will change with temperature.

There is publish paper trying to calculate lens temperature distribution; the lens heat is absorbed from high energy light source. This study is applying FEM, radiometry and ray tracing solved lens temperature distribution. The each incident ray path is separate into many sections, the each section calculate the heat generated from heat absorption in the lens. Therefore, the heat generated in incident rays sections are weighting to finite element grids, and solving temperature distribution. The lens non-uniform temperature distribution will cause incident rays Optical Path Difference (OPD). The each incident rays OPD can fit by Zernike polynomials, the fitting results bring into optical software can be used to evaluate the thermal effect on lens heat absorption.

9573-22, Session 7

Techniques for analyzing lens manufacturing data with optical design applications *(Invited Paper)*

Morris I. Kaufman, National Security Technologies, LLC (United States); Brandon B. Light, Optimax Systems, Inc. (United States); Robert M. Malone, National Security Technologies, LLC (United States); Michael K. Gregory, Optimax Systems, Inc. (United States)

Optical designers assume a mathematically derived statistical distribution of the relevant design parameters for their Monte Carlo tolerancing simulations. However, there may be significant differences between the assumed distributions and the likely outcomes from manufacturing. Of particular interest for this study are the data analysis techniques and how they may be applied to optical and mechanical tolerance decisions. The effect of geometric factors and mechanical glass properties on lens manufacturability will be also be presented. Although the present work concerns lens grinding and polishing, some of the concepts and analysis techniques could also be applied to other processes such molding and single-point diamond turning.

9573-23, Session 7

Dependency between removal characteristics and defined measurement categories of pellet-tools

Christian Vogt, Rolf Rascher, Christine Wuensche, Hochschule Deggendorf (Germany)

Optical surfaces are usually machined by grinding and polishing. To achieve short polishing times it is intended to grind with best possible form accuracy and with low sub-surface damages. This leads to the use of very fine-grained grinding tools for the finishing process. These often show time-dependent problems regarding cutting ability in conjunction with tool wear.

Fine grinding tools for manufacturing of optics are often comprised of

grinding pellets. For a successful grinding process the tools must show a constant self-sharpening performance. A constant, at least predictable wear and cutting behavior is crucial for a deterministic machining.

This work describes a method to determine the characteristics of pellet grinding tools by tests conducted with a single pellet. The determination of the effective material removal rate and the derivation of the G-ratio are carried out here. Especially their change from the newly dressed via the quasi-stationary to the worn status of the tool is followed up. By recording the achieved roughness with the single pellet, a conclusion is possible for the expected roughness from a series pellet tool made of the same pellet specification.

From the results of these tests the usability of a pellet grinding tool for a special grinding task can be determined without testing a comparatively expensive serial tool.

The results are verified by a production test with a serial tool under series conditions.

The collected data can be stored and used in an appropriate data base for tool characteristics and be combined with useful applications.

9573-24, Session 7

Q-switched 1064nm laser source for photomechanical ablation in obsidianus lapis

Alfredo I. Aguilar-Morales, José Alfredo Álvarez-Chávez, A J. Morales-Ramírez, Ctr. de Investigación e Innovación Tecnológica (Mexico); Moises A. Ortega Delgado, Michael Panzner, Fraunhofer IWS Dresden (Germany)

The process of ablation in obsidianus lapis is mainly governed by laser pulse energy and scanning speed. The rate of material ablation is influenced by its chemical and physical properties. In this work, laser energy at 1064nm, the main commercially available wavelength for this application, has been used for ablation behavior in Q-switch regime. A >40W, CW Nd:YAG source with energy pulses ranging from 2.0mJ to nearly 7mJ, achieved surface damages up to 160μm of depth. Photo-mechanical ablation in terms of scanning speed showed a maximum depth of nearly 500μm at 130mm/s, and the maximum pulse energy of 8mJ was required for a 170μm depth. Highly efficient ablation in obsidianus lapis for artistic work is an interesting field of application.

9573-25, Session 7

The aspherical plastic lens molding stress residue and OPD analysis

Ming-Ying Hsu, Instrument Technology Research Ctr. (Taiwan)

The large size aspherical plastic lens is widely use in commercial optical product. The lens warpage and stress residue will introduce optical aberration into optical system. This paper is trying to link mould flow and optical design software by opto-mechanical analysis. Mold flow software is generally used in injection molding simulation to calculate the plastic lens stress residue of the injection process. Meanwhile, the optical ray path through the lens can be calculated by optical software. The stress residue results can be weighted to the optical ray path, and to evaluate the stress Optical Path Different (OPD) in each ray path. Each ray path OPD can be transformed to an optical axis sag, giving feedback on optical software estimate stress residue effect lens optical performance, and optimizing the injection model design.

9573-26, Session 7

A high-contrast 400- to 2500-nm hyperspectral checkerboard consisting of Acktar material cut with a femtosecond laser

Janos C. Keresztes, KU Leuven (Belgium); Anne Henrottin, Laser Engineering Applications S.A. (Belgium); Mohammad Goodarzi, Niels Wouters, Jeroen Van Roy, Wouter Saeys, KU Leuven (Belgium)

Visible-near infrared (Vis-NIR) and short wave infrared (SWIR) hyperspectral imaging (HSI) are gaining interest in the food sorting industry. As for traditional machine vision (MV), spectral image registration is an important step which affects the quality of the sorting system. Unfortunately, it currently still remains challenging to accurately register the images acquired with the different imagers as this requires a reference with good contrast over the full measurement range. Therefore, the objective of this work was to provide an accurate high contrast checkerboard over the full spectral range. From the investigated white and dark materials, Teflon and Acktar were found to present very good contrast over the full spectral range from 400 to 2500 nm, with a difference of 60%. The Metal Velvet self-adhesive coating from Acktar was selected as it also provides high specular absorbance. This was taped onto a near Lambertian polished Teflon plate, with further one out of two square removed after laser cutting the dark coating with an accuracy below 0.1 mm. As standard technologies such as nano-second pulsed lasers generated unwanted damages on both materials, a pulsed femto-second laser setup from Lasea with 60 um accuracy was used to manufacture the checkerboard. This pattern was monitored with an Imec Vis-NIR and a Headwall SWIR HSI line scanners. The camera intrinsic parameters were further extracted from the acquired images using computer vision. The contrast and effective focal length for different wavebands of each HSI are presented.

9573-27, Session 8

Unit moment analysis as a guide to mirror mount design

Daniel Vukobratovich, Patrick A. Coronato, Raytheon Missile Systems (United States)

Unit moment analysis minimizes the computational overhead associated with mirror mount design. Since mirrors operate in the linear domain with respect to stress/strain, it is possible to use the principle of superposition to determine overall optical surface deflection from a variety of sources. Surface deflection is calculated by FEA (finite element analysis) when applying unit loads at single mounting point. Deflection coefficients relating moments with surface deflection can be derived from the results of this analysis. These deflection coefficients are then applied, using the principle of superposition, to find the maximum tolerable moments associated with the mirror mount. Finally, manufacturing tolerances as well as environmental effects can be included to determine the required mirror mount compliance. This design approach is applicable to a wide range of mounting types, including classical kinematic and flexure mounts.

9573-28, Session 8

Mechanical design of a precision linear flexural stage for 3D x-ray diffraction microscope at the Advanced Photon Source

Deming Shu, Wenjun Liu, Argonne National Lab. (United States); Steven Kearney, Argonne National Lab. (United States) and Univ. of Illinois at Chicago (United States);

Jonathan Z. Tischler, Argonne National Lab. (United States)

The 3-D X-ray diffraction microscope is a new nondestructive tool for the three-dimensional characterization of mesoscopic materials structure. A flexural-pivot-based precision linear stage has been designed to perform a wire scan as a differential aperture for the 3-D diffraction microscope at the Advanced Photon Source, Argonne National Laboratory. The mechanical design and finite element analyses of the flexural stage, as well as its initial mechanical test results with laser interferometer are described in this paper.

* Work supported by the U.S. Department of Energy, Office of Science, under Contract No. DE-AC02-06CH11357.

9573-29, Session 8

Pre-construction of giant steerable science mirror for TMT

Fei Yang, Haibo Jiang, Qichang An, Hongchao Zhao, Peng Guo, Changchun Institute of Optics, Fine Mechanics and Physics (China)

The Changchun Institute of Optics, Fine Mechanics and Physics (CIOMP) team is developing the Giant Steerable Science Mirror (GSSM) for Thirty Meter Telescope (TMT) which will get into the preliminary design phase in 2016. To develop the passive support structure system for the largest elliptic-plano flat mirror, the smoothest tracking mechanism for the gravity-invariant condition, CIOMP is designing and building a 1/4 scale, functionally accurate version of the GSSM prototype. The prototype will incorporate the same opto-mechanical system and electric control system as the GSSM. The size of the prototype mirror is 898.5mm?634mm?12 mm with elliptic-plano figure and will be supported by 18 points whiffletree on axial and 12 points whiffletree on lateral. The mirror surface figure will be evaluated by SlopeRMS which is the final evaluation method used in the actual GSSM. The prototype allows the mirror point to and be tested in five specified gravity orientations and meet the requirements of SlopeRMS. The prototype testing platform will have the interfaces with direct drive systems. The jitter testing will be implemented on the prototype system to verify the bearing, the encoder, the servo control algorithm in the low speed up to 5 arcsecond per second. The total prototype system configured mirror surface figure will be better than 1 micro radian SlopeRMS in each tested orientation. The positioner jitter will be less than 0.1 arcsecond RMS for tilt and rotator axis respectively and will be analysed with frequency domain to meet the requirements of the TMT adaptive optics system. The pre-construction will be completed at the beginning of 2016 and provide the technical support to the preliminary design of GSSM.

Conference 9574: Material Technologies and Applications to Optics, Structures, Components, and Sub-Systems II

SPIE. OPTICS+ PHOTONICS OPTICAL ENGINEERING+ APPLICATIONS

Monday - Thursday 10–13 August 2015

Part of Proceedings of SPIE Vol. 9574 Material Technologies and Applications to Optics, Structures, Components, and Sub-Systems II

9574-25, Session PMon

Numerically modeling diffraction efficiency of holographic volume grating formatted in photopolymer materials

Haoyu Li, Yue Qi, Ra'ed Malallah, John T. Sheridan, Univ. College Dublin (Ireland)

Based on the developed three-dimensional nonlocal photo-polymerization driven diffusion (NPDD), the non-linear response between the light intensity and material polymerization has been significantly presented in photopolymer material layer. The resulting spatial distribution of grating refractive index is not ideal sinusoidal as exposing pattern. Thus we denote that the harmonics of orders for the refractive index should not be just the zero and first order. In this paper we calculate the periodical distribution refractive index using the Lorentz-Lorentz relation and expanding it as four orders Fourier series. Then an effective first harmonic refractive index modulation which is time and space varying to describe the formatted volume grating is introduced. To do so the effects of the distortion effects produced by higher harmonics of refractive index can be considered into the refractive index modulation. The predictions are examined numerically for different physical conditions. The experimentally obtained deviation that the grating diffraction efficiency cannot reach the theoretical maximum value (?max = 100%) and the minimum value (?min = 0%) corresponding to the typical "sin2" curve during modulation and over-modulation exposure time, can be explained applying this model assumed in an acrylamide/polyvinyl alcohol (AA/PVA) photopolymer material.

9574-26, Session PMon

White-emitting SrAl2O4:Ce3+ phosphor for solid-state lighting

Luis Armando Díaz-Torres, Ctr. de Investigaciones en Óptica, A.C. (Mexico); David A. Chávez, Univ. Autónoma de Coahuila (Mexico); Carlos R. García, Maria T. Romero, Univ. Autonoma de Coahuila (Mexico); Jorge Oliva, Ctr. de Investigaciones Ópticas (Mexico)

Pure and Ce3+ doped SrAl2O4 phosphors were obtained by a combustion synthesis followed by a post-annealing process in reductive atmosphere at high temperature. The Ce3+ doping molar concentrations (x) were varied as follows x = 0.0, 0.5, 1.0, 2.0, 3.0, 5.0 and 10.0 mol%. Structural, morphological, optical and luminescent characterizations were performed by means X-ray diffraction, scanning electron microscopy, diffuse reflectance and photoluminescence spectroscopy, respectively. X-ray diffraction analysis showed a single monoclinic phase SrAl2O4 even for higher Ce3+ doping concentrations, suggesting that the Ce3+ ions are well incorporated into the host lattice. SEM micrographs show irregular micro-grains with sizes in the range of 1-100 μm. A broadband white emission from 390 nm to 650 nm, with a maximum peak at lambda1=435 nm and a strong shoulder at lambda2= 520 nm, is observed when the phosphor is excited with UV light at lambdaexc= 351 nm. The maximum peak observed is attributed to the 5d-4f allowed transitions of Ce3+ ions substituted in the Sr sites within the SrAl2O4 monoclinic lattice. The excitation spectrum depicted a broadband profile from 250 nm to 400 nm, showing that the SrAl2O4:Ce3+ phosphors can be excited by near UV LEDs. The higher luminescent intensity was achieve by the x= 0.5 mol% doped SrAl2O4 phosphor. Due to this feature the SrAl2O4:Ce3+ phosphors are good candidates for white light generation LEDs technology.

9574-27, Session PMon

Focus tunable device actuator based on ionic polymer metal composite

Yi Wei Zhang, Guo-Dung J. Su, National Taiwan Univ. (Taiwan)

The voice coil motors (VCMs) are widely used in autofocus cameras in electronic portable devices recently. In this paper, we used ionic polymer metallic composite (IPMC) to replace VCMs because of its light weight and low driving voltage. To lower the driving voltage, we used silver as electrodes and demonstrated that silver can be deposited by either electro- or electroless-plating. The IPMC made of silver electrode required 30% less driving voltage and the response speed could also improve almost 2 times in comparison with traditional platinum electrodes. Furthermore, the light-weighted microlens arrays with 0.7 mm in diameter made by micromachining technology can be moved by the IPMC actuators proposed in this paper. The modeling of this IPMC is presented as well. We believe the lower operating voltage and the relatively fast response speed of Ag-IPMC could be used in various optical applications.

9574-1, Session 1

Design and manufacturing considerations for 0.25-1.5 meter beryllium telescopes for current and future space missions

Mike N. Sweeney, Mark R. Warren, Joseph Ho, Jeff Calvert, Jeff Ruzan, General Dynamics Corp. (United States)

Recently there has been resurging interest in beryllium telescopes ranging in aperture from 0.25-1.5 meter for various NASA space missions. The central design feature for each mission currently under consideration is an axially symmetric, all beryllium telescope.

Design considerations include achieving minimized mass simultaneous with demanding structural, thermal, and optical requirements on orbit after sustaining the rigors of space launch. Modern analysis tools and modeling techniques enable simulation of telescope wavefront errors resulting from environmental effects and the influences of bi-metallic bending. Manufacturing considerations include diamond point turning, coordinate measurement machine profilometry, computerized grinding and polishing, brazing of complex beryllium structures, very thin electroless nickel plating, and other advanced manufacturing technologies imperative to successful visible–NIR optical performance. Current design and manufacturing efforts on 0.60, 0.80, and 1.0 meter beryllium telescopes are profiled to illuminate the confluence of applicable design and manufacturing technologies.

9574-2, Session 1

New decade of shaped beryllium blanks

Don Hashiguchi, Jeffrey Campbell, Materion Brush Beryllium & Composites (United States); Aaron Sayer, Amanda Morales, Materion Corp. (United States)

Near-net-shape powder consolidation technology has been developing over the past 30+ years. One relatively recent example is production of hexagonal shaped beryllium mirror blanks made for the James Webb Space Telescope. More cost saving examples, specifically from the past decade, utilizing growing experience and lesson's learned whether from a mirror substrate or structure will be discussed to show the latitude of production

technology. Powder consolidation techniques include Hot Isostatic Pressing (HIP) for either round or shaped blanks and Vacuum Hot Pressing (VHP) consolidation for round blanks. The range of sizes will be presented to further illustrate the latitude of current production capability.

9574-3, Session 1

Design and manufacturing considerations for high-performance gimbals used for land, sea, air, and space

Mike N. Sweeney, Lafe Redd, Tom Vettese, David Uchida, General Dynamics Corp. (United States)

High performance stabilized EO/IR surveillance and targeting systems are in demand for a wide variety of military, law enforcement, and commercial assets for land, sea, air, and space. Operating ranges, wavelengths, and angular resolution capabilities define the requirements for EO/IR optics and sensors, and line of sight stabilization. Many materials and design configurations are available for EO/IR pointing gimbals depending on trade-offs of size, weight, power, performance, and cost. Space and high performance military aircraft applications are often driven toward expensive but exceptionally performing beryllium and aluminum beryllium components. Commercial applications often rely on aluminum and composite materials.

Gimbal design considerations include achieving minimized mass and inertia simultaneous with demanding structural, thermal, optical, and scene stabilization requirements when operating in dynamic operational environments. Manufacturing considerations include precision lapping and honing of ball bearing interfaces, brazing, welding, and casting of complex aluminum and beryllium alloy structures, and molding of composite structures. Several notional and previously developed EO/IR gimbal platforms are profiled that exemplify applicable design and manufacturing technologies.

9574-4, Session 1

Fabrication of stable lightweight Be-38Al optics and optical support structures

Robert Hardesty, Kelsey Parker, Peregrine Falcon Corp. (United States)

This paper will describe recent aerospace applications where Be-38Al (AlBeMet) has been successfully applied to produce optics and stable support structures. The information presented will touch on historical uses of beryllium and beryllium-aluminum in satellite optical systems, and then address the latest developments in regards to Be-38Al and its application to optical substrates and stable support structures. Peregrine has ongoing development activities and will provide the latest progress concerning pertinent applications and designs from Be-38Al.

9574-5, Session 1

Application and testing of additive manufacturing for mirrors and precision structures

Mike N. Sweeney, Martyn Acreman, Tom Vettese, Ray Myatt, Mike Thompson, General Dynamics Corp. (United States)

Additive Manufacturing (aka AM, and 3-D printing) is widely touted in the media as the next industrial revolution. Beneath the hype, AM does offer profound advantages in lead-time, dramatically reduced consumption of expensive raw materials, while enabling new and innovative design forms that cannot be produced by other means. General Dynamics and industry partners have begun to challenge and embrace this technology for mirrors and precision structures used in the aerospace, defense, and precision instrumentation industries. Aggressively light-weighted, open and closed back mirror designs, 75-150 mm in size, were first produced by AM. Subsequent optical finishing and test experiments have exceeded expectations for density, surface finish, dimensional stability and isotropy of thermal expansion on the optical scale of measurement. Materials currently under examination include aluminum, titanium, beryllium, AlBe MMC, Inconel, stainless bronze, and PEKK polymer.

Design considerations for AM include the expanding availability of material choices, producible wall thicknesses, build overhang criteria, and powder removal considerations. Manufacturing considerations include scaffolding during build processes, heat treat, thermal cycling, hot isostatic pressing diamond point turning, optical polishing, The finished specimen were then subjected to thermal cycles to verify dimensional stability at room temperature and then measured under vacuum at hot and cold temperature excursions using laser interferometry. Both flat and spherical optical reference surfaces were used to differentiate longitudinal and transverse effects.

9574-6, Session 2

Structured surfaces on metal optics

Ralf Steinkopf, Johannes Hartung, Andreas Gebhardt, Stefan Risse, Ramona Eberhardt, Fraunhofer-Institut für Angewandte Optik und Feinmechanik (Germany)

Diamond machining of metal optics is an excellent way to manufacture structured elements on different surface geometries. Especially curved substrates such as spheres, aspheres, or freeforms in combination with structured elements enable innovative products like headlights of automobiles or spectrometers of telescopes in space applications. With diamond turning, servo turning, milling, and shaping, different technologies for almost any geometry are available. The addressed wavelengths are typically in the range of IR and NIR optical applications. Applying additional finishing processes, diamond machining is also used for optics applicable down to the EUV spectral range. The materials used for metal optics provide an additional advantage. Caused by manufacturing the mirror substrate and the mirror frame from materials with the same thermal expansion coefficient and even the same material, respectively, the completed optical systems are very robust and operationally stable within a wide temperature range. To achieve athermal optics, the alloy components are especially designed to match certain material components of the optical system. An exemplary model is the presented combination of AlSi42 and NiP.

Due to the complexity of the process chain for manufacturing freeform elements and structured surfaces, it is important to think about the right technologies from the beginning and to choose designs for series productions with time and cost effective processes, respectively. The paper shows the background to the effective use of manufacturing processes derived from the optical design and concentrates on the technologies for diamond machining of structured surfaces.

9574-7, Session 2

Physical and mechanical properties of LoVAR: a new lightweight particle-reinforced Fe-36Ni alloy

Robert Michel, Materion Brush Beryllium & Composites (United States); Andrew Tarrant, Materion Aerospace Metal Composites Ltd. (United Kingdom); Jason R. Clune, Materion Brush Beryllium & Composites (United States); David Tricker, Materion Aerospace Metal Composites Ltd. (United Kingdom); Tim A. Stephenson, NASA Goddard Space Flight Ctr. (United States)

Because of its low thermal expansion, Fe-36Ni is the alloy of choice for optical, instrument and electrical applications where dimensional stability is critical. This paper will outline the development of a particle-reinforced

Fe-36Ni MMC that offers reduced density, lower CTE, improved temporal stability and greater specific stiffness compared to the conventional wrought alloy. A summary of processing capability will be given relating the composition and microstructure to mechanical and physical properties.

9574-8, Session 2

Advanced thermal control for spacecraft applications

Robert Hardesty, Kelsey Parker, Peregrine Falcon Corp. (United States)

In optical, infrared and advanced systems just like all other space borne systems, thermal control plays an important role. In fact, most advanced designs are plagued with volume constraints that further complicate the thermal control challenges for even the most experienced systems engineers. Peregrine will present advances in satellite thermal control based upon passive heat transfer technologies to dissipate large thermal loads. This will address the use of high thermal conducting products that are at least five times better than aluminum on a specific basis providing enabling thermal control while maintaining structural support.

9574-9, Session 3

New polishable R-SiC layer on ultra-lightweighted SiC substrates

Eric Ruch, REOSC (France)

Silicon Carbide is a material of high interest in the design and manufacturing of space telescopes, thanks to its mechanical and thermal properties. Since many years, Reosc has gathered a large experience in the polishing, testing, integration and coating of large size Silicon Carbide mirrors and also in the integration of full SiC TMAs.

Reosc has manufactured the 3 TMAs of the NIRSpec instrument that will take place on board JWST. Reosc has also polished 2 sets of mirrors for the Japanese HISUI instruments. Reosc has also polished the 1.5m primary mirrors of the GAIA instrument and currently polishing the scan mirrors of the MTG telescope and the 1,3m diameter primary mirror of the EUCLID instrument.

Based on this experience, Reosc is still improving its capability in the field of SiC mirrors. Two main activities are currently on-going:

1. replacement of CVD SiC by a new polishable layer R-SiC

2. development of ultra-lightweighted SiC mirror

The polishing of usual SiC mirrors does not provide very low micro-roughness. This is why it is required to coat the mirror with a layer that allows the polishing with a low micro-roughness (typically < 1nm RMS). The current process uses CVD SiC that has some drawbacks, mainly in terms of sizability to very large mirrors. This is why Reosc has developed an alternative material for polishing layers, R-SiC. The main requirements (low micro-roughness polishing, CTE compatibility with substrate, environment compatibility) have been successfully demonstrated. The next phase of the technology research program run in collaboration with ESA was to manufacture a 300mm demonstrator.

Reosc has successfully polished two ultra-lightweighted SiC mirrors, with R-SiC polishable layer, with an areal density of 20kg/m?. The design and the manufacturing process are representative of a 1.5 to 2m diameter mirror class. The goal is to develop the process and the tools allowing the polishing of this mirror including the quilting conditions.

9574-10, Session 3

9574-11, Session 3

Low-stress silicon cladding made by pulsed-ion-assisted evaporation

David A. Sheikh, ZeCoat Corp. (United States)

ZeCoat Corporation has developed a low-stress silicon cladding process, which is super-polishable for meter-class SiC mirrors. The coating process is based on a low temperature, ion-assisted, evaporation technique (IAD), whereby the coating stress of a silicon film may be reversed periodically from compressive to tensile, in order to produce a near-zero net stress for the complete layer. A cladding with little intrinsic stress is essential to minimize bending that would otherwise distort the figure of very lightweight mirrors. ZeCoat has demonstrated silicon claddings 100-microns thick, with less than 50 MPa of compressive stress.

Large silicon carbide (SiC) mirrors (4+-meters in diameter) are being considered for future space-based UVOIR astronomy missions. These lightweight mirrors may require a highly-polishable layer of silicon (10 to 100-microns) applied on top of a SiC mirror substrate. A relatively thick layer of Si is desirable for the purpose of reducing figuring time and for achieving a super-polished surface, suitable for UV astronomy.

This paper presents coating stress data and polishing results for silicon claddings manufactured by the pulsed ion-assist process.

9574-12, Session 4

Trade-off study of all-SiC lightweight primary mirror and metering structure for spaceborne telescope *(Invited Paper)*

Haeng Bok Lee, Agency for Defense Development (Korea, Republic of); Jinyoung SUK, Chungnam National Univ. (Korea, Republic of); Jongin BAE, Hanwhathales (Korea, Republic of)

Silicon carbide is the best material for various telescope mirrors since it is high stiffness, low density, high thermal stability and fine surface optical quality. This paper describes a conceptual design trade studies that explores the structural views for the lightweight primary mirror made by SiC as well s the metering structure in half-metric GSD class telescope for space application.

9574-13, Session 4

T300HoneySiC: a new near-zero CTE molded C/SiC material

William A. Goodman, Trex Enterprises Corp. (United States); Mehrdad N Ghasemi-Nejhad, University of Hawaii (United States); Stan Wright, Ultracor Inc (United States); Darren Welson, Starfire Systems Inc (United States)

Trex enterprises and teammates were successful in producing a 12-inch by 12-inch by 0.5-inch vented, lightweight,Honeycomb C/SiC panel which had a density relative to bulk silicon carbide of 11% (89% lightweighting). The so-called T300/HoneySiC panel and facesheet stock material were fabricated into ASTM standard coupons and tested at Southern Research

Institute to obtain basic materials properties data. The materials properties data showed that we had made a near-zero coefficient of thermal expansion (CTE, from -196 to +24 deg C = -0.22 ppm/degC) ceramic matrix composite (CMC) C/SiC material with good strength. This material will be ideal for space opto-mechanical structures and optical benches due to it's near Zero-CTE and lightweight. The material is initially molded and then converted to a C/SiC ceramic matrix composite. Thus the fabrication time can be less than 3 weeks from start to finish, resulting in low cost.

9574-14, Session 4

Fabrication of extreme light-weighted ceramic mirrors

Matthias Krödel, ECM Engineered Ceramic Materials GmbH (Germany); Daniel Waechter, Fraunhofer-Institut für Produktionstechnologie (Germany); Frank Stahr, FAP Plasmatechnik GmbH (Germany); Claus-Peter Soose, fineoptix GmbH (Germany)

This paper will present the recent development achievements of a German SME supply chain to manufacture super light-weighted HB-Cesic mirrors for IR to visible applications. We will present recent design developments for achieving extreme light-weighted mirror substrates with extremely high stiffness and performance and in the second part the newly established German supply chain for the manufacturing of such extreme light-weighted mirror substrates.

9574-15, Session 4

Extreme stable and complex structures for optomechanical application

Matthias Krödel, ECM Engineered Ceramic Materials GmbH (Germany)

This paper will present the possibility to design and fabricate extreme stable and complex structure for opto-mechanical space application. Due to the fabrication features of our technology it is possible to fabricate complex light weighted structures for different thermal environments. We will present the complete process starting from the design up to the qualification of such structures. Finally we present some successful fabricated structures for such applications.

9574-16, Session 5

GRIN and homogeneous infrared materials for compact broadband IR imagers *(Invited Paper)*

Daniel J. Gibson, Shyam Bayya, Vinh Q. Nguyen, Jasbinder S. Sanghera, U.S. Naval Research Lab. (United States); Mikhail Kotov, Sotera Defense Solutions, Inc. (United States); Gryphon Drake, Univ. Research Foundation (United States)

The increasing reliance on simultaneous imaging in two or more spectral bands (visible, shortwave, mid-wave and long-wave infrared) on military platforms and technological advances in focal plane arrays (FPAs) highlight the need for compact multi-spectral IR imagers. Multi-spectral imagers based on reflective optics are typically large and limited to narrow field of view (FOV) applications. The small number of refractive materials that simultaneously transmit the SWIR, MWIR and LWIR wavelength regions imposes design constraints on multi-band imagers and the resulting designs can contain many elements making them heavy and complex with very tight tolerances. At the Naval Research Laboratory (NRL) we are developing new technologies for multispectral optics: new homogeneous broadband IR materials and IR gradient index (IR-GRIN) optical materials. This paper will present the latest progress in the development of these materials including their properties, and availability. Topics include refractive index, dispersion, index and dispersion gradients, design space guidelines and preliminary mechanical properties.

9574-17, Session 5

Homogeneity of material and optical properties in HEM grown sappire

Melissa Stout, Douglas L. Hibbard, II-VI Optical Systems (United States)

Sapphire crystal boules, approximately 34 cm in diameter and 22 cm tall, grown by the Heat Exchanger Method (HEM) are currently being sliced, ground and polished for use as window substrates in a variety of aerospace applications. As the need for larger volumes of higher quality material increases, it is necessary to evaluate and understand the homogeneity of optical and material properties within sapphire boules to ensure the needs of the industry can be met. The optical homogeneity throughout the full useable thickness of a representative sapphire boule was evaluated by measuring the transmitted wavefront error of multiple thin slices. This approach allowed the creation of a full-volume three-dimensional homogeneity map. Additionally, the uniformity of other critical characteristics of the material was evaluated at multiple locations within a boule. Specific properties investigated were equibiaxial flexural strength, index of refraction, Knoop hardness, coefficient of thermal expansion and modulus of elasticity. The results of those evaluations will be reported.

9574-18, Session 5

Strength of Zerodur(R) for mirror applications

Stephanie Behar-Lafenetre, Thales Alenia Space (France); Laurence Cornillon, Thales Alenia Space (France); Sonia Ait Zaid, Ctr. National d'Études Spatiales (France)

Zerodur® is a well-known glass-ceramic used for optical components because of its unequalled dimensional stability under thermal environment. In particular it has been used since decades in Thales Alenia Space's optical payloads for space telescopes, especially for mirrors. The drawback of Zerodur® is however its quite low strength, but the relatively small size of mirrors in the past had made it unnecessary to further investigate this aspect, although elementary tests have always shown higher failure strength. As performance of space telescopes is increasing, the size of mirrors increases accordingly, and an optimization of the design is necessary, mainly for mass saving. Therefore the question of the effective strength of Zerodur® has become a real issue.

Thales Alenia Space has investigated the application of the Weibull law and associated size effects on Zerodur® in 2014, under CNES funding, through a thorough test campaign with a high number of samples (300) of various types. The purpose was to accurately determine the parameters of the Weibull law for Zerodur® when machined in the same conditions as mirrors.

The proposed paper will discuss the obtained results, in the light of the Weibull theory. The applicability of the 2-parameter and 3-parameter (with threshold strength) laws will be compared. The expected size effect has not been evidenced therefore some investigations are led to determine the reasons of this result, from the test implementation quality to the data post-processing methodology. Eventually, the reliability of a proposed new allowable value for the studied surface finish will be discussed.

9574-19, Session 5

Low-temperature GRISM direct bonding

Gerhard Kalkowski, Gerd Harnisch, André L. Matthes, Uwe D. Zeitner, Stefan Risse, Fraunhofer-Institut für Angewandte Optik und Feinmechanik (Germany)

For high resolution spectroscopy in space, grating prism (GRISM) designs have been developed /1/ and are gaining increasing relevance. Common manufacturing proceeds either by directly "ruling" the grating structure into the prism surface, or by sophisticated high temperature diffusion bonding of a grating to a prism (to avoid the drawbacks of adhesive interlayers in the optical path).

We currently investigate an alternative approach for GRISM production, by using hydrophilic direct bonding at low temperatures /2/ to join gratings and prisms. Fig. 1 shows exemplary results of bonding lithographically structured fused silica glass plates of dimensions 25x35x6.35 mm? to right angle prisms of edge length 25 mm at temperatures of about 200°C in vacuum. The glass plates were furnished with binary gratings of size about 20x30 mm? in the bonding area and periods of about 600 nm. Flatness and roughness of both bonding surfaces are decisive for successful bonding. Our contribution describes the bonding process and characterizes bonding strength and optical performance of selected specimen.

This work was supported by BMWI/DLR (Germany) under contract No. 55EE1204.

9574-20, Session 5

Polymers with customizable optical and rheological properties based on an epoxy acrylate based host-guest system

Uwe Gleissner, Thomas Hanemann, Jost Hobmaier, Univ. of Freiburg (Germany)

We report an easy way to tune the optical refractive index and viscosity of an epoxy acrylate-based host-guest system which can be used for the fabrication of optical waveguides. This allows fast and precise modification of the material system for different replication methods like hot embossing, inkjet printing or spin coating.

To modify the refractive index n, an electron-rich organic dopant such as phenanthrene is added to a commercially available reactive polymer based resin. Moreover, changes in viscosity can be achieved by using a comonomer with suitable properties like benzyl methacrylate (BMA).

We used a commercially available UV-curable epoxy acrylate based polymer matrix to investigate both the influence of phenanthrene and of benzyl methacrylate. First, mixtures of the pure polymer and benzyl methacrylate with a ratio of 30, 50, and 80 wt% benzyl methacrylate were produced. Second, phenanthrene was added with 5 and 10 wt%, respectively. All components were mixed and then polymerized by UV-irradiation and with a thermal postcure.

Characterization of the system with respect to viscosity, refractive index, Abbe number, glass transition temperature and optical damping was performed.

The viscosity of the mixtures decreased at 20°C linearly from 1.5 Pa•s (30 wt%) to 8 mPa•s (80 wt%), whereas the refractive index decreased at the same time by a small amount from 1.570 to 1.568 (@589 nm, 20°C). By adding phenanthrene refractive index increased to a maximum of n = 1.586 (50 wt% BMA, 10 wt% phenanthrene). Abbe numbers for the compositions without phenanthrene ranged from 35 to 38.

9574-21, Session 5

Low-strain laser-based solder joining of mounted lenses

Thomas Burkhardt, Marcel Hornaff, Andreas Kamm, Diana Burkhardt, Erik Schmidt, Erik Beckert, Ramona Eberhardt, Andreas Tünnermann, Fraunhofer-Institut für Angewandte Optik und Feinmechanik (Germany)

A novel laser based soldering technique – Solderjet Bumping – using liquid solder droplets in a flux-free process with only localized heating is demonstrating the all inorganic, adhesive free bonding of optical components and support structures that is suitable for optical assemblies and instruments under harsh environmental conditions. Low strain bonding with a following high precision adjustment turning process is presented, addressing components and subsystems for objectives for high power and short wavelengths. The discussed case study will show large aperture transmissive optics (diameter approx. 80 mm) made of fused silica and LAK9G15, a radiation resistant glass, bonded to thermally matched metallic mounts. The process chain of Solderjet Bumping – cleaning, solderable metallization, handling, bonding and inspection – is discussed. This multi-material approach requires numerical modelling for dimensioning according to thermal and mechanical loads. The findings of numerical modelling, process parametrization and environmental testing (thermal and vibrational loads) are presented. Stress and strain introduced into optical components as well as deformation of optical surfaces can significantly deteriorate the wave front of passing light and therefore reduce system performance significantly. The optical performance with respect to stress/strain and surface deformation during bonding and environmental testing are evaluated using non-contact optical techniques: polarimetry and interferometry, respectively.

9574-22, Session 6

State-of-the-art cryogenic CTE measurements of ultra-low thermal expansion materials *(Invited Paper)*

Thomas Middelmann, Alexander Walkov, René Schödel, Physikalisch-Technische Bundesanstalt (Germany)

Absolute length measurements performed by imaging phase stepping interferometry allow for investigation of dimensional properties such as thermal expansion, length relaxation and long term stability with highest accuracy. The accurate knowledge of these properties is essential for development and characterization of ultra stable materials needed e.g. in the semiconductor industry or for aerospace applications. Accurate data on the coefficient of thermal Expansion (CTE) at cryogenic temperatures are especially important for construction and operation of space-borne telescopes as the Herschel Space Observatory or the James Webb Space Telescope of the European Space Agency, where large diameter mirrors are used at cryogenic temperatures.

Inside the extended measurements pathway of PTB's ultra precision interferometer the temperature can be varied from 7 K to 293 K. We have measured the absolute length of two samples made from different sorts of silicon nitride ceramics. We use these measurements to determine the CTE with an uncertainty below 5E-9/K in the temperature range from 10 K to 290 K. The CTE is defined via the derivative of the length with respect to temperature. To obtain the derivative the functional dependence of length versus temperature needs to be known. For this we fitted a physically motivated model to the length data. This model supports a low uncertainty by a low number of fit parameters. The physically motivated model is appropriate above 45 K but fails at lower temperatures. Thus in the temperature range from 7 K to 45 K we use a 5th order polynomial fit instead.

9574-23, Session 6

Next-generation dilatometer for highest accuracy thermal expansion measurement of ZERODUR(R)

Ralf Jedamzik, Axel Engel, Clemens Kunisch, Gerhard Westenberger, Peter Fischer, Thomas Westerhoff, SCHOTT AG (Germany)

In the recent years, the ever tighter tolerance for the Coefficient of thermal expansion (CTE) of IC Lithography component materials is requesting significant progress in the metrology accuracy to determine this property as requested.

ZERODUR® is known for its extremely low CTE between 0°C to 50°C. The current measurement of the thermal expansion coefficient is done using push rod dilatometer measurement systems developed at SCHOTT. In recent years measurements have been published showing the excellent CTE homogeneity of ZERODUR® in the one-digit ppb/K range using these systems. The verifiable homogeneity was limited by the CTE(0°C,50°C) measurement repeatability in the range of +- 1.2 ppb/K of the current improved push rod dilatometer setup using an optical interferometer as detector instead of an inductive coil.

With ZERODUR® TAILORED, SCHOTT introduced a low thermal expansion material grade that can be adapted to individual customer application temperature profiles. The basis for this product is a model that has been developed in 2010 for better understanding of the thermal expansion behavior under given temperature versus time conditions. In the ideal case, this model should match with real thermal expansions measurements. For this purpose a dilatometer setup is required with excellent stability and accuracy over long measurement times of several days.

In the past few years SCHOTT spent a lot of effort to drive a dilatometer measurement technology based on the push rod setup to its limit, to fulfill the continuously demand for higher CTE accuracy and deeper material knowledge of ZERODUR®. This paper reports on the status of the dilatometer technology development at SCHOTT.

Measurement of an optical surface roughness by of optical gradient waveguide method

Nikolai D. Espinosa, Univ. de las Fuerzas Armadas (Ecuador)

Theoretically and experimentally, we measured and analysis the scattering spectrum of the roughness optical surface using the multimodes optical planar gradient waveguide method. Described the method of preparation of prototypes (gradient waveguides) and the used methodology to perform the corresponding measurements.

With the acquired parameters (scattering spectrum) we proceed to perform recovery of the surface roughness. Analysis of experimental results is made and compared with the theoretical results.

Conference 9575: Optical Manufacturing and Testing XI

Sunday - Tuesday 9 –11 August 2015

Part of Proceedings of SPIE Vol. 9575 Optical Manufacturing and Testing XI

9575-1, Session 1

Examination of the quality of 120 degree silicon double mirror for a micro-optical laser gyroscope

Thalke Niesel, Ingmar Leber, Andreas H. Dietzel, Technische Univ. Braunschweig (Germany)

For use in a novel micro optical laser gyroscope, 120° silicon double mirrors have been developed in order to maximize the robustness of the sensor design against alignment errors. The idea being pursued to the use of double mirrors with an angle between these two mirrors that is intrinsically defined by silicon crystallography and with a total reflection angle that is robust against misalignment. As a consequence, measurement errors can be minimized.

In this work the manufacturing of the special mirror elements were described. For the fabrication of these mirrors silicon wafers are used which are almost in [100] orientation but are tilted by 5.3 ° towards [011] direction and, therefore, provide an etching facet with a slope of 60° by KOH/IPA wet chemical etching. Two wafers structured in such way are connected by silicon direct bonding and then cut into small mirror elements which are mounted onto the gyroscope micro platform. Subsequently, the quality of the mirror surface is examined to confirm their suitability for the micro optical gyroscope. In addition, the angle accuracy of the elements and the stability after reflection at several elements is measured. Finally, the current sensor design is described and an outlook is given.

9575-2, Session 1

INAF-OAB deflectometry facility calibration

Giorgia Sironi, Rodolfo Canestrari, INAF - Osservatorio Astronomico di Brera (Italy)

A deflectometrical facility was developed at Italian National Institute for Astrophysics – OAB in the context of the ASTRI project to characterize free-form segments for Cherenkov optics. Our setup allows performing an inverse Ronchi test, it works illuminating the reflecting surface with a known light pattern and observing how the surface local shape error acts warping the reflected image. Knowing the geometry of the system it is possible to convert this optical test, classically adopted as a qualitative test, in quantitative surface slope error. The test suitability for Cherenkov mirrors characterization was proved comparing directly the mirror PSF with the PSF expected by a mirror with the measured surface errors.

In this paper we present the INAF-OAB facility calibration obtained testing the components of the system and comparing the measurements obtained on sample optics with coordinate measurements machine data.

9575-3, Session 1

JWST pathfinder telescope optical alignment, integration, and test program

Gary W. Matthews, Scott Kennard, Ronald Broccolo, John Amon, Stephen Mt.Pleasant, James Ellis, Walter Hahn, Exelis Inc. (United States); Lee D. Feinberg, NASA Goddard Space Flight Ctr. (United States)

The James Webb Space Telescope (JWST) is a 6.5m, segmented, IR telescope that will explore the first light of the universe after the big bang. In 2014, a major risk reduction effort related to the Alignment, Integration, and Test (AI&T) of the segmented telescope was completed. The Pathfinder telescope was built at the Goddard Space Flight Center SSDIF which includes integrating two Primary Mirror Segment Assemblies (PMSA's) and the Secondary Mirror Assembly (SMA) onto a flight-like composite telescope backplane. This pathfinder allowed the JWST team to assess the alignment process and to better understand the various error sources that need to be accommodated in the flight build. The successful completion of the Pathfinder Telescope provides a final integration roadmap for the flight operations that will start in August 2015.

9575-4, Session 1

JWST pathfinder telescope risk reduction cryo test program

Gary W. Matthews, Thomas R. Scorse, John Spina, Exelis Inc. (United States); Ritva A. Keski-Kuha, Juli A. Lander, Mark F. Voyton, Lee D. Feinberg, NASA Goddard Space Flight Ctr. (United States); Carl A. Reis, NASA Johnson Space Ctr. (United States); Tony L. Whitman, Exelis Inc. (United States)

The James Webb Space Telescope (JWST) is a 6.5m, segmented, IR telescope that will explore the first light of the universe after the big bang. In 2014, the Optical Ground Support Equipment was integrated into the large cryo vacuum chamber at Johnson Space Center (JSC) and an initial Chamber Commissioning Test was completed. This insured that the support equipment was ready for the three Pathfinder telescope cryo tests. The Pathfinder telescope which consists of two primary mirror segment assemblies and the secondary mirror was delivered to JSC in February 2015 in support of this critical risk reduction test program prior to the flight hardware. This paper will detail the Chamber Commissioning and first optical test of the JWST Pathfinder telescope.

9575-5, Session 2

Optomechanical design and tolerance of a microscope objective at 121.6 nm

Derek S. Keyes, Thiago S. Jota, Weichuan Gao, Dakota Luepke, Victor E. Densmore, Thomas D. Milster, College of Optical Sciences, The Univ. of Arizona (United States); Gun Hee Kim, Korea Basic Science Institute (Korea, Republic of)

Utilizing the Hydrogen-Lyman-? (HLA) source at 121.6 nm we hope to achieve an intrinsic resolution of 247 nm at 0.3 NA and 92 nm at 0.8 NA. The motivation for 121.6 nm microscopy is a transparent window in the air absorption spectrum, which allows for the sample to be in air while the microscope is in an enclosed environment of nitrogen. The microscope objective consists of two reflective optics and a LiF window, and has been designed to demonstrate diffraction limited performance over a 160µm full field at 121.6 nm. The optomechanical design consists of mechanical subcells for each optical component, precision spacers and a barrel bore, which allows for submicron control of tolerance parameters.

9575-6, Session 2

Thermal optical metrology development for large lightweight UV to IR mirrors and future space observatory missions

Ron Eng, Markus A. Baker, William D. Hogue, Jeffrey R.

Kegley, Richard D. Siler, H. Philip Stahl, John M. Tucker, Ernest R. Wright, NASA Marshall Space Flight Ctr. (United States)

Optical metrology in an active thermal controlled environment plays a critical mission enabling role for future exoplanet and astrophysics exploration programs. The optical metrology results will validate concurrent integrated thermal, structural, and optical performance modeling effort. This paper summarizes the objectives and development effort in order to test different mirror architectures currently being developed by industry and government partners for NASA's Advanced Mirror Technology Development program. These lightweight mirror systems will be tested at the Marshall Space Flight Center's X-Ray & Cryogenic Facility, and the facility is currently being modified for testing mirrors up to 6 meters in diameter with metrology instruments housed inside the thermal vacuum test chamber.

9575-7, Session 2

Metrology requirements for the serial production of ELT primary mirror segments

Paul C. T. Rees, Caroline Gray, Glyndwr Univ. (United Kingdom)

The manufacture of the next generation of large astronomical telescopes, the extremely large telescopes (ELT), requires the rapid manufacture of greater than 500 1.44m hexagonal segments for the primary mirror of each telescope. Both leading projects, the Thirty Meter Telescope (TMT) and the European Extremely Large Telescope (E-ELT), have set highly demanding technical requirements for each fabricated segment. These technical requirements, when combined with the anticipated construction schedule for each telescope, suggest that more than one optical fabricator will be involved in the delivery of the primary mirror segments in order to meet the project schedule. For one supplier, the technical specification is challenging and requires highly consistent control of metrology in close coordination with the polishing technologies used in order to optimise production rates. For production using multiple suppliers, however the supply chain is structured, consistent control of metrology along the supply chain will be required. This requires a broader pattern of independent verification than is the case of a single supplier.

This paper outlines the metrology requirements for a single supplier throughout all stages of the fabrication process. We identify and outline those areas where metrology accuracy and duration have a significant impact on production efficiency. We use the challenging ESO E-ELT technical specification as an example of our treatment, including actual process data. We further develop this model for the case of a supply chain consisting of multiple suppliers. Here, we emphasise the need to control metrology throughout the supply chain in order to optimise net production efficiency.

9575-9, Session 2

Functionalization of UV-curing adhesives for surface-integrated single-mode polymer optical fibers

Bechir M. Hachicha, Ludger Overmeyer, Leibniz Univ. Hannover (Germany)

Polymer optical waveguides, especially single-mode waveguides are increasingly used for short distance communication, as well as for sensing applications. In this context, we are investigating an automated integration method of single-mode POF onto metallic substrates. Using microdispensing process, we functionalize UV-curing adhesives as cladding for single-mode optical cores. Furthermore, the adhesives are used for inherent bonding to the substrate. In this paper we pinpoint the necessary optical and mechanical characterization of these adhesives. Based on experiment results we inferred limits and opportunities, which this method offers.

9575-10, Session 3

Surface roughness when diamond turning RSA 905 optical aluminium

Timothy Otieno, Khaled Abou-El-Hossein, Nelson Mandela Metropolitan Univ. (South Africa); Wei-Yao Hsu, Yuan -Chieh Cheng, Instrument Technology Research Ctr. (Taiwan); Zwelinzima Mkoko, Nelson Mandela Metropolitan Univ. (South Africa)

Ultra-high precision machining is used intensively in the photonics industry for the production of various optical components. Aluminium alloys have proven to be advantageous and are most commonly used over other optical materials. Recently, the increasing demands from optical systems have led to the development of newly modified grades of aluminium alloys produced by rapid solidification during foundry process, characterised by finer microstructures and refined mechanical and physical properties. Their machining database is very limited and more research is still required in their machining performance when these modified aluminium alloys are diamond turned. This work investigates the machinability of rapidly solidified aluminium RSA 905 by varying cutting parameters and measuring the surface roughness over a cutting distance of 4 km. The machining parameters varied were cutting speed, feed rate and depth of cut. Statistical analysis was performed and a model was developed to predict the surface roughness from the cutting parameters. The results showed a common trend of decrease in surface roughness with increasing cutting distance. The lowest Ra result obtained after 4 km was 3.2 nm, where the parameters were cutting speed 1750 rpm, feed rate 5 mm/min and depth of cut 25 μm. The results showed that cutting speed to be the most influential parameter on resulting surface roughness, while depth of cut was the least influential. Contour maps were developed to determine zones where the cutting parameters would produce the best surface quality.

9575-11, Session 3

Aspects of ultra-high-precision diamond machining of RSA443 optical aluminium

Zwelinzima Mkoko, Khaled Abou-El-Hossein, Nelson Mandela Metropolitan Univ. (South Africa)

Optical aluminium alloys such as 6061-T6 are traditionally used in ultra-high precision manufacturing for making optical mirrors for aerospace and other applications. However, the optics industry has recently witnessed the development of more advanced optical aluminium grades that are capable of addressing some of the issues encountered when turning with single-point natural monocrystalline diamond cutters. The advent of rapidly solidified aluminium (RSA) grades has generally opened up new possibilities for ultra-high precision manufacturing of optical components. In this study, experiments were conducted with single-point diamond cutters on rapidly solidified aluminium RSA 443 material. The objective of this study is to observe the effects of depth of cut, feed rate and rotational speed on the tool wear rate and resulting surface roughness of diamond turned specimen. This is done to gain further understanding of the rate of wear on the diamond cutters versus the surface texture generated on RSA 443 material. Results obtained thus far have yielded machined surfaces which are less reflective but with consistent surface roughness values. Cutting tools were observed for wear through scanning microscopy; relatively significant wear pattern was evident on the cutters that were subjected to higher depth of cut and increased feed rate

9575-12, Session 3

The role of robotics in computer-controlled polishing of large and small optics

David D. Walker, Zeeko Research Ltd. (United Kingdom)

and Univ. College London (United Kingdom) and Glyndwr Univ. (United Kingdom); Matthew Bibby, Zeeko Research Ltd. (United Kingdom); Guoyu Yu, Caroline Gray, Paul C. T. Rees, Glyndwr Univ. (United Kingdom); Hsing Yu Wu, Univ. College London (United Kingdom); Xiao Zheng, Peng Zhang, Glyndwr Univ. (United Kingdom); Christina R. Dunn, Univ. College London (United Kingdom)

Following formal acceptance by ESO of three 1.4m hexagonal off-axis prototype mirror segments for the E-ELT produced at OpTIC, and certification of the optical test facility including 1.5m Master Spherical Segment, we summarise the state-of-the-art and then turn our attention to the challenge of segment mass-production.

In particular, we focus on the role of industrial robots in this and similar process-chains, particularly involving aspheric and free-form surfaces. We highlight the complementarity of robots and Zeeko machines, particularly regarding the inferior positional precision but higher motion-speeds delivered by robots. We have previously reported on pseudo-random tool-paths that fill any aperture but cross themselves nowhere – which avoids the double removals when paths cross. These paths are appropriate for the relatively slow tool-path motions of CNC machines. However, the high-speed motions that robots can deliver, open a new paradigm where the tool does not follow rectilinear or spiral tracks, but curved paths that cross essentially everywhere. We demonstrate how these paths can be optimised for effective smoothing, and present experimental results to justify this.

We then report on progress in an adventurous project that is marrying robots and Zeeko machines to automate currently manual operations on the Zeeko platform, such as changing tools, changing (smaller) parts, deploying on-machine metrology instrumentation, and washing-down prior to metrology. We demonstrate how automating such operations in a unified software environment, constitute important steps towards our future vision of the fully autonomous manufacturing cell.

We conclude by showing how the combination of robotic processing per se, and robotic automation of CNC machines, are expected to have significant impact throughout the optical manufacturing community and beyond.

9575-13, Session 3

Evaluation and control of spatial frequency errors in reflective telescopes

Xue-jun Zhang, Li-gong Zheng, Xuefeng Zeng, Changchun Institute of Optics, Fine Mechanics and Physics (China)

In this paper, the influence on the image quality of manufacturing residual errors was studied. By analyzing the statistical distribution characteristics of the residual errors and their effects on PSF and MTF, we divided those errors into low, middle and high frequency domains using the unit “cycles per aperture”. For current deterministic polishing processes, such as MRF or IBF, there are two types of mid-frequency errors, the algorithm intrinsic and the tool path induced. We studied several deconvolution algorithms and their contributions to so called “ringing effect”, and proposed a conformal transform approach to pre-process the data map prior to deconvolution operation. It was found that the algorithm intrinsic mid-frequency errors could be reduced. Finally, tool path optimization methods in MRF or IBF process were presented.

9575-14, Session 3

Combined fabrication technique for ultra-precision optical surfaces

Hao Hu, Wenlin Liao, Yifan Dai, Feng Shi, Guilin Wang, National Univ. of Defense Technology (China)

The specifications of surface accuracy and surface smoothness made on optical components are becoming more and more stringent with the performance improvement of modern optical systems. Nowadays, deterministic figuring technologies are developed to meet the growing demands of such high-precision optical components. This presentation will report the fabrication process for ultra-precision optical surfaces in our laboratory, which combines magnetorheological finishing (MRF), smoothing polishing (SP) and ion beam figuring (IBF). We will highlight their applications for the nanometer/sub-nanometer fabrication of high-performance optics.

IBF is a highly deterministic, highly stable, non-contact method, and can provide an ultra-precise fabrication method for optical surfaces. All these advantages distinguish IBF as the final procedure for high precision optics manufacture. However, there are still some issues existing in IBF for high precision surfaces, such as its low material removal rate and sensitivity to mid-to-high frequency surface errors. Fortunately, MRF is a deterministic method with very high convergence and high material removal rates and SP is excellent in eliminating mid-to-high spatial frequency surface ripples and high slope errors. These two polishing methods just can overcome the disadvantages of the IBF process. Consequently, the combined fabrication technique is developed to fabricate the ultra-precision optical surfaces with high machining efficiency. Additionally, ultra-smooth surfaces are also vitally important for these high-performance optical components. The complex microscopic morphology evolution is investigated to improve the surface smoothness during the combined polishing process. The final experiments made on some spherical and aspherical samples will validate the high-efficiency of this combined fabrication technique for ultra-precision and ultra-smooth optical surfaces.

9575-57, Session 3

Correction of mid-spatial-frequency errors by smoothing in spin motion for CCOS

Yizhong Zhang, Chaoyang Wei, Jianda Shao, Xueke Xu, Shijie Liu, Chen Hu, Haichao Zhang, Haojin Gu, Shanghai Institute of Optics and Fine Mechanics (China)

Smoothing is a convenient and efficient way to correct mid-spatial-frequency errors. Quantifying the smoothing effect allows improvements in efficiency for finishing precision optics. A series experiments in spin motion are performed to study the smoothing effects about correcting mid-spatial-frequency errors. Some of them use a same pitch tool at different spinning speed, and others at a same spinning speed with different tools. Introduced and improved Shu’s model to describe and compare the smoothing efficiency with different spinning speed and different tools. From the experimental results, the mid-spatial-frequency errors on the initial surface were nearly smoothed out after the process in spin motion and the number of smoothing times can be estimated by the model before the process. Meanwhile this method was also applied to smooth the aspherical component, which has an obvious mid-spatial-frequency errors after Magnetorheological Finishing processing. As a result, a high precision aspheric optical component was obtained with PV=0.1? and RMS=0.02?.

9575-15, Session 4

Spectral characteristics and control of machining errors of KDP optical elements in ultra-precision turning

Guilin Wang, Feng Shi, Shengyi Li, Wenlin Liao, Furen Li, National Univ. of Defense Technology (China)

The laser induced damage threshold of optical elements can be reduced by the machining errors, and the performances of high-power laser system will be badly influenced. Therefore, the magnitude and the distributing features of machining errors must be strictly controlled. The ultra-precision turning technology is suitable for manufacturing KDP optical elements which are used as frequency switching unit in high-power laser system, but the machining stripes are easily to be found after ultra-precision turning, and this can introduce the working damage of KDP elements. In the presentation, the machining characteristics and the error morphology of KDP elements are analyzed in the process of ultra-precision turning,

and the measuring results show that low frequency errors are dominant on the machining surface. The relation between machining parameters and error spectrum are studied by using the power spectral density (PSD). The results show that the feeding rate and the spindle speed have obvious influences on the PSD of surface errors, the cutting depth has hardly any influence on the spectrum of PSD, but it will clearly affect the magnitude of PSD. Furthermore, the reasonable machining parameters are given for ultra-precision turning of KDP elements. Taking a typical KDP element as machining object, the distributing features and the microscopic evolution of surface errors are investigated. The PSD of low frequency errors is controlled within 103 nm2•mm by using the compensating turning method, the PSD of mid-to-high frequency errors is under "Not-to-Exceed" line applied in national ignition facility which is presented by Lawrence Livermore National Laboratory, and the working requirements for high-power laser system can be well satisfied.

9575-16, Session 4

Monolithical freeform element

Sven R. Kiontke, asphericon GmbH (Germany)

For 10 years there has been the asphere as one of the new products to be accepted by the market. All parts of the chain design, production and measurement needed to lear how to treat the asphere and what it is helpful for. The aspherical optical element now is established and accepted as an equal optical element between other as a fast growing part of all the optical elements.

Now we are focusing onto the next new element with a lot of potential, the optical freeform surface. Manufacturing results will be shown for fully tolerance optic including manufacturing, setup and optics configurations including measurement setup. The element itself is a monolith consisting of several optical surfaces that have to be aligned properly to each other. All surfaces are measured for surface form tolerance (irregularity, slope, Zernike, pv). In addition roughness will be qualified as well as reference surfaces.

9575-17, Session 4

The fabrication of freeform optics

Todd Blalock, Kate Medicus, Jessica D. Nelson, Optimax Systems, Inc. (United States)

Freeform surfaces on optical components have become an important design tool for optical designers. Non-rotationally symmetric optical surfaces have made solving complex optical problems easier. The manufacturing and testing of these surfaces has been the technical hurdle in freeform optic's wide-spread use. CNC optics manufacturing technology has made the fabrication of optical components more deterministic and streamlined for traditional optics and aspheres. Optimax has developed a robust freeform optical fabrication CNC process that includes generation, high speed VIBE polishing, sub-aperture figure correction, surface smoothing and testing of freeform surfaces. Two of the main benefits of the VIBE process are the high speed associated with the process and the ability to maintain the form introduced during generation. The process flow consists of

CNC Generate --> Pre-Polish --> Measurement --> Deterministic Figure Correction --> VIBE Smoothing

The VIBE polishing process is shown to work well with freeform surface by the full-aperture tooling and optimized compliant layers on the tool. The stiffness of the compliant layer is selected for optimal figure correction. The VIBE polishing process then removes the mid-spatial frequencies. This process has been shown to limit the amount of mid-spatial frequency surface error on the optic. We will show the reduction of mid-spatial frequencies and form error in a variety of freeform optical shapes using specialized tooling and processes.

9575-19, Session 4

Ion beam figuring of glass moulds for the integration of x-ray optics

Mauro Ghigo, Gabriele Valsecchi, Stefano Basso, Marta Civitani, Enrico G. Mattaini, Giovanni Pareschi, Giorgia Sironi, INAF - Osservatorio Astronomico di Brera (Italy)

The INAF-Astronomical Observatory of Brera (INAF-OAB) is studying the glass technology needed to reach the 5 arcsec requested to the ATHENA telescope optics, currently approved by ESA. During this study we have developed a direct hot slumping technique assisted by pressure, in which the glass optical surface is in contact with a ceramic mould and a pressure is applied in order to force the glass to copy the mould shape. After this step, the integration of the slumped glass foils is made by means of the IMA, a purpose built machine, able to stack the foils and create the X-ray Optical Unit, the building block of the final optical module. During this phase the foils are held in position and pressed against an integration mould made of glass, with a very precise shape since it controls the final optical performances of the individual glass segments. To improve the optical figure of these moulds, we foresee the use of the Ion Beam Figuring that is available internally in OAB. The institute has two facilities, one for large optics up to 1.4 meters in diameter and a second one for relatively small optics, up to 350 mm. The aim of this work is to bring the optical accuracy of the present moulds from 5-6 arcsec down to 2 arcsec HEW. Since the moulds are made in BK7 and it is known that this material can suffer distortions deriving from the thermal load from the ion source beam, this issue must be taken into account properly. In this paper we describe the achieved results in the correction of the integration moulds, and the steps implemented to mitigate the thermal load.

9575-49, Session 4

Measuring skew in average surface roughness as a function of surface preparation

Mark T. Stahl, NASA Marshall Space Flight Ctr. (United States)

Characterizing surface roughness is important for predicting optical performance. Better measurement of surface roughness reduces polishing time, saves money and allows the science requirements to be better defined. This study characterizes statistics of average surface roughness as a function of processing time. Average surface roughness is measured at 81 locations using a Zygo white light interferometer at regular intervals during the polishing process. Each data set is fit with various Normal and Largest Extreme Value (LEV) distributions; then tested for goodness of fit. We show that the skew in the data changes as a function of polishing time.

9575-20, Session 5

Development of practical Ge immersion grating

Takashi Sukegawa, Takeshi Suzuki, Yukinobu Okura, Yukiya Enokida, Canon Inc. (Japan)

Immersion grating is a powerful optical device for the infrared high-resolution spectroscope.(Marsh et al.(2007),Kuzmenko et al.(2006)) Ge is the best material for a mid-infrared immersion grating because of Ge has very large reflective index (n=4.0). On the other hands, there is no practical Ge immersion grating around 5um use. Our original free-forming machine has accuracy of a few nano-meter in positioning and stability. We already fabricated the large CdZnTe immersion grating with groove area (77mm x 21mm) which was found to have the scattered energy loss at 5 um was 0.07 %, the ghost intensity ratio at 5 um was < 0.0026%. We are developing Ge immersion grating that can be a good solution for high-resolution

infrared spectroscopy with the large ground-based / space telescopes and laser frequency comb. Our first Ge immersion grating has the entrance clear aperture of 19mm x 19mm, grooved area of 75mm(ruled direction) x 19mm(groove width), the groove pitch of 144.44um and the blaze angle of 75 degrees. Even this small size, the theoretical spectral resolution is 120,000 at 5um. And second Ge immersion grating has the groove pitch of 91.74um. The typical grooves performance are the spacing accuracy of <5nmRMS, the surface roughness of <2nmRMS and the surface irregularity of 52nm(PV) / 12nm(RMS) at first grating and 45nm(PV) / 5nm(RMS) at second grating. .In this paper, we report our development of practical Ge immersion grating especially optical performance results and also discuss further development for larger size (> 100mm) and productivity.

9575-21, Session 5

Status of the Advanced Mirror Technology Development (AMTD) phase 2 1.5m ULE mirror

Robert M. Egerman, Gary W. Matthews, Albert J. Ferland, Matthew Johnson, Exelis Inc. (United States)

The Decadal Survey stated that an advanced large-aperture ultraviolet, optical, near-infrared (UVOIR) telescope is required to enable the next generation of compelling astrophysics and exoplanet science; and, that present technology is not mature enough to affordably build and launch any potential UVOIR mission concept. Under Science and Technology funding, NASA's Marshall Space Flight Center (MSFC) and Exelis have developed a more cost effective process to make up to 4m monolithic spaceflight UV quality, low areal density, thermally and dynamically stable primary mirrors. Under a Phase I program, a proof of concept mirror was completed at Exelis and tested down to 250K at MSFC which would allow imaging out to 2.5 microns. In 2014, Exelis and NASA started a Phase II program to design and build a 1.5m mirror to demonstrate lateral scalability to a 4m monolithic primary mirror. The current status of the Phase II development program will be provided along with a Phase II program summary

9575-22, Session 5

Improving profitability through slurry management: A look at the impact of slurry pH on various glass types

Abigail R. Hooper, Harry W. Sarkas, Nathan Hoffmann, Kevin Cureton, Nanophase Technologies Corp. (United States)

When building an optical system, optical fabricators and designers meticulously choose the glass type for their application knowing that each one will have different chemical, thermal and mechanical properties. As the requirements for new optical systems have grown more demanding, the range of available glass types has vastly expanded and the specifications on the produced products have grown tighter. In an attempt to simplify processes and streamline consumable purchases, optical polishing houses often rely on one polishing slurry to manage these vast array of glass types. An unforeseen consequence of these practices can be a reduction in productivity by reduced removal rate, poor yields and frequent re-work all translating into higher costs and reduced profitability.

In this paper, the authors will examine the impact slurry pH has on glass types of different compositions and chemical, thermal and mechanical properties when using a double-sided polishing process. Experiments will use material removal rate, surface quality and surface figure to provide insight into improving process control of changing glass types. Further guidance will be provided on how simple on-site monitoring and adjustment can deliver improved profitability on challenging substrates.

9575-23, Session 5

Material removal characteristics of orthogonal velocity polishing tool for efficient fabrication of CVD SiC mirror surfaces

Hyunju Seo, Yonsei Univ. (Korea, Republic of) and Korea Astronomy and Space Science Institute (Korea, Republic of); Jeong-Yeol Han, Korea Astronomy and Space Science Institute (Korea, Republic of); Sug-Whan Kim, Yonsei Univ. (Korea, Republic of); Sehyun Seong, SphereDyne Co., Ltd. (Korea, Republic of) and Yonsei Univ. (Korea, Republic of); Siyoung Yoon, Kyungmook Lee, Samsung Thales Co., Ltd. (Korea, Republic of); Haengbok Lee, Agency for Defense Development (Korea, Republic of)

Today, CVD SiC mirrors of small and medium sizes are available in the market. However, it is well known to the community that the key surface fabrication processes and, in particular, the material removal characteristics of the CVD SiC mirror surface varies sensitively depending on the shop floor polishing and figuring conditions. We investigated the material removal characteristics of CVD SiC mirror surfaces using a new and patented polishing tool called orthogonal velocity tool (OVT) that employs two orthogonal velocity fields generated simultaneously during polishing and figuring machine runs. We built an in-house OVT machine and its operating principle allows for generation of pseudo Gaussian shapes of material removal from the target surface. The shapes are very similar to the tool influence functions (TIFs) of other polishing machine such as IRP series polishing machines from Zeeko. Using two CVD SiC mirrors of 150 mm in diameter and flat surface, we ran trial material removal experiments over the machine run parameter ranges from 12.901 to 25.867 psi in pressure, 0.086 m/sec to 0.147 m/sec in tool linear velocity, and 5 to 15 sec in dwell time. An in-house developed data analysis program was used to obtain a number of Gaussian shaped TIFs and the resulting material removal coefficient varies from 3.124 to 11.954 um/psi hour m/sec with the mean value to 6.140 ± 1.377(standard deviation). We report the technical details of the new OVT machine and the data analysis program, of the experiments and the results together with the implications to the future development of the machine and process for large CVD SiC mirror surfaces.

9575-24, Session 5

Surface errors in the course of machining precision optics

Rolf Rascher, Christine Wuensche, Heiko Biskup, Alexander Haberl, Hochschule Deggendorf Technologiecampus Teisnach (Germany)

Precision optical components are usually machined by grinding and polishing in several steps with increasing accuracy. Spherical surfaces will be finished in a last step with large tools to smooth the surface. The requested surface accuracy of non-spherical surfaces only can be achieved with tools in point contact to the surface. So called mid-frequency errors MSFE accumulate with zonal processes.

This work is on the formation of spatial errors from grinding to polishing by conducting an analysis of the surfaces in their machining steps by contact and non-contact interferometric methods. In both cases all describing data of the surface are collected as far as the technology allows. The errors on the surface can be distinguished as described in DIN 4760. 3rd order errors are usually so called MSFE.

By appropriate filtering of the measured data frequencies of errors can be suppressed in a manner that only defined spatial frequencies will be shown in the surface plot. It can be observed that some frequencies already may be formed in the early machining steps like grinding and main-polishing. Additionally it is known that MSFE can be produced by the process itself and other side effects.

Beside a description of spatial errors based on the limits of measurement technologies, different formation mechanisms for selected spatial

frequencies are presented. A correction may be only possible by tools that have a lateral size below half of the wavelength of the error structure. The presented considerations may be used to develop proposals to handle spatial errors.

9575-59, Session 5

The effect of HF etching on the surface quality and figure of fused silica optics

Jiafeng Xu, Xueke Xu, Chaoyang Wei, Wenlan Gao, Minghong Yang, Jianda Shao, Shijie Liu, Shanghai Institute of Optics and Fine Mechanics (China)

Impurity cation in polishing layer contributes to the deposition of etching product. Residual micron grinding cracks and submicron crack pits are etched into digs which are not more than 1?m deep. These digs worsen the surface roughness. Digs also frosts the sample. Abrasives of large size or the agglomeration of abrasives creates submillimeter scratches. These short scratches appear as sparkling points under the high power lamp when they are exposed through etching. The average total length of millimeter scratches on single surface is over 200 mm. Not all millimeter scratches can be exposed until removal depth of up to 2?m. Etching on the edge of the upper surface of samples placed horizontally goes faster than on the inside parts, and the surface of samples placed vertically assume a more complicated removal distribution, which can be both explained in terms of “fringe tip effect” and the diffusion of etching product and acid. How surface PV evolves is dependent of the initial surface figure feature as well as the etching removal distribution.

9575-26, Session 6

Using frictional power to model LSST removal with conventional abrasives

Richard G. Allen, William H. Hubler, The Univ. of Arizona (United States)

The stressed lap on the Large Polishing Machine (LPM) at the Steward Observatory Mirror Lab has recently been used to polish the M1 and M3 surfaces of the 8.4-m mirror for the Large Synoptic Survey Telescope (LSST). Loadcells in the three 4-bar links that connect this lap to the spindle of the machine allow the translational forces and torque on the lap to be measured once a second. These force readings and all other available machine parameters are sent to a history file that can be used to create 2-D removal maps after the stroke is finished. While the Preston equation has been used for many years to predict removal in conventional polishing processes, we have adopted a new equation that assumes that removal is proportional to the energy that is transferred from the lap to the substrate via friction. Specifically, the instantaneous removal rate at any point is defined to be the product of four parameters – an energy conversion factor called the Allen constant, the coefficient of friction, the lap pressure, and the speed of the lap. The Allen constant is the ratio of volumetric removal to frictional energy for a particular combination of pad material, abrasive, and substrate. Because the removal calculations take into account changes in the coefficient of friction between the lap and mirror, our 2-D maps usually correlate well with optical data. Removal maps for future polishing strokes are created in simulations that track the position and speed of individual lap pads.

9575-27, Session 6

Influence of coolant on ductile mode processing of binderless nanocrystalline tungsten carbide through ultraprecision diamond turning

Marius Doetz, Fritz Klocke, Olaf Dambon, Fraunhofer-Institut für Produktionstechnologie (Germany); Oliver W. Fähnle, FISBA OPTIK AG (Switzerland)

Molds made of tungsten carbide are typically used for the replicative mass production of glass lenses by precision glass molding due to their high temperature hardness and the chemical behavior of the material in contact with glass. For the manufacturing of these inserts, the ultra-precision grinding process with a subsequent manual polishing operation is conventionally applied. These processes are time consuming and have a relatively low reproducibility.

An alternative manufacturing technology, with a high predictability and efficiency, which additionally allows a higher geometrical flexibility, is the diamond turning technique. However, the extreme hardness and the chemical properties of tungsten carbide lead to significant tool wear and therefore the impossibility of machining the work pieces in an economical way. One approach to enlarge the tool life is to affect the contact zone between tool and work piece by the use of special cutting fluids.

This publication emphasizes on the most recent investigations and results in direct machining of nano-grained tungsten carbide with mono crystal diamonds under the influence of various kinds of cutting fluids. Therefore basic ruling experiments were performed, where the tool performed a linear movement with a steadily increasing depth of cut. As the ductile cutting mechanism is a prerequisite for the optical manufacturing of tungsten carbide these experiments serve the purpose for establish the influence of different cutting fluid characteristics on the cutting performance of mono crystal diamonds.

9575-28, Session 6

Optimizing computer control ball polishing of spherical surfaces

Rasool Koosha, Peiman Mosaddegh, Hosein Hashemi, Isfahan Univ. of Technology (Iran, Islamic Republic of)

About half a century ago, computer controlled-polishing (CCP) was represented as a respond to great demand for precision glass manufacturing. Since then, CCP is developed to challenge the difficulties of manufacturing of more complex optical components. Simulation of polishing process and optimization of dwell time are the most prominent key factors of CCP in which numerous papers are published. In this paper, a new model based on discretizing tool path with sub-millimeter distances in length is presented to simulate polishing process. As a result, complex polishing tool path as spiral or epicyclical tool path can be easily and precisely modeled with 50-100 micron accuracy. Converting continuous tool path to discrete points with small steps would improve surface quality in an optimum time and it also reduces fluctuation in tool feed rate. This smooth gradient in feed rate can improve final quality and prevent any damage to polishing machine. Then, a fuzzy algorithm is programmed to optimize the dwell time of polishing process. Considering initial surface error under tool positions and tool influence removal rate, the method calculates optimum dwell time distribution to reduce surface roughness in a short period of time. Both polishing simulation and dwell time fuzzy optimization algorithms are easy to program and could be conducted to operate the CCP on a 3 axis CNC machine. The methodology developed in this study is used for ball polishing of spherical lenses. To establish the authenticity of represented method, a BK7 flat lens with 130 mm in diameter and 320 mm radius in curvature was selected to perform CCP process. The result of initial surface measurement shows 1.114μm of surface roughness for PV (Peak to Valley) and 175 nm for rms (Root Mean Square). The represented method was applied to calculate the optimum dwell time distribution over a spiral tool path with 1 mm in step over. Based on the simulation results, the 3axis CNC machine was programmed to operate polishing process. Based on the final surface measurement, the surface roughness was reduced to 394 nm for PV and 74 nm for RMS. The experimental results show that surface error declined by 64% in PV and 57% in rms which are in good agreement with the modeling.

9575-58, Session 6

The effect of the pad groove feature on the material removal rate and mid-spatial frequency error in CCOS

Jianwei Ji, Chaoyang Wei, Shijie Liu, Xueke Xu, Jianda Shao, Shanghai Institute of Optics and Fine Mechanics (China)

One of important factors that influencing the polishing results is pad groove feature in the process of CCOS(Computer Controlled Optical Surfacing). A comparative study has been done on material removal rate and mid-spatial frequency error with pads which have different groove feature. Firstly, derive the removal functions in the smooth running mode and carried out the experiments according to suitable parameters with pads which have different groove feature, and the experimental results were explained. Furthermore, a series of simulations about mid-spatial frequency error which were caused by pads groove were done using the numerical superposition method in the smooth running mode, the groove feature including groove patterns, groove width, and groove intensive degree , and the simulation results consistent with the experimental results. This lay the foundation for NC machining which have high material removal rate and low mid-spatial frequency error.

9575-60, Session 6

Influence of temperature distribution in the workpiece-lap interface on surface figure controlling during continuous polishing

Meijuan Hong, Xueke Xu, Minghong Yang, Chaoyang Wei, Shijie Liu, Jianda Shao, Shanghai Institute of Optics and Fine Mechanics (China)

During continuous polishing, temperature is the main source of processing uncertainty. However, few scholars have studied the temperature distribution in the workpiece-lap interface, most of their attention are paid to the environment temperature and its variation. It's our main approach to achieve deterministic processing that we study the temperature distribution in the workpiece-lap interface and find out its influence on surface figure controlling. Hence, we explored the temperature distribution in the workpiece-lap interface by simulation and actual measurement using infrared thermal imager. And, simulations have been done to research the diversity response to temperature distribution of different material workpieces, which coincides with the experiments. We find that since when temperature changes, the workpieces will have different deformation, even though they are all well matched to the lap (which means, by this time, they have the same surface figure), when they are done of polishing and off the lap, the temperature changes, they will have different deformation (or we can call it shrink), which results in different surface figure. The temperature distribution in the Workpiece-lap Interface plays a crucial role in surface figure controlling. To achieve Deterministic processing, we attempted many methods to decrease the effects of temperature distribution, such as circulation slurry injection, broaden and deepen the Groove-Scale, which have been tested in our experiments and turned out to be useful.

9575-25, Session PMon

Influence of different rigid tool groove in polishing process

Kai Meng, Fan Wu, Yongjian Wan, Institute of Optics and Electronics (China); Hsing Yu Wu, Univ. College London (United Kingdom)

During optical polishing process, there are a lot of factors which affect the polishing results like material removal rate and surface roughness. According to Preston equation, the pressure between tool and processed surface affects the material removal rate effectively. However, different tool has different groove which causes different tool deformation and pressure distribution. This paper mainly focuses on the deformation and pressure of rigid tool using Finite Element Method (FEM) and statistical analysis. Four kinds of tool groove pattern types are investigated on this paper: non-groove, grid grove, annular groove and radial groove and each tool has two different loading conditions. Firstly, the different tool deformation and pressure models are built using FEM. Secondly, we got the deformation and pressure data on contact regions. Thirdly, data on different part faces and edges of the groove are separated. Finally, these separated data are analyzed using statistical method, which indicates that the tool groove needs more optimization and the edge effects of groove needs more attention and research as edge tool influence function control.

9575-45, Session PMon

Investigation of rapidly-solidified aluminum with diamond turning and magnetorheological finishing (MRF) process

Yuan-Chieh Cheng, Wei-Yao Hsu, Ching-Hsiang Kuo, Instrument Technology Research Ctr. (Taiwan); Khaled Abou-El-Hossein, Timothy Otieno, Nelson Mandela Metropolitan Univ. (South Africa)

The metal mirror has been widely used in optical application for a longtime. Especially the aluminum 6061 is often considered the preferred material for manufacturing optical components for ground-based astronomical applications. One reason for using this material is its high specific stiffness and excellent thermal properties. However, a large amount of data exists for this material and commercially available aluminum 6061 using single point diamond turning (SPDT) and polishing process can achieve surface roughness values of approximately 2 to 4 nm, which is adequate for applications that involve the infrared spectral range, but not for the shorter spectral range. A novel aluminum material, fabricated using a rapid solidification process that is equivalent to the conventional aluminum 6061 alloy grade has been used in optical applications in recent years because of its smaller grain size. In this study, the surface quality of the rapid solidification aluminum after single point diamond turning and followed by magnetorheological finish (MRF) process is investigated and compared with conventional aluminum 6061. Both the surface roughness Ra and power spectral density (PSD) were evaluated using white light interferometers. Finally, indicators such as optimal fabrication parameter combination and optical performance are discussed.

9575-46, Session PMon

Optical diffraction interpretation: an alternative to interferometers

Stephane Bouillet, Commissariat à l'Énergie Atomique (France)

The Laser MégaJoule (LMJ) is a French high power laser project that requires thousands of large optical components. The wavefront performances of all those optics are critical to achieve the desired focal spot shape and to limit the hot spots that could damage the components. Fizeau interferometers and interferometric microscopes are the most commonly used tools to cover the whole range of interesting spatial frequencies. Anyway, in some particular cases like diffractive and/or coated and/or aspheric optics, an interferometric set-up becomes very expensive with the need to build a costly reference component or a specific to-the-wavelength designed interferometer. Despite the increasing spatial resolution of Fizeau interferometers, it may even not do the job, if you are trying to access the highest spatial frequencies of a transmitted wavefront for instance. The method we developed is based upon laser beam diffraction intermediate

field measurements and their interpretation with a Fourier analysis and the Talbot effect theory. We demonstrated in previous papers that it is a credible alternative to classical methods. In this paper we go further by analyzing main error sources (source, pupil shape and position, ghost light...) and discussing main practical difficulties. We also show a qualification of the method thanks to cross-measurements with a Fizeau interferometer.

9575-47, Session PMon

Effect of aging on photoelectrical properties of AlInGaP LEDs

Donatas Me?kauskas, Laurynas Daba?inskas, Arturas ?ukauskas, Vilnius Univ. (Lithuania)

One of the advantages of light-emitting diodes (LEDs) against conventional sources of light is a slow degradation rather an abrupt burn-out. However, the physical reasons of the degradation of LEDs are not completely understood so far and require searching for new approaches to the characterization of LEDs. In this work we present results on the effect of aging on photoelectrical properties of AlGaInP LEDs (short-circuit photocurrent and photoconductivity sampled from differential photovoltage under excitation by modulated light). Commercial high-power AlGaInP LEDs with the peak wavelength of 640 nm were investigated during the stress by rated forward current. At the interruptions of the aging process, the photoelectrical properties of the LEDs were investigated using photoexcitation by shorter-wavelength radiation. Also, common I-V and L-I characteristics were measured. After about three hours of aging, the LEDs exhibited a minimum of short-circuit photocurrent, the highest effect of photoconductivity on the reduction of series resistance, the highest value of the ideality factor, and a drop of radiant output at low forward currents. Within the subsequent 1000 hours, these parameters restored to their initial values. The observed non-monotonous behavior of the photoelectrical properties of LEDs under aging was attributed to the rearrangement of defects in the semiconductor structure due to self-annealing caused by electrical, thermal and photo-induced processes. Our results indicate on the usefulness of photoelectrical properties for understanding the aging effects of LEDs.

9575-48, Session PMon

Noninvasive method for determination of parameters of cemented doublet

Petr Pokorn?, Antonín Mik?, Jirí Novák, Pavel Novák, Czech Technical Univ. in Prague (Czech Republic)

A cemented doublet is a very frequently used optical element in the design of various optical systems, which is composed of two lenses cemented together where the second radius of curvature of the first lens and the first radius of curvature of the second lens is identical. In practice it is often needed to analyze the unknown geometrical and optical parameters of the cemented doublet in a non-destructive way without a separation of individual lenses of the doublet.

In our work we propose and analyze an experimental method for the determination of internal parameters of the doublet on a basis of measurement external geometric parameters and paraxial properties and aberrations of the doublet. We describe a procedure for the calculation of unknown parameters of the doublet from experimentally measured geometrical and optical parameters of the doublet using an optimization method. The method calculates unknown parameters (central thicknesses, refractive indices, and second radius of curvature) in such a way that it corresponds to experimentally measured parameters of the doublet. It is also analyzed an influence of individual measured input parameters on uncertainties in calculated geometrical and optical parameters of the doublet. This method is nondestructive and one can determine internal parameters of the doublet without any damage to the doublet. The proposed method and analysis can be also used for the determination of parameters of fluidic lenses with a variable focal length. The method is presented on several examples.

9575-50, Session PMon

Detection of subsurface defects and measurement of thickness of screen layers made of graphene and carbon nanotubes with application of full-field optical coherence tomography in Linnik configuration

Paulina Mlynarska, Slawomir Tomczewski, Anna Paku?a, Grzegorz Wróblewski, Marcin Sloma, Leszek Salbut, Warsaw Univ. of Technology (Poland)

Optical coherence tomography (OCT) is a noncontact and a nondestructive interferometric method which allows visualization of an internal structure of investigated sample. Till now it has found many applications in measurements of biological tissues, technical materials and conservation of art. Optical coherence tomography in full-field configuration is a great technique for visualization of subsurface structures of measured sample with high resolution. In this technique en-face data acquisition is applied, enabled by application of high numerical aperture microscope objectives therefore the depth of focus. Microscopes objectives allow obtaining ultra high transverse resolution like in traditional microscopy. Additionally light source with broad spectrum, like cheap incandescent lamps, allow obtaining micrometer scale axial resolution.

In this paper authors present application of full-field optical coherence tomography with Linnik microscope for measurement of thickness of screen layers made of graphene and carbone nanotubes. Thickness has a huge impact on a layer resistivity. There is a direct correlation between the thickness of graphene layer and its electrical resistance. Graphene is a new and very promising material, which is durable, flexible and has a good adhesion to diverse substrates. It gives a theoretical possibility to create flexible electronics, such as graphene bendable screens. The aim is to obtain uniformly luminous surface - that means a surface of constant resistance. To reach this goal a method of precise measurement of the graphene layer thickness is required. Using proposed OCT setup we can evaluate the quality of printed layer and detect subsurface damages.

9575-51, Session PMon

Subsurface damage characterization with nonlinear high-numerical microscopy

Phat Lu, Thomas D. Milster, The Univ. of Arizona (United States)

Sub-surface damage characterization occurs in semiconductor device fabrication, like diamond turning and milling. Third harmonic generation (THG) microscopy can help to characterize subsurface damage, because nanometer sized asperities caused by defects amplify the THG signal. The goal is to investigate the theory of the THG field of enhancement due to the defects, as well as the possibility to apply the theory in surface and subsurface characterization. With the use of solid immersion lens, a higher resolution can be achieve at the same time.

9575-52, Session PMon

Comparison of experimental and simulation results of pupil plane polarization effects in a 1.6 numerical aperture solid immersion lens microscope from surface and subsurface damage

Victor E. Densmore, Phat Lu, Young-Sik Kim, The Univ. of Arizona (United States); Geon-Hee Kim, Korea Basic Science Institute (Korea, Republic of); Thomas D. Milster,

The Univ. of Arizona (United States)

Precision fabrication of brittle material surfaces is an important aspect of many high-technology products. These fabrication techniques often produce some amount of surface microstructure and sub-surface damage, both of which can be detrimental to device performance. Therefore, testing for surface variations and subsurface damage is critical for the successful production of high-performance devices. A solid immersion lens microscope (NA=1.6) has been designed to provide a means for high resolution, non-destructive testing of optical surfaces by using pupil plane polarimetry. Relationships between the defect geometries and polarization effects in the pupil plane are not known a priori. As such, simulation methods adapting rigorously coupled wave theory are explored and compared to experimental data. Reference samples are precision fabricated with nano-features from a focused ion beam machine to serve as a baseline and validate the high-NA solid immersion lens microscope in conjunction with polarization modulated pupil plane imaging as a means for surface and subsurface damage detection in optical materials.

9575-53, Session PMon

Designing null phase screens to test a fast plano-convex aspheric lens

Jesús DelOlmo-Márquez, Diana N. Castán-Ricaño, Maximino M. Avendaño-Alejo, Jose Rufino Díaz-Uribe, Univ. Nacional Autónoma de México (Mexico)

We have obtained a formula to represent the wavefront produced by a plano-convex aspheric lens with symmetry of revolution considering a plane wavefront propagating parallel to the optical axis and impinging on the refracting surface, it is called a phase-zero wavefront. As is well know the phase-zero wavefront is the first wavefront to be out of the optical system. Using a concept of differential geometry called parallel curves it is possible to obtain an analytic formula to represent the wavefront propagated at arbitrary distances through the optical axis. We modify an interferometer Tywman-Green in order to evaluate quantitatively a plano-convex aspheric lens as follow: In the reference beam we use a plane mirror and the test beam we use a light spatial modulator SLM to compensate the phase produced by the lens under test. It will be called a null phase interferometer. The main idea is to recombine both wavefronts in order to get a null interferogram, otherwise we will associate the patterns of the interferogram to deformations of the lens under test. The null phase screens are formed with concentric circumferences assuming different gray levels printed on SLM.

9575-54, Session PMon

Null screens type Hartmann to test simple lenses

Alfredo Gozález-Galindo, Gabriel Castillo-Santiago, Maximino M. Avendaño-Alejo, Jose Rufino Díaz-Uribe, Univ. Nacional Autónoma de México (Mexico)

In order to evaluate either qualitative or quantitatively the shape of fast plano-convex aspheric lenses, a method to design null screens type Ronchi-Hartmann is proposed. The null screens are formed with non-uniform spots, which allow us to have uniform images at detection's plane. The screens are printed on a foil sheet and placed in front of the lens under test, they are illuminated with a collimated monochromatic beam propagating along the optical axis, in such a way that through the process of refraction will form a uniform spot patterns which are recorded at a predefined plane of detection, finally processing its image recorded we could be able to get a quantitative evaluation of the lens under test. The designs of these null screens are based on the equations of the caustic surface produced by refraction. The null screens can be printed in gray levels on a foil sheet. A preliminary test for a fast plano-convex aspheric lens with F/# = 0:8 is presented in this work. This method also could be applied to alignment of optical systems.

9575-55, Session PMon

Fringe projection method to evaluate the quality of the shape of a parabolic solar collector

Agustín Santiago-Alvarado, Univ. Tecnológica de la Mixteca (Mexico); Eduardo Torres Moreno, Victor I. Moreno-Oliva, Univ. del Istmo (Mexico); Moisés E. Ramírez Guzmán, Cuauhtémoc H. Castañeda Roldan, Ángel S. Cruz-Félix, Univ. Tecnológica de la Mixteca (Mexico)

Fringe projection technique has been widely used for 3D objects reconstruction and some of the reported applications of this technique include the digitalization of museum archeological pieces and the evaluation of reflective surfaces. In this work we apply this technique to evaluate the surface shape of a parabolic trough solar collector that employs wind turbines and are used in low power aerogenerators. The evaluation process consist in the projection of lines over the surface under study and to capture the reflexion of such lines by means of a CCD, later a pre-processing method is performed for the smoothing, thinning, skeletonization and discretization of the captured image fringes. Finally, the spot centroids are found to perform the integration of the information in order to obtain the surface shape. We apply genetic algorithms and linear programming to obtain the analytical form of the best fit shape. We show preliminary results.

9575-56, Session PMon

Estimation of optimal parameters of material removal by milling to minimize the surface roughness

Agustín Santiago-Alvarado, Orquídea Sánchez López, Ignacio Hernández Castillo, Cuauhtémoc H. Castañeda Roldán, Ángel S. Cruz-Félix, Univ. Tecnológica de la Mixteca (Mexico)

Different processes of material removal are used in the manufacture of industrial components and milling by computerized numerical control (CNC) is one of the most used; several machining milling parameters have to be considered such like the cut velocity, feed rate, work piece material and coating of the cutting tool among others. The election of the parameter have influence in the surface quality of the finished piece, and they determine the manufacture cost. In this work we determine the optimal values of the following milling parameters: cut velocity, cut depth and feed rate. We employ stainless steel as machine tool and we used the surface response method and genetic algorithms in order to obtain mathematical models to estimate surface roughness. On the other hand, we employed an interferometric test and a profilometer for the measurement of the roughness of the finished piece.

9575-30, Session 7

Measuring the tilt and decenter of bi-aspheric lenses

Scott DeFisher, Mitchell Sedore, David E. Mohring, OptiPro Systems (United States)

Wedge and centration are common measures for optical lenses and are characterized using accurate spindles and run-out indicators. These parameters are both defined relative to the edge of a lens. Tilt and decenter are defined as a relationship between the upper and lower optical surfaces regardless of the edge. A technique will be presented in this paper to measure and calculate the tilt and decenter of bi-aspheric lenses using contact and non-contact profilometry. The method employs a specially designed kinematic mount. The bi-aspheric lens is fixed in the center with both optical surfaces exposed. Three spheres on the perimeter of the mount

are used as the reference for each measured trace. The tilt, decenter, form error, and thickness between of the two aspheric surfaces are calculated with a registration and alignment algorithm. Multiple diametral traces are recorded for each aspheric surface to ensure tilt and decenter are calculated in two dimensions. A standard contact profilometer with a programmable rotation and translation stage were used to perform the measurements. In-addition, the methodology was implemented on a multi-axis, non-contact metrology system for nearly automatic operation. The contact profilometer employs stylus with a micron sized diamond tip or millimeter sized ruby sphere. The non-contact system measures with a single point chromatic confocal sensor. Results will be presented from both contact and non-contact metrology systems.

9575-31, Session 7

Bamboo book stitching interferometer

Po-Chih Lin, Chao-Wen Liang, Yi-Chun Chen, Hung-Sheng Chang, Jia-Wei Chen, National Central Univ. (Taiwan)

Aspherical optical surface testing has always been considered a crucial challenge. There are several methods being used to evaluate this task such as stylus profiler, null optics, CGH and subaperture stitching interferometer (SSI). Among of them, the SSI has been proved to be the only method to be non-contact, flexible, high dynamic range, and high precision. However, it still has limitation for measuring steep aspherical surface since the fringe resolvable region of the subaperture can be small. In order to stitch the adjacent sub-aperture taken in SSI measurement, the number of sub-apertures must to be increased at the cost increasing number of sub apertures and thus time. Or, one can use the auxiliary null optics to null the sub aperture aberration for maximum resolvable fringe area.

In this research, we utilize the vibration modulated interferometer to acquire the interference phase while the tested lens is rotating. Instead of nulling the fringe over the complete sub-aperture as before, we null the fringe only along the tangential and sagittal directions. By nulling the fringe along a line, the capability of aspherical surface measuring of the vibration interferometer is significantly increased. After the line interference phase is recovered, the line phases of different directions are stitched in to a complete tested surface in a similar way as the ancient Chinese bamboo book.

9575-32, Session 7

Subaperture stitching surface errors due to noise in a circular subaperture ring

Greg A. Smith, James H. Burge, The Univ. of Arizona (United States)

Subaperture stitching is a popular method for extending small, subaperture interferometer measurements to cover large-aperture optics. The method is simple in that there are only two steps: 1) make multiple measurements across the surface and 2) use well-established software techniques to merge the individual measurements into one surface estimate. Because parts of the system must move between measurements, small misalignments between subapertures are unavoidable, but easily accommodated within the software. Unfortunately this process has the potential to introduce errors.

In this work, we show how random noise in a circular ring of subapertures creates artifacts in low-order surface shape estimates. The magnitude of these errors depends on setup parameters such as the number of subapertures and their overlap, as well as the measurement noise within a single subaperture. Understanding the relationships between subaperture stitching configuration and surface artifacts is important when designing high-accuracy metrology systems which rely on stitching. This work will help metrology system designers incorporate subaperture stitching into error budgets and tolerances.

9575-33, Session 7

An iterative subaperture position correction algorithm

Weng-Hou Lo, Po-Chih Lin, Yi-Chun Chen, National Central Univ. (Taiwan)

??The subaperture stitching interferometry is a technique suitable for testing high numerical-aperture optics, large-diameter spherical lenses and aspheric optics. In the stitching process, each subaperture has to be placed at its correct position in the global coordinate, and the positioning precision would affect the accuracy of stitching result. However, the mechanical limitations in the alignment process as well as vibrations during the measurement would induce inevitable subaperture position uncertainties.

??In our previous study, a rotational scanning subaperture stitching interferometer has been constructed. This paper provides an iterative algorithm to correct the subaperture position without altering the interferometer configuration. Each subaperture is first placed at its geometric position estimated with the F number of reference lens, the measurement null angle and the number of pixels along the width of subaperture. By using the concept of differentiation, a shift compensator along the radial direction of the global coordinate is added into the stitching algorithm. The algorithm is divided into two parts: one with four compensators of piston, two direction tilts and defocus, and the other with the shift compensator. The two parts are computed iteratively to minimize the phase differences in the overlapped regions of subapertures on a least-squares sense. The simulation results demonstrate that the proposed method works to the precision of rounding errors both for the single-ring and multiple-ring measuring configurations. Preliminary verification with single-ring experimental data also shows the effectiveness of the algorithm. Further studies on multiple-ring experimental data are underway.

9575-38, Session 7

Wavefront analysis of a large sic mirror of 700 mm in diameter due to the surface figure error

Jinsuk Hong, Samsung Thales Co., Ltd. (Korea, Republic of)

SiC is very interesting material for mirror and structure for a large optical system working in a severe condition due to its thermal stability. However when manufacturing this material in a mirror form requires a lot of new techniques and analysis. We have been designed the system with SiC material and manufacturing SiC mirrors in various form up to 700mm in diameter. We've performed structural and optical analysis of the mirror itself and the system. We can confirm the manufacturability of the components assigning proper WFE budget to each component. We present the result of the wavefront error analysis in the component level as well as the system level.

9575-34, Session 8

Direct light scattering characterization of optical components

Sven Schröder, Alexander von Finck, Angela Duparré, Fraunhofer-Institut für Angewandte Optik und Feinmechanik (Germany)

Surface roughness is a critical parameter for the specification of an optical component in order to ensure a certain performance. The main reason is that even the smallest levels of residual surface roughness give rise to light scattering which degrades the imaging properties and reduces the throughput. However, surface defects, subsurface damage, interference effects caused by dielectric coatings, photonic structures, and rough absorbing structures also produce light scattering which is usually much

more complicated to describe. For some applications, scattering properties must therefore be carefully specified and measured directly. Bidirectional Reflectance and Transmittance Distribution Functions (BRDF / BTDF) are used to quantify the angle resolved scattering properties. The data can be used as an input for optical engineering software like FRED, ASAP, or ZEMAX for stray light modeling. In addition, analysis of the scattered light can provide valuable information about the relevant imperfections. The presentation provides an overview of instrumentation for light scattering measurements at wavelengths ranging from the visible to the extreme ultraviolet and the infrared spectral regions. Examples of applications will be discussed ranging from superpolished mirrors to diffraction gratings, interference coatings, and black absorbing coatings.

9575-35, Session 8

Roughness, homogeneity, and defect characterization using light scattering techniques

Sven Schröder, Marcus Trost, Tobias Herffurth, Angela Duparré, Fraunhofer-Institut für Angewandte Optik und Feinmechanik (Germany)

The assessment of surface properties like roughness, homogeneity, and the distribution of defects gains more and more importance in particular close to, or even in, manufacturing processes. Light scattering is a fast, non-contact, extremely robust, and at the same time highly sensitive approach to meeting this challenging requirement. Several tools will be presented that enable measurements to be performed even on very large (diameter > 600 mm) and curved surfaces with 100% coverage of the surface. Examples are discussed ranging from smooth mirrors to structured surfaces. Surface power spectral densities and surface roughness are determined from the scattering results and compared to results obtained by white light interferometry and atomic force microscopy. In addition to laboratory instruments, compact table-top tools and sensors are presented that can be used close to or even during manufacturing.

9575-36, Session 8

Measuring and quantifying scatter from non-isotropic sources

John C. Stover, The Scatter Works Inc. (United States)

The usual definition for BRDF assumes that the illuminated surface is isotropic. This is why when the primary source of scatter is a surface pit or particle the differential scattering cross-section is used to quantify scatter. In these cases the DSC is independent of changes in illumination spot size and thus is a more meaningful characterization than the measured BRDF. The same thing is true for other situations. These include scatter from isolated scratches, non-isotropic roughness (such as a rolled surface) and scatter from the edge or corner of a surface. In these situations the measurements may be done differently and the quantified scatter often has different units – such as area/sr or 1/deg instead of the common 1/sr associated with BRDF. If the data is being taken for use in one of the stray radiation codes this can cause problems. This paper reviews these situations for both measurement and analysis issues.

9575-37, Session 8

Fabrication and qualification of roughness reference samples for industrial testing of surface roughness levels below 0.5 nm Sq

Oliver W. Fähnle, Eckhard Langenbach, Frank Zygalsky, FISBA OPTIK AG (Switzerland); Frank Frost, Renate Fechner, Axel Schindler, Leibniz-Institut für Oberflächenmodifizierung e.V. (Germany); Matthias Cumme, Carl Zeiss Jena GmbH (Germany); Christine Wuensche, Heiko Biskup, Rolf Rascher, Technische Hochschule Deggendorf (Germany)

Applying reactive ion beam etching (RIBE) processes at the Leibniz Institute of Surface Modification (IOM), several reference samples to be used in industry for calibrating of roughness testing equipment have been generated with the smoothest sample featuring 0.1 nm rms Sq. Subsequently these reference samples have been measured cross-site in industry applying atomic force microscopy (AFM), white light interferometry (WLI), Nomarski microscopy (NM) and scatterometry (iTIRM) determining the appropriate range of measurable rms surface roughness for each industrial measuring device. This paper reports on the newly developed fabrication process to generate reference samples with sub-nanometer level of surface roughness in Si wafers. Especially the capability of generating different samples featuring the same level of roughness while differing in the generated surface spatial wavelength (e.g. 2 nm rms with 2, 4 and 10 micron waviness, respectively) is very useful for the calibration of measurement equipment. Their use as calibration samples has been demonstrated by carrying out cross-site tests in R&D and industry achieving good compliances between AFM, WLI, Nomarski and iTIRM.

9575-39, Session 9

Integrated Ray Tracing (IRT) simulation of SCOTS measurement of GMT fast steering mirror surface

Ji Nyeong Choi, Yonsei Univ (Korea, Republic of); Dongok Ryu, Sug-Whan Kim, Yonsei Univ. (Korea, Republic of); Dae Wook Kim, Peng Su, Run Huang, College of Optical Sciences, The Univ. of Arizona (United States)

Software Configurable Optical Testing System (SCOTS) is one of new testing methods for large mirror surfaces. Integrated Ray Tracing (IRT) technique can be applicable to the SCOTS simulation by performing end-to-end ray tracing in the real scale. In this study, we construct IRT SCOTS simulation model for Fast Steering Mirror (FSM) surface of Giant Magellan Telescope (GMT). GMT FSM is off-axis ellipsoidal concave mirror of 1064 mm diameter and PV 1.7 mm in aspheric departure. The surface error requirement is less than 20 nm rms. The screen is modeled as an array of 500 by 500 screen pixels of 0.2 mm in pitch size. The screen is considered as a lambertian scattering surface. The camera model has an iris of 1mm diameter, singlet in BK and a detector as an array of 125 by 125 pixels of 40 ?m in pitch size. The screen and the camera are positioned 4378 mm away from the mirror and separated by 70 mm from each other. Light source is 10 cycles of sinusoidal patterns generated by ten million rays per one screen pixel. 0.1 % of initially generated rays are finally received by the camera's detector and contribute to form distorted pattern images. These images are used and converted to the slope and height of the mirror surface. As a result, the height difference between input surface and reconstructed surface is 10.74 nm rms. The study also shows that the same SCOTS setup also useful to GMT FSM for measurement of the surface error from 10 nm to 1.0 ?m rms. Finally, this study shows applicability of IRT model to SCOTS simulation with nanometer level numerical accuracy.

9575-40, Session 9

Oil defect detection of electrowetting display

Hou-Chi Chiang, National Chiao Tung Univ. (Taiwan); Yu-Hsiang Tsai, Industrial Technology Research Institute (Taiwan); Yung-Jhe Yan, Ting-Wei Huang, Ou-Yang Mang, National Chiao Tung Univ. (Taiwan)

In recent years, transparent display is an emerging topic in display technologies. Apply in many fields just like mobile device, shopping or advertising window, and etc. Electrowetting Display (EWD) is one kind of

potential transparent display technology advantages of high transmittance, fast response time, high contrast and rich color with pigment based oil system. In mass production process of Electrowetting Display, oil defects should be found by Automated Optical Inspection (AOI) detection system. It is useful in determination of panel defects for quality control. According to the research of our group, we proposed a mechanism of AOI detection system detecting the different kinds of oil defects. This mechanism can detect different kinds of oil defect caused by oil overflow or material deteriorated after oil coating or driving. We had experimented our mechanism with a 6-inch Electrowetting Display panel from ITRI, using an Epson V750 scanner with 1200 dpi resolution. Two AOI algorithms were developed, which were high speed method and high precision method. In high precision method, oil jumping or non-recovered can be detected successfully. This mechanism of AOI detection system can be used to evaluate the oil uniformity in EWD panel process. In the future, our AOI detection system can be used in quality control of panel manufacturing for mass production.

9575-41, Session 9

Deflectometry measurement of Daniel K. Inouye Solar Telescope primary mirror

Run Huang, Peng Su, James H. Burge, The Univ. of Arizona (United States)

SCOTS (software configurable optical test system) is a high-precision slope measurement technique based on deflectometry. It utilizes well calibrated commercial LCD screen and diffraction limited camera to provide high dynamic range, non-contact and full field metrology of reflective/refractive optics at high accuracy but low cost. Recently, we applied this metrology method on the fabrication of the primary mirror of Daniel K. Inouye Solar Telescope (DKIST), which is a 4.2 meter off-axis parabolic segment with more than 9 mm peak-to-valley aspheric departure. Sophisticated calibrations and compensation including camera aperture, camera distortion and screen shape bending were performed to achieve high accuracy measurement results. Benefiting from the combination of phase shifting and line scanning method, the absolute slope of each mirror pixel can be calculated with short measurement time. By measuring the mirror at different orientations, non-symmetrical systematic errors are eliminated. The metrology system also includes dual cameras that provide verification test. The measurement results are being used to guide the fabrication process.

9575-42, Session 9

The use of diffractive imitator optics as calibration artefacts

Paul C. T. Rees, John B. Mitchell, Glyndwr Univ. (United Kingdom); Andy Volkov, Nanomobile Ltd. (United Kingdom); Jean-Michel Asfour, Frank Weidner, Dioptic GmbH (Germany); Alexander G. Poleshchuk, Ruslan K. Nasyrov, Institute of Automation and Electrometry (Russian Federation)

The testing of highly aspheric optics often requires complex test arrangements. Optical test systems designed for testing aspherical optical surfaces can be multi-element and will have both fabrication and alignment errors present in the test wavefront. It may not be feasible to calibrate such systems with conventional optical shop practice. The use of diffractive imitator optics, with carefully controlled fabrication uncertainties, can be used to characterise these systems.

We describe the use of reflective imitator CGH optics as calibration artefacts in the calibration of an optical test system used to test ELT primary mirror segments. The optical test system is designed to have two operational modes: one to measure a spherical reference optic; and one to measure the primary mirror segment. The use of diffractive imitators in this test system is designed to provide traceability between these two operational configurations, to quantify residual alignment aberrations, and to quantify fabrication errors in part of the test system. We outline the design of the optical test system, the design of three imitator CGH artefacts required to provide traceability between the two optical test modes, and our calibration approach.

We demonstrate the calibration performance achieved with this approach. Without the use of these imitator artefacts, the absolute accuracy of the optical test is estimated to be 136 nm RMS wavefront, of which 57 nm RMS is attributed to midspatial wavefront errors and 116 nm RMS is attributed to alignment and prescription errors. The repeatability of this calibration has been established as better than 7 nm wavefront standard deviation, with an absolute accuracy of 19 nm RMS wavefront.

9575-43, Session 9

Local frequency estimation from intensity gradients in spatial carrier fringe pattern analysis

Ruihua Zhang, Hongwei Guo, Shanghai Univ. (China)

Spatial carrier fringe pattern analysis is an effective tool in optical measurement, e.g. in interferometry and fringe projection technique. With it, the very large phase deformations in a spatial carrier fringe pattern may increases the bandwidth of fringe component thus leading to difficulties in retrieving its phase map. In order to overcome this problem, many local-adaptive methods have been developed for processing the spatial carrier fringe pattern with large phase variations, and in fact the local spatial frequency estimation is central to these methods. This paper introduces a simple algorithm for estimating the local frequencies of a fringe pattern with spatial carrier. First, the intensity gradients of the fringe pattern are calculated, and then the standard deviations (SDs) of the intensity gradients at each pixel are estimated from its neighborhood. Finally the local frequencies are estimated from the SDs just calculated simply using an arccosine function. This algorithm is potential in developing effective techniques for retrieving phases from a spatial carrier fringe pattern with large phase variations. For example, we can recover the phase map by directly integrating the local frequencies or by use of an adaptive spatial carrier phase shifting algorithm (SCPS) with the local frequencies being the local phase shifts. It can also be used in Fourier transform method for exactly determining the carrier frequencies, or for extrapolating aperture in order to reduce the boundary effect. Combined with time-frequency techniques such as windowed Fourier transform and wavelet transform methods, it is helpful for alleviating the computational burdens.

9575-44, Session 9

Triple-wavelength phase unwrapping for dispersive objects

Behnam Tayebi, Yonsei Univ. (Korea, Republic of)

Here, we present a novel triple-wavelength unwrapping technique to measure phase of the dispersive objects without using unwrapping algorithms. Dual- wavelength method can unwrap phase of the reflective objects, successfully. However, for unwrapping transparent dispersive objects it is failed. Adding another wavelength and Cauchy equation allow us to unwrap dispersive objects without using numerical techniques. The feasibility of this technique is demonstrated experimentally.

9576-23, Session PMon

Study of high-contrast mark used for imprint lithography alignment

Liang Wang, Li Ding, Jin Qin, Univ. of Science and Technology of China (China)

Moiré fringes for overlay used two sets of gratings with slightly different periods, which can magnify the tiny misalignment to an observable quantum. During imprint lithography alignment process, imprint resist will deteriorate the intensity and contrast of the Moiré fringes which is a drawback for high precision alignment. This paper proposed a novel high contrast alignment mark used for imprint lithography. Through coating optically dens materials inside or on the surface of the imprint mask and changing the material and thickness of coating, high contrast Moiré patterns can be obtained. Simulations based on Rigorous coupled-wave analysis (RCWA) are performed to calculate the reflection efficiency and contrast of the obtained Moiré fringes. We found that the coating material, thickness, etching depth and pitch size of grating all have significant influence on the reflection efficiency and contrast of alignment pattern. Optimized alignment marks were fabricated and measured to verify the findings. Experiments demonstrated that the simulation results are correct and feasible.

Rapid three-dimensional chromoscan system of body surface based on digital fringe projection

Bin Wei, Jin Liang, Xi'an Jiaotong Univ. (China); Jie Li, Shijiazhuang Information Engineering Vocational College (China); Maodong Ren, Xi'an Jiaotong Univ. (China)

This paper proposes a rapid body scanning system that uses optical digital fringe projection method. Twelve cameras and four digital projectors are placed around the human body from four different directions, so that the body surface three-dimensional(3D) point cloud data can be scanned in 5-8 seconds. It can overcome many difficulties in a traditional measurement method, such as laser scanning causes damage to human eye and low splicing accuracy using structured white light scanning system. First, an accurate calibration method based on close-range photogrammetry, is proposed and verified for calibrating the twelve cameras and the four digital projectors simultaneously, where a 1m?2m plate as calibration target with feature points pasted on its two-sides is used. An experiment indicates that the proposed calibration method, with a re-projection error less than 0.05pixels, has a considerable accuracy. The whole 3D body surface color point cloud data can be measured without splice different views of point cloud, because of the high accuracy calibration results. Then, in order to measure the whole body point cloud data with high accuracy, a combination of single and stereo camera measuring method, based on digital fringe projection, has presented to calculating 3D point cloud data. At last, a novel body chromoscan system is developed and a human body 3D digital model was scanned, by which a physical body model was manufactured using 3D printing technology.

9576-26, Session PMon

Two-detector digital holographic smart camera for holographic imaging and digital holographic interferometry

Jakub P. Zak, Michal Józwik, Malgorzata Kujawi?ska, Warsaw Univ. of Technology (Poland)

Although digital holographic camera may be a versatile tool and digital holography itself experiences growing interest and development, it is still fairly limited. The most crucial problems are resolution and the size of a single pixel in available detectors. These parameters limit the size of an object that can be registered and its viewing angle. Also, the functionality and flexibility of the system in use for different 3D objects or scenes are strongly limited.

In this paper we present the design and proof of concept of functionality of a monochromatic holographic camera system consisting of two matrix detectors and Liquid Crystal on Silicon Spatial Light Modulator. The device allows capturing both Fresnel and Fourier holograms in flexible configuration, matched to an object/scene requirements. The two detectors are meant to increase the viewing angle of the camera or even to create synthetic aperture holograms for static objects. The SLM serves as an active element in the reference arm of the system. The use of LCOS SLM enables:

- formation and modification of the reference beam(s) through designing and displaying a diffractive element in full or divided SLM aperture,

- execution of the Temporal Phase Shifting algorithm or introducing carrier frequency

A model of the camera was tested for a variety of engineering objects (loaded cylinder, a distributed group of objects under different load conditions) in imaging and DHI modes.

9576-27, Session PMon

Uncertainties in strain measurements with birefringence

José G. Suárez-Romero, Instituto Tecnológico de Querétaro (Mexico); Eduardo Hernandez-Gomez, Instituto Tecnologico de Queretaro (Mexico)

Strain is an important test applied to materials in order to measure its mechanical properties and to evaluate the suitability of mechanical components. There are many experimental methods to measure strain, for example by use of strain gages, by measure of capacitance changes, by moire methods and others, but a very accepted method is by birefringence. Birefringence has the characteristic that it can show the whole strain distribution of the tested piece in a visual way. Other methods measure strain only in a small region and give a mean value. In the case of birefringence we have a continues of values. These advantages of birefringence can be properly used to validate numerical modulations in engineering, where techniques like finite element are used to model the mechanical performance of designs. Validation of numerical calculations is a procedure where the numerical results are compared with another accepted method whose reproducibility and uncertainty are known.

Therefore in this work the possible errors and uncertainties are analyzed. Between the possible errors introduced in the method is the difference of the poisson coefficient of the material to be analyzed and the poisson coefficient of the material used in the birefringence test. The difference between both coefficients is a source of error in the reproducibility of the results. The uncertainties considered are due to thinness of material, wavelength, the material optical constant and the order of diffraction. The most important source of uncertainty is the order of diffraction, when the orders take values close to one.

9576-28, Session PMon

Evaluation of optical surfaces using heuristic techniques in the information integration stage

Agustín Santiago-Alvarado, Moisés E. Ramírez Guzmán, Erik G. Ramos Pérez, José Y. Luis-García, Ángel S. Cruz-

Félix, Univ. Tecnológica de la Mixteca (Mexico)

There exist a large amount of interferometric methods that are used to evaluate optical surfaces and several of them use the implementation of an optical device that is placed right in the area where light is concentrated. However, when the optical surface does not concentrate the light in a single spot, these methods are impossible to use and alternative techniques are developed in order to being used in such cases. By means of certain implemented measurements, these techniques acquire a set of points coordinates over the surface under study and then an integration process is performed in order to obtain the surface profile. In this work, several heuristic techniques are studied in order to know which of them perform a best integration process of the set of points to obtain the surface profile. The time on which the process is done to evaluate the surface is analyzed as the precision achieved of each one of them. The obtained results and analysis from the evaluation of the surface of a parabolic solar collector are presented

9576-29, Session PMon

A model to perform bandwidth-spectral-correction in spectrophotometers

Juan B. Hurtado-Ramos, Paulina Arrieta-Navarro, Instituto Politécnico Nacional (Mexico); José G. Suárez-Romero, Instituto Tecnológico de Querétaro (Mexico)

Two functions for modeling a spectrophotometer line-spread characteristic function are analyzed. These models are used to calculate the corrected spectral transmittance of holmium oxide and didymium oxide, which are often used as calibration standards. Correction is carried out through Fourier transform techniques; we show a comparison between the spectral transmittance measured with a 4 nm bandwidth spectrophotometer corrected with our technique, and the spectral transmittance measured with a 0.1 nm bandwidth spectrophotometer.

9576-30, Session PMon

Auto-elimination of fiber optical path-length drift in a frequency scanning interferometer for absolute distance measurements

Long Tao, Zhigang Liu, Weibo Zhang, Xi'an Jiaotong Univ. (China)

Because of its compact size and portability, optical fiber has been wildly used as optical paths in frequency-scanning interferometers for high-precision absolute distance measurements. However, since the fiber is sensitive to ambient temperature, its length and refractive index change with temperature, resulting in an optical path length drift that influences the repeatability of measurements. To improve the thermal stability of the measurement system, a novel frequency-scanning interferometer composed of two Michelson-type interferometers sharing a common fiber optical path is proposed. One interferometer defined as origin interferometer is used to monitor the drift of the measurement origin due to the optical path length drift of the optical fiber under on-site environment. The other interferometer defined as measurement interferometer is used to measure the distance to the target. Because the optical path length drift of the fiber appears in both interferometers, its influence can be eliminated by subtracting the optical path difference of the origin interferometer from the optical path difference of the measurement interferometer. A prototype interferometer was developed in our research, and experimental results demonstrate its robustness and stability. Under on-site environment, an accuracy about 4 ?m was achieved for a distance of about 1 m.

9576-1, Session 1

A rugged stereoscopical device for surface inspection

Florian Dannenberg, Cornelius F. Hahlweg, bbw Hochschule (Germany); Lukas Pescoller, Peret GmbH (Italy)

The paper is understood as a continuation of a series of papers on surface metrology for application in quality control of printed matter. A stereoscopic method for extremely rugged applications, expecially in quality controk in printing industry, is presented. The deivce developed is based on variable tilted delay elements, which allow the use of a single imaging sensor and robust definition of parallax shift. Variable orthogonal delay elements were already used for variation of plane of focus in surface inspection, as described in previous papers. The method can be applied for macroscopical as well as for microscopical imaging. Beside mechanical design issues, the theoretical descirption, geometrical-optical approaches, Fourier-optical aspects, polarization issues, and especially the treatment of the dispersion problem are discussed. Experimental results are included.

9576-2, Session 1

In-line roll-to-roll metrology for flexible electronics

Bradley T. Kimbrough, 4D Technology Corp. (United States)

The flexible electronics market continues to grow at a rapid pace. Increasing numbers of applications employ the flexible components including displays, biomedical devices, smart apparel, and advanced sensors. To maintain performance and lifetime, many characteristics of the substrate and deposited layers must be monitored. This includes defects, surface roughness, and feature alignment. Ideally, in-situ metrology can be employed in roll-to-roll (R2R) equipment to allow for real-time process control. This presents the necessary three-dimensional metrology system with several challenging requirements: high vertical and transverse resolution, large field-of-view, extremely fast measurement times, and robust vibration immunity.

This paper will discuss the design and performance of a compact, low-cost, large-field interferometric probe for in-situ measurement of R2R substrates. Samples with a variety of known and unknown features and roughnesses will be measured to characterize the performance of the system. Static and moving substrates will be measured to examine effects on results. Optimization of processing to allow for on-board analysis will be examined. Lastly, the paper will discuss how such probes may be arrayed to provide a high degree of areal coverage of the flexible substrate under test.

9576-3, Session 1

Three-dimensional speckle imaging employing a frequency-locked tunable diode laser

Bret D. Cannon, Bruce E. Bernacki, John T. Schiffern, Albert M. Mendoza, Pacific Northwest National Lab. (United States)

We describe a high accuracy frequency stepping method for a tunable diode laser to improve a three dimensional (3D) imaging approach based upon interferometric speckle imaging. The approach, modeled after Takeda, exploits tuning an illumination laser in frequency as speckle interferograms of the object (specklegrams) are acquired at each frequency in a Michelson interferometer. The resulting 3D hypercube of specklegrams encode spatial information in the x-y plane of each image with laser tuning arrayed along its z-axis. The specklegrams are processed by Fast Fourier Transformation (FFT) along the z-axis of the hypercube and the center of the peak in

the resulting power spectrum for each pixel encodes its surface height. Alternatively, Takeda's method can be followed which uses the phase of the FFT, unwraps it, and determines the surface height encoded in the slope of a line fitted to the phase. Wraparound of modulations above the Nyquist limit results in ambiguity in the optical path difference (OPD) between test and reference surfaces. Wraparound also amplifies measurement noise caused by errors and jitter in frequency stepping the illumination laser. By locking the laser frequency to successive cavity modes of a reference confocal interferometer, tuning is precisely controlled resulting in dramatically improved imaging accuracy. We present laboratory data of before and after results showing enhanced 3D imaging resulting from precise laser frequency control.

9576-4, Session 1

Aperiodic sinusoidal fringes in comparison to phase-shifted sinusoidal fringes for high-speed three-dimensional shape measurement

Stefan Heist, Peter Lutzke, Peter Kühmstedt, Fraunhofer-Institut für Angewandte Optik und Feinmechanik (Germany); Gunther Notni, Technische Univ. Ilmenau (Germany)

Reconstructing the three-dimensional (3D) surface shape of moving objects or deformation processes has become an important task in many application areas, such as in-line quality control or medical sciences. Structured-light 3D scanners are well-established for performing these measurements since they allow full-field measurement and contactless operation. However, their measurement speed is limited by both camera and projector frame rate. Whereas high-speed cameras have been commercially available for some time, efforts are still necessary to develop high-speed projectors.

In previous contributions, we presented an array projector, enabling projection frame rates of several 10 kHz. In contrast to a large number of 3D sensors, instead of projecting well-known phase-shifted sinusoidal fringes, aperiodic sinusoidal fringes are projected onto the measurement object and observed by two cameras. Instead of comparing phase values, homologous pixels are found by cross-correlation.

In this contribution, we want to analyze the similarities and differences between both approaches. In particular, this includes theoretical considerations on designing a sequence of aperiodic sinusoidal fringes that leads to an accuracy as well as completeness of the 3D point cloud as high as possible. The results of extensive simulations of a specific 3D sensor setup are presented, and the achievable accuracy of both pattern approaches is compared.

The subsequent experimental investigations are based on the simulated sensor setup and include comparative measurements of different test specimens. The experimental results are discussed and compared with the simulated results. The main purposes are to derive criteria for the design of optimal sequences of aperiodic sinusoidal fringes and to compare the number of patterns of both approaches necessary for comparable accuracies.

9576-5, Session 1

Development of three-dimensional speckle deformation measurement method with same sensitivities in three directions

Yasuhiko Arai, Kansai Univ. (Japan)

The speckle interferometry is a useful optical deformation measurement method concerning the object with rough surfaces. The speckle interferometry has been improved to the electronic speckle pattern interferometry, ESPI, by introducing some TV technologies. Furthermore, the high resolution deformation measurement methods have been developed by using fringe scanning methods in the 1980s. The deformation measurement method by using only two speckle pattern has also been proposed in ESPI by using Fourier transform. Then, the method can perform not only the out-of-plane but also the in-plane deformation measurement of the objects with rough surfaces in high resolution. The methods can also measure three-dimensional deformation. Some kinds of the three-dimensional deformation measurement methods based on the speckle interferometry have been proposed. However, the sensibilities of ordinary methods in three directions are not always same. Generally, the parameters in sensibility matrices of these methods are not same in each direction. In this paper, the novel analysis method of which sensibilities in three directions are same is proposed. The optical system is set up under the idea of the proposed method. The multi-recording technology of the signals of the deformations in three dimensional using one camera is employed.

The feature of the measurement based on the multi-recording technology of the signals is investigated. Then, it is confirmed that there is not difference between the single and the multi recording-methods in the measuring accuracy. From the experimental results, the validity of the novel method is confirmed.

9576-6, Session 1

3D interferometric microscope: visualization of sample in real color appearance benefits industrial samples assessment

Joanna Schmit, Matt Novak, Bruker Nano Surfaces, Inc. (United States)

3D microscopes based on white light interference [1] which scan vertically for height data collection provide excellent vertical resolution and very good lateral resolution for surface topography measurements in industry.

Besides the precise measurement of a sample, often the display of an object in its true colors, as observed under white light illumination, is desired [2,3,4] . Color images are not only appealing to the eye and great for presentations, but also may provide a very useful and quick evaluation of certain characteristics of the sample, such as defects, delamination, or deposition of different materials.

In order to digitally observe a sample in its natural color, at minimum white light illumination and a color camera are needed, or a combination of RGB (three) cameras and a white light or RGB source. Separate RGB illumination sources and a B&W camera also can be used. Some considerations need to be made when choosing the illumination-camera combination as different options affect the lateral or vertical system resolution, add system cost or increase the system to a much larger size. Some choices also may significantly slow down the measurement if, for example, RGB illumination is sequential.

Interferometric objectives deliver excellent 3D topography, but good quality color determination is not straightforward as in the use of standard bright-field objectives[2,3,4]. There are a few main issues that need to be overcome in acquisition of images using an interferometric objective, namely: the presence of interference fringes, poor color quality and low visibility of object features. The first issue is that fringes present at the best focus obscure the view of the sample and must be removed (e.g., by frames averaging around the best focus). The second issue is that interferometric objectives introduce additional background intensity from the reference mirror causing the image of low reflectivity samples to have low saturation and low contrast colors.

To illustrate these issues, the image of a paper sample as observed with a color camera and using a 5X Michelson interferometric objective under white light LED illumination can be examined. In standard scanning interferometric microscopes, such a sample exhibits little color content due to low reflectivity and the small numerical aperture of the objective. In addition, the sample itself is difficult to see under observation. However, enhanced interferometric color imaging can provide quality 3D mapping in a single interferometric scan and result in a satisfactory 3D color image.

We will show that 3D microscopes based on white light interferometry have color imaging capabilities similar to an ordinary microscope. This color imaging and precise surface topography measurement capability, along

with different degrees of process automation, makes 3D microscopes based on WLI a very attractive metrology tool for different automotive, medical or printing industry areas, where color images can also provide valuable information to the user.

9576-7, Session 2

Binary pseudorandom test standard to determine the modulation transfer function of optical microscopes

Ian Lacey, Valeriy V. Yashchuk, Erik H. Anderson, Nikolay A. Artemiev, Lawrence Berkeley National Lab. (United States); Christophe Peroz, Sergey Babin, Guiseppe Calafiore, Abeam Technologies, Inc. (United States); Elaine R. Chan, Stefano Cabrini, Lawrence Berkeley National Lab. (United States); Peter Z. Takacs, Brookhaven National Lab. (United States)

This work reports on the development of a binary pseudo-random test sample optimized to calibrate the MTF of optical microscopes. The sample consists of a number of 1-D and 2-D patterns, with different minimum sizes of spatial artifacts from 300 nm to 2 microns. We describe the mathematical background, fabrication process, data acquisition and analysis procedure to return spatial frequency based instrument calibration. We show that the developed samples satisfy the characteristics of a test standard: functionality, ease of specification and fabrication, reproducibility, and low sensitivity to manufacturing error. This work was supported in part by the UC Office of the President, Proof of Concept Grant ID No. 268826 and by the U.S. Department of Energy Office of Science, Office of Basic Energy Sciences Energy Small Business Technology Transfer (STTR) program under Award Number DE-SC0011352, and by the U. S. Department of Energy under contract number DE-AC02-05CH11231.

9576-8, Session 2

Performance analysis of a full-field full-range swept-source OCT system

Johann Krauter, Institut für Technische Optik (Germany)

The optical coherence tomography (OCT) is an optical measurement technique that has been developed for ophthalmological applications at first. However, in dermatology the default analysis technique of malign tissues is still the traditional biopsy, whose drawback is a long diagnosis time and its invasiveness. Recent, OCT systems are also emerging in the traditional field of dermatology and permit non-invasive 3D optical biopsies of skin. In the research project VIAMOS (Vertically Integrated Array-type Mirau-based OCT System) an approach for a new generation of sensor systems for the skin analysis is developed. Micro-Opto-Electro-Mechanical Systems (MOEMS) enable a low-cost, miniaturized and hand-held OCT device. This concept combines swept-source OCT, full-field detection, phase-shifting interferometry and MOEMS, providing 3D tomograms of the human skin from a volume of 8 x 8 x 0.5 mm? with an axial and transverse resolution of 6 μm. The key component of this system is a wafer stacked 4 x 4 array detector. Each measurement channel consists of an active Mirau interferometer with an oscillating reference mirror, which introduces an additional phase shift between the reference and object path.

A prototype OCT setup is developed in a laboratory environment based on the same design parameters as the final VIAMOS system. This reference setup uses a Linnik interferometer microscope with a swept-source, operating in the 850 nm range with a full-tuning range of 50 nm and a minimal linewidth of one single wavelength of 0.05 nm. The Linnik interferometer uses two equally infinity-corrected microscope objective lenses, where the reference path is mounted together with a Piezo-driven actuator for phase shifting.

This paper presents performance analysis of the signal detection process, focusing on the improvement of decreasing the complex conjugate artifact and system sensitivity analysis. At first, the sensor performance under ideal conditions is simulated and measured using the experimental setup. Furthermore influence of phase-shifter instabilities and a discussion of the system limitations are presented. The key figure of merit for OCT is the system sensitivity and resolution. For biological tissues the target values for sensitivity are more than 80 dB and a lateral and axial resolution of 5 μm.

9576-9, Session 2

Framework for removal of outliers in high-speed fringe projection profilometry

Shijie Feng, Yuzhen Zhang, Qian Chen, Chao Zuo, Nanjing Univ. of Science and Technology (China)

Fringe projection profilometry combining with the temporal phase unwrapping is widely used for high-speed, real-time acquisition of three-dimensional shapes. However, when the object is not motionless during the acquisition process, some unreliable results may emerge, especially around the contours of the measured object. The main reason for this is that the same point in the projected pattern sequence can map to different points within the camera images resulting from depth changes over time. We present a novel framework to identify those invalid pixels affected by such an error. By carefully examining the captured fringe pattern, comparing two modulation maps, utilizing the phase relationship between two neighboring pixels, and employing a Gaussian filter to detect the protruding points, the bad measurement pixels (outliers) can be detected and filtered out effectively. The whole procedure is of low computational complexity because of the introduced lookup table based fast data processing method. Some experimental results are presented to verify the validity of our method.

9576-10, Session 2

Geometric superresolution using an optical mask

Ihtsham U. Haq, Pakistan Council of Scientific & Industrial Research (Pakistan) and Pakistan Institute of Engineering and Applied Sciences (Pakistan); Asloob A. Mudassar, Pakistan Institute of Engineering and Applied Sciences (Pakistan); Ihtram U. Haq, A. Ikram, Univ. of Karachi (Pakistan); A. Haleem, S. Raja, Pakistan Council of Scientific and Industrial Research (PCSIR) (Pakistan)

Today, in everyday imaging in science and research, a digital imager – despite of its lower resolution than conventional film camera, is the first choice due to its obvious advantages. Assuming the imaging system to be diffraction limited, this low resolution is due to two geometrical characteristics of the detector array (CCD/CMOS) used in it at image plane. These two characteristics are pitch and non-zero pixel size – which do sampling and averaging of optical information over pixel spatial area respectively and dictates geometric resolution limit of digital imager.

In this paper, we are proposing an efficient optical mask for achieving geometric super-resolution – having high SNR. Keeping the target-imager relatively static, the mask is scanned over CCD by one pixel in subpixel steps. The mask optically codes the image. The resulting coded digital images are then decoded computationally to get a superresolved image –

enhanced in resolution by subpixel step factor N. By this, each CCD-pixel is virtually resolved into a matrix of subpixels. The proposed mask has an intelligent profile design that lead to high SNR, quick computation, always stable and solvable solution. The mathematical model developed for the proposed scanning methodology is efficient enough to calculate result quickly in just one mathematical step.

The 2D simulation results are presented – showing an improvement in resolution by given super-resolution factor - in both x and y directions. Increasing the super-resolution factor more makes the result more close to original. The given superresolution technique can be applied to microscopy, medical imaging, machine vision, industrial inspection, metrology (specifically dimensional metrology), defense, satellite imaging and astronomy.

9576-11, Session 3

Digital focusing schlieren imaging

Benjamin D. Buckner, Spectabit Optics, LLC (United States); James D. Trolinger, MetroLaser, Inc. (United States); Drew M. L'Esperance, Spectabit Optics, LLC (United States) and Pomona College (United States)

Since its invention in the 19th century, schlieren imaging has been an essential method for studying many aerodynamic effects, particularly convection and shock waves, but the classical method using parabolic mirrors is extremely difficult to set up and very expensive for large fields of view. Focusing schlieren methods have made large- area schlieren more feasible but have tended to be difficult to align and set up, limiting their utility in many applications We recently developed an alternative approach which utilizes recent advances in digital display technology to produce simpler schlieren system that yields similar sensitivity with greater flexibility.

The digital schlieren concept combines analog optical components, most significantly a cutoff grid (usually a Ronchi ruling), with a digital display device such as a flat screen television or digital projector. A portable computer and digital camera measure the transmission of the cutoff grid and compute a complementary display in the background. This digital measurement step obviates many of the long-standing problems with focusing schlieren techniques that are associated with precisely matching the cutoff grid to the background light pattern. Because the system is digital, the control software has great freedom to perform real-time image enhancement as well. Consequently, the most severe hardware production and alignment restrictions are now software problems that are solved continuously, quickly, and inexpensively in real time. This capability enables the system to compute and compensate for imperfect windows and optics, optical aberrations, misalignments, and temporal changes in the system and subject.

9576-12, Session 3

Digital speckle-based stereo microscope strain measurement system for forming limit diagram prediction by hydraulic bulge tests

Maodong Ren, Jin Liang, Lizhong Wang, Bin Wei, Xi'an Jiaotong Univ. (China)

A digital speckle based stereo microscope strain measurement system is developed to investigate the forming limit diagram (FLD) of miniature sheet metal under hydraulic bulge testing conditions. A stochastic speckle pattern is sprayed on the surface of the tested metal before forming. A series of images are recorded by two cameras mounted on a binocular stereo microscope during the hydroforming process. The critical major and minor strains are then calculated and plotted to construct the forming limit curve. The key technologies applied in the system are discussed in detail, including stereo microscope calibration and large deformation strain filed determination. First, considering complex optical paths and high magnification of the stereo microscope, an accurate orthogonal projection model is proposed to optimize the intrinsic and extrinsic parameters of the stereo microscope. Then, to solve the problem of strain measurement of the tested metal in large deformation situation, a three dimensional strain calculation method is specially used to calculate the full-field strains. And an algorithm of limit strain determination based on spline model is proposed to calculate the critical strains at the onset of plastic instability. Finally, with our self-developed stereo microscope imaging system and sheet metal hydraulic bulging setup, FLD determination tests are conducted to validate the performance of the system. And the measured FLD is compared with the traditional experimental FLD as well as with that predicted by the finite element method. The simulation and experimental results confirm that the proposed system is feasible to measure the full-field strain during the whole bulging processes and provides a better solution for forming limit diagram prediction.

9576-13, Session 3

Background-oriented schlieren for the study of large flow fields

James D. Trolinger, MetroLaser, Inc. (United States); Benjamin D. Buckner, Spectabit Optics, LLC (United States)

Flow fields around large structures are difficult to observe because of the size of optics typically employed with conventional flow visualization systems like shadowgraph, schlieren, and interferometry. More recently, digital imaging and processing methods have allowed extending these methods to cover much larger fields of view. Background oriented schlieren imaging enables analysis of refractive index gradients in large fields of view by observing the effects on an image of a background structure behind the field. This is achieved computationally by subtracting reference backgrounds from the distorted background images and inverting the difference to extract information about the refractive index field. The background can be a natural structure, such as a cloudy sky, mountains, trees, or the ground or in some cases a specially designed backdrop. Applications include observing flow fields associated with full sized aircraft, helicopters, automobiles, explosives, and buildings. This paper presents some of the applications and measurement capabilities in aero optics and explosives testing.

9576-14, Session 3

Interferometric strain measurements with a fiber-optic probe

Ethan D. Burnham-Fay, Douglas Jacobs-Perkins, Jonathan D. Ellis, Univ. of Rochester (United States)

Experience at the Laboratory for Laser Energetics has shown that broadband base vibrations presents difficulty in positioning cryogenic inertial confinement fusion targets. These effects must be mitigated for National Ignition Facility scale targets; to this end an active vibration stabilization system is proposed. A single mode optical fiber strain probe and a novel fiber contained heterodyne interferometer have been developed as a position feedback sensor for the vibration control system. A resolution limit of 54.5~n$epsilon$ is measured with the optical strain gauge, limited by the Lock In Amplifier. Experimental measurements of the sensor are presented, which show good agreement with reference resistive strain gauge measurements.

9576-15, Session 3

An iterative approach to measuring two-dimensional gradient-index profiles based on external measurements of laser beam deflection

Di Lin, James R. Leger, Univ. of Minnesota, Twin Cities (United States)

We present a numerical method for calculating the refractive index profile of two-dimensional gradient-index optical materials. Using boundary values of ray position and angle obtained by deflectometry to approximate trajectories for the measured interrogating rays, we show that the inverse problem can be reduced to a sparse linear system. The linear system is subsequently inverted using the LSQR method to obtain the refractive index distribution. We demonstrate our method through simulation and reconstruct the index profile of a hypothetical rectangular gradient-index medium, where RMS index errors below 0.5% of the index range (n_max-n_min) are achieved if boundary values of the refractive index are measured. If the boundary values of the refractive index are unknown, we take an iterative approach to obtain a solution that is consistent with Snell's law of refraction at the boundaries of the gradient-index medium. We demonstrate our technique in simulation and reconstruct the test index distribution from ray angles measured outside the gradient-index medium, resulting in RMS index errors below 1% of the index range. In addition, the approximate ray trajectories used initially for solving the inverse problem are corrected through an iterative ray trace procedure until the solution becomes consistent with the ray equation of geometric optics. Furthermore, we identify three primary sources of error contributing to the inversion process and assess the importance of data redundancy and system conditioning in accurate reconstructions of the index distribution. The principles developed in our method are fully extendable to three-dimensions as well as more complex geometries.

9576-16, Session 4

Three-dimensional digital holographic aperture synthesis for rapid and highly-accurate large-volume metrology

Randy R. Reibel, Brant M. Kaylor, Stephen Crouch, Bridger Photonics, Inc. (United States); Zeb Barber, Montana State Univ. (United States)

Currently large volume, high accuracy three-dimensional (3D) metrology is dominated by laser trackers, which typically utilize a laser scanner and cooperative reflector to estimate points on a given surface. The dependency upon the placement of cooperative targets dramatically inhibits the speed at which metrology can be conducted. To increase speed, laser scanners or structured illumination systems can be used directly on the surface of interest. Both approaches are restricted in their axial and lateral resolution at longer stand-off distances due to the diffraction limit of the optics used. Holographic aperture ladar (HAL) and synthetic aperture ladar (SAL) can enhance the lateral resolution of an imaging system by synthesizing much larger apertures by digitally combining measurements from multiple smaller apertures. Both of these approaches only produce two-dimensional imagery and are therefore not suitable for large-volume 3D metrology. We combined the SAL and HAL approaches to create a swept frequency digital holographic 3D imaging system that provides rapid measurement speed for surface coverage with unprecedented axial and lateral resolution at longer standoff ranges. The technique yields a "data cube" of Fourier domain data, which can be processed with a 3D Fourier transform to reveal a 3D estimate of the surface. In this talk, we will outline the theoretical background for the technique and show experimental results based on an ultra-wideband frequency modulated continuous wave (FMCW) chirped heterodyne ranging system showing sub-100 micron lateral and axial precisions at >10m standoff distances.

9576-17, Session 4

Development of a non-contact center thickness optical metrology system

Peter Roos, Michael Thorpe, Jason Brasseur, Bridger Photonics, Inc. (United States)

The last place an optics manufacturer wants to physically touch a lens is at the center. However, this is precisely what is currently done to measure center thickness of lenses. Using contact methods, the question is not whether the optic is damaged, it is whether the resulting damage is acceptably low. At Bridger Photonics, we have proven the feasibility of a non-contact center thickness metrology system to address this need. The apparatus uses a technique similar to swept-frequency optical coherence tomography to measure both physical thickness and optical thickness. From these measurements, the group index of refraction can also be determined. Moreover, the phase index can be determined, given the Sellmeier coefficients. In this presentation, we will report our demonstrated measurement range of 75 mm optical thickness (larger possible), as low as 20 nm precision, and group index of refraction determined to better than 5 parts is 10^5. We believe the metrology system resulting from these proof-of-principle demonstrations will be a valuable tool for precision optics manufacturing.

9576-18, Session 4

Moire interferometry patterns for rotational alignment of structures

Esmaeil Heidari, Kevin G. Harding, GE Global Research (United States)

In some manufacturing applications the alignment of fine structures formed on the surface of a part such as micro-scribed patterns on solar panels can be critical to the panel performance. Variations in pattern uniformity may degrade the efficiency of the solar panel if the pattern deviates significantly from designed parameters. This paper will explore the use of moire patterns to interpret the angular alignment of such structures on 3 dimensional non-planar shapes. The moire interferometry pattern creates a beat between the scribed pattern and a reference pattern that is a function of both the shape of the part as well as the shape of the scribed pattern. Both the part shape variations and the patterns of interest are typically much smaller than can be seen visually. Similar challenges exist when inspecting specular models or testing low quality optics. The moire effect allows small displacements to be measured from patterns that are well below the resolution of the camera systems that are used to view the patterns. Issues such as the separation of the shape of the part from the alignment of the fine structure as well as resolution and robustness of the technique will be explored in this paper.

9576-19, Session 4

Digital holography microscopic array for measuring of mechanical properties on biological samples

Cesar G. Tavera, J. M. Flores, Ctr. de Investigaciones en Óptica, A.C. (Mexico)

Nowadays, the different areas of biomedical science are eager to indeed comprehend internal organic structures as a whole and foreseeing its behavior under specific controlled excitation signals and stimuli. The development of imaging reconstruction by optical techniques, such as Digital Holographic Microscopy (DHM), has allowed determination of shape and measuring of deformations on different kind of materials.

Since cells and organic structures of biological organisms can be viewed as liquid-liquid or liquid-air interfaces, in this work we use a DHM technique to be implemented in a Mach-Zehnder interferometer in order to observe not only the shape, but also, to characterize mechanical and thermal properties on organic material by non-destructive excitation. This measurements are possible by taking advantage from interfacial models on "thermal lensing" [1-3] and "optical pressure radiation" over liquid-liquid interfaces [4]. By using non-contact excitation methods, [5,6] it would be possible (to be proved) to determine some opto-mechanical parameters (i.e. refraction index, group velocity, surface tension, etc.) by quantifying the thermal and optical pressure phenomena. The level of murky samples will represent the discriminating element to make measuring on total or local areas of the element under study. This testing is performed over fields of view of hundreds of microns. Deformations are in the order of a few nanometers of resolution. Numerical algorithms will be adapted and employed for reconstruction and processing of the recorded holographic images. This

information will be valuable for engineering design of antibiotics, control of cellular growing and in bio-chemical science.

9576-20, Session 4

A novel extrinsic calibration method of ToF cameras based on a virtual multi-cubes shaped object

Lei Ao, Yongqi Liu, Xin Dong, Ze Zhang, Chinese Academy of Sciences (China)

In recent years, due to their ability to capture 3D range data at video frame-rate, time-of-flight (ToF) cameras have been widely used in many fields, such as mobile robotics, automotive engineering and industrial engineering. Researchers concentrate on extrinsic calibration methods used to eliminate the measurement errors which is typically caused by the disparity between the world coordinate system and the measurement coordinate system. Generally, calibration accuracy is affected by accumulated errors which are generated by recognition of objects with multi-characteristics such as checkerboard. Thus, in this paper, we propose a novel extrinsic calibration method of ToF cameras with a virtual multi-cubes shaped object. First, we establish the motion model of a 3-axis translation stage composed of three linear translation stages which are orthogonal to each other. Then, a virtual multi-cubes shaped object with multi-characteristics is generated from an optimized combination of multi-motions of the 3-axis translation stage. The proposed extrinsic calibration of ToF cameras is accomplished by recognizing corner characteristics of this multi-cubes shaped object and performing least square adjustment method. Experiment results show that the measurement accuracy of a ToF camera is improved from ±10mm to 6.85mm, which is much better than that of the conventional method based on a 2D plane checkerboard. The proposed method is very simple and has the ability to improve calibration accuracy to a high level. It may find great potential applications in many fields.

9576-21, Session 4

Fiber coupler end face wavefront surface metrology

David C. Compertore, Filipp V. Ignatovich, Michael A. Marcus, Lumetrics, Inc. (United States)

Despite significant technological advances in the field of fiber optic communications, one area remains surprisingly ‘low-tech’: fiber termination. In many instances it involves manual labor and subjective visual inspection. At the same time, high quality fiber connections are one of the most critical parameters in constructing an efficient communication link. The shape and finish of the fiber end faces determines the efficiency of a connection comprised of coupled fiber end faces. The importance of fiber end face quality becomes even more critical for fiber connection arrays and for in the field applications.

Here we propose and demonstrate a quantitative inspection method for the fiber connectors using reflected wavefront technology. The manufactured and polished fiber tip is illuminated by a collimated light from a microscope objective. The reflected light is collected by the objective and is directed to a Shack-Hartmann wavefront sensor. A set of lenses is used to create the image of the fiber tip on the surface of the sensor. The wavefront is analyzed by the sensor, and the measured parameters are used to obtain surface properties of the fiber tip, and estimate connection loss. For example, defocus components in the reflected light indicate the presence of bow in the fiber end face.

This inspection method provides a contact-free approach for quantitative inspection of fiber end faces and for estimating the connection loss, and can potentially be integrated into a feedback system for automated inspection and polishing of fiber tips and fiber tip arrays.

9576-22, Session 4

Optical range finder using semiconductor laser frequency noise

Takahiro Saito, Katsuki Kondo, Yuuya Tokutake, Shinya Maehara, Niigata Univ. (Japan); Kohei Doi, Tokyo Univ. (Japan); Hideaki Arai, Takashi Sato, Masashi Ohkawa, Yasuo Ohdaira, Shuichi Sakamoto, Niigata Univ. (Japan)

Semiconductor laser range-finder systems use so-called “time-of-flight” methods, in which we need to modulate semiconductor laser’s intensity or frequency and detect those of reflected lights in order to compare optical paths to the reference and the target. But, accurate measurement requires both high-speed modulation and detection systems. Taking advantage of semiconductor lasers’ broad- spectrum frequency noise, which has a range of up to a few GHz, and converting it to intensity noise; we were able to generate a set of high-speed physical random numbers that we used, to precisely measure the distance.

We tuned the semiconductor laser’s oscillation frequency loosely to frequency discriminators, such as Rb absorption lines, and converted laser’s frequency noise to intensity noise in the transmitted light. Observed through a frequency discriminator, beams traveling along two different paths will share intensity noise patterns, but there is a time lag. We compare these two signals and calculate their cross-correlation by sweeping the time lag of two signals. The time lag, at which the highest correlation was observed, was that corresponding to the distance between two optical paths.

Through our experiments, we confirmed that the system was accurate to a distance of up to 50 m, at a resolution of 0.03 m, when the sampling rate was adjusted to 0.2 ns.

9577-21, Session PMon

Laser generation of ultrasound in adhesively-bonded multilayered structure

Yan Zhao, Bixing Zhang, Liping Xue, Nanjing Univ. of Science and Technology (China)

An analytical model for the pulsed laser generation of ultrasound in an adhesively bonded multilayered structure is presented. The model gives the time domain displacement of the structure as a function of laser characteristics and materials properties. Simulation of ultrasonic wave motion in multilayered structures is solved here with the finite element analysis. Detailed descriptions of ultrasonic waves are presented. The simulation allows a better understanding of generation and propagation by creating a window of observation in the multilayered structure.

Sensitivity of a capillary fiber resonator for measuring the fluid pressure and humidity

Duber A. Avila Padilla, Univ. Popular del Cesar (Colombia) and Univ. de Sucre (Colombia); César O. Torres Moreno, Univ. Popular del Cesar (Colombia)

In this work studied and compared the sensitivity of a micro-resonator capillary fiber made of a polymer (PMMA) for measuring fluid pressure and humidity of the environment. In the measurement we obtained and compared measurements of sensitivities from the coupling of the field of a Taper fiber. During the coupling of the field within the device, the resonance peaks device moved with the change in pressure and humidity of the environment. We conclude that there may be cross-sensitivity when the device is subjected to large changes in pressure and humidity of the environment simultaneously.

9577-23, Session PMon

Modeling of waveguide-couplers for the use in a micro-optical laser gyroscope

Ingmar Leber, Thalke Niesel, Andreas H. Dietzel, Technische Univ. Braunschweig (Germany)

A new concept for the realization of a micro optical laser gyroscope was developed. This new concept consists of a passive free space ring resonator in which the light is circulating by reflections at three double mirrors. An external light source will be used to activate the resonator. To couple the light in and out of the resonator there will be waveguide-couplers used. This paper reports on simulations of these waveguide-coupler structures. The modeled coupler structures consist of two parallel waveguides. Both waveguides have a rectangular profile. They are in close proximity over a certain path length and separated by a narrow gap. The influence of the gap width (1?m to 5?m), the proximity path length and the size (maximum profile edge length: 50?m) of the waveguides are systematically investigated. Furthermore there have been micro fabricated waveguide-coupler structures optically characterized. These experimental results are compared to the results of the simulation.

It can be ascribed to the fabrication process of the couplers that for narrow gaps waveguide material remains in these gaps. Thus in some structures there is a connection between the two parallel waveguides. Neither the experimental results nor the simulations show a considerable coupling effect when there is a great cap (maximum 5?m) and no waveguide material links the two waveguides. Thus the comparison shows that for an efficient coupling within the scope of the tested waveguide sizes there have to be a connection. These results will be used to determine the best geometry of the coupler structure for the use in the new gyroscope.

9577-1, Session 1

Using integrated modeling to assess performance of the Transiting Exoplanet Survey Satellite

Gerhard P. Stoeckel, Keith B. Doyle, MIT Lincoln Lab. (United States)

The Transiting Exoplanet Survey Satellite (TESS) is an instrument consisting of four wide field-of-view CCD cameras dedicated to the discovery of exoplanets around the brightest stars, and understanding the diversity of planets and planetary systems in our galaxy. Each camera utilizes a seven-element lens assembly with low-power and low-noise CCD electronics. The system orbits the Earth in a highly eccentric orbit. Using internally developed integrated modeling software, the point spread function is computed for multiple field points over the orbit and used to predict pointing errors for each of the four cameras. The pointing errors are caused by thermoelastic distortions of the structure and optics, and thermally induced variations in refractive index of lenses. These errors are then compared against the requirement for the maximum allowable angular rate of change, and design modifications are implemented to ensure top-level performance requirements of the TESS instrument are met.

9577-2, Session 1

Advanced Mirror Technology Development (AMTD) thermal trade studies

Thomas Brooks, H. Philip Stahl, NASA Marshall Space Flight Ctr. (United States); William R. Arnold Sr., a.i. solutions, Inc. (United States); Brent Knight, Mike R. Effinger, W. Scott Smith, NASA Marshall Space Flight Ctr. (United States)

Advanced Mirror Technology Development (AMTD) is being done at Marshall Space Flight Center (MSFC) in preparation for the next large aperture UVOIR space observatory. A key science mission of that observatory is the detection and characterization of 'Earth-like' exoplanets. Direct exoplanet observation requires a telescope to see a planet which will be 10^-10 times dimmer than its host star. To accomplish this using an internal coronagraph requires a telescope with an ultra-stable wavefront error (WFE). This paper investigates parametric relationships between primary mirror physical parameters and thermal WFE stability.

Candidate mirrors are designed as a mesh and placed into a thermal analysis model to determine the temperature distribution in the mirror when it is placed inside of an actively controlled cylindrical shroud at Lagrange point 2. Thermal strains resulting from the temperature distribution are found and an estimation of WFE is found to characterize the effect that thermal inputs have on the optical quality of the mirror. This process is repeated for several mirror material properties, material types, and mirror designs to determine how to design a mirror for thermal stability.

9577-3, Session 1

AMTD: Advanced mirror technology development in mechanical stability

Joseph B. Knight, NASA Marshall Space Flight Ctr. (United States)

Analytical tools and processes are being developed at NASA Marshal Space Flight Center in support of Advanced Mirror Technology Development (AMTD) efforts. One facet of optical performance is the mechanical stability of a mirror system. Dynamic inputs into the optical system, such as navigational maneuvers and reaction wheel or antenna motion, will potentially result in mirror deformations due to modal responses that would roll into the total Wave Front Error (WFE). The analytical process/tool reported herein makes pertinent predictions for a case study mirror design and the corresponding results. The utility of such results include being the basis for spacecraft vibration isolation systems derived performance requirements, prediction of the time required for modal responses to diminish, and contributing to the overall systems WFE predictions.

9577-4, Session 1

Unified optomechanical modeling: Stabilizing the line-of-sight of an IR imager

Alson E. Hatheway, Alson E. Hatheway Inc. (United States)

A challenge for optomechanical engineers is to make the structure sufficiently stiff to support the optical elements and stabilize the image on the detector. A complementary challenge, in an existing design, is to determine which elements need more stiffness and which others are satisfactory.

When presented with evidence (either empirical or analytical) that the image is unstable it is often not obvious which optical elements are the prime offenders. The uncertainty arises because both the elements' motions and their optical properties contribute the image motions. Since both the motions and the properties may vary by orders of magnitude in a particular design, neither one is a reliable guide for identifying major contributors to the problem.

Unified optomechanical modeling provides a vehicle for tracing offending image motions to particular optical elements and their supporting structure. The unified modeling method imports the optical elements' properties into a finite element structural model of optical system. It convolves the elements' motions and their optical properties in a single optomechanical modeling medium. This provides the engineer with a tool that discloses each element's contribution to the offending motions of the image on the detector.

This paper presents the theory of unified optomechanical modeling as used in Nastran finite element codes. The steps used in developing a unified optomechanical model will be described in detail. Comparisons of the unified modeling technique to both analytical and empirical validation studies are shown.

9577-5, Session 1

Research on model identification of ultra-precision motion stage

Sheng Qiang, Bin Wang, Harbin Institute of Technology (China)

Lithography is a high-precision manufacturing equipment of electromechanical integration, involving precision machinery, precision control, precision measurement and other subjects. It is limited by the development of optical properties, electrical properties, measurement resolution, machining capabilities, control performance, etc. The performance of lithography can be improved by the design of controllers that can ensure the high speed and high precision. The core devices of lithography is wafer stage and reticle stage, which is composed of coarse and fine motion stage with gas-lubricated bearings. Permanent magnet linear motor and voice coil motor drive the coarse and fine motion stage respectively, so as to achieve six degrees of freedom motion. For optimizing the mechanical structure and validating of advanced control methods, it is necessary to identify the ultra-precision motion platform model with resonance characteristics.

This paper analyzes the structure of precision motion platform and builds mathematical model of linear motors and voice coil motors, thereby SDOF macro-micro coupling theoretical models and 6-DOF mechanical model are established, which can reflect the combined effect of multiple motors motion characteristics. Theoretical model is the basis of model identification. The unknown parameters of the SDOF macro-micro coupling theoretical model are identified by adaptive real-coded genetic algorithm. Considering the great disturbance generated by mechanical resonance, the mechanical resonance model is built, and the parameters of the model are identified based on the hierarchical identification principle. Then the notch filter that can be used to suppress the mechanical resonance is designed to improve the dynamic response of the system. Validity of the precision motion platform model has been verified. The model will bring great convenience in designing and debugging of lithograph control system.

9577-6, Session 1

Integrated modeling: a look back

Clark Briggs, ATA Engineering, Inc. (United States)

Applications and implementation approaches for integrated modeling of structural systems with optics over the past 30 years will be provided. While much of the development work focused on control system design, significant contributions were made in system modelling and computer aided environments. Early work appended handmade line of sight models to traditional finite element models, such as the HALO spacecraft concept from the ACOSS program. The IDEAS2 computational environment built in support of Space Station collected a wider variety of existing tools around a parametric database. Later, IMOS supported interferometer and large telescope mission studies at JPL with Matlab modeling of structural dynamics, thermal analysis and geometric optics. IMOS's predecessor was a simple FORTRAN command line interpreter for LQG controller design with additional functions that built state space FEM models. Specialized language systems such as CASEY were formulated to provide more complex object oriented functions suited to control structure interaction. A more recent example of optical modeling directly in mechanical CAD is used to illustrate possible future directions. While the value of directly posing the optical metric in the system dynamics terms is well understood today, the eventual payoff will be illustrated briefly via project-based examples.

9577-7, Session 2

The different (yet similar) realms of illumination and stray light modeling

Edward Freniere, Michael A. Gauvin, Lambda Research Corp. (United States); Richard N. Youngworth, Riyo LLC (United States)

The field of non-imaging optics is a currently a diverse and fertile ground for innovation and analysis. Modeling systems for illumination and stray light effects influences a wide variety of electrical, optical, mechanical, material science, and system design decisions. Applications are also diverse in non-imaging including not only modeling of effects in imaging systems, but also important technologies such as solar energy, illumination, and projection systems, to name just a few areas of interest. In this paper, two optical engineers meet for the first time. One engineer is an expert illumination system designer. The other engineer is a stray light analysis expert. Both engineers have been pure in their disciplines. Hence, before they meet neither of them knows anything about the other engineer's world of modeling non-imaging effects. Through their interaction, an understanding of the differences and similarities in modeling these two different (yet alike) fields is covered in detail.

9577-8, Session 2

Simulating the 2D PSF of multiple-reflection optical systems with rough surfaces

Kashmira Tayabaly, INAF - Osservatorio Astronomico di Brera (Italy) and Politecnico di Milano (Italy); Daniele Spiga, Giorgia Sironi, Rodolfo Canestrari, Giovanni Pareschi, Paolo Conconni, INAF - Osservatorio Astronomico di Brera (Italy)

The Point Spread Function (PSF) is a key figure of merit for specifying optical systems' angular resolution. As the demand for higher and higher angular resolution increases, surface finishing must be seriously considered even in optical telescopes. From the instrument's optical design, well-established ray-tracing routines allow computing and display of the PSF based on geometrical optics but does not directly account for the scattering caused by surface microroughness, which is interferential in nature. Although the scattering effect can be separately modeled, its inclusion in the ray-tracing routine requires assumptions that are difficult to verify. Therefore, a purely physical optics approach is more appropriate as it remains valid regardless of the shape and size of the defects appearing on the optical surface. Such a computation, when performed in two-dimensional consideration, is memory and time consuming as it requires processing a surface map with a few micron resolution, and this becomes even more complicated for multi-reflection optical systems. Fortunately, in the far-field configuration, the computation comes down to calculate Fourier Transforms. However, to date this method was used only to study the PSF for single reflection systems. In this paper, we extend this method to multiple reflections layouts, accounting for physical optics effects. As a test case, we simulate the PSF of an ASTRI Cherenkov telescope mirror panel using physical optics approach, including measured surface defects, and we compare the result with the corresponding simulation obtained from ray-tracing and the experimental image observed in the laboratory.

9577-9, Session 2

General physically-realistic BRDF models for computing stray light from arbitrary isotropic surfaces

Alan W. Greynolds, Retired (United States)

Proposed twenty-five years ago specifically for stray light computations, a general BRDF model that automatically enforces continuity, positivity, reciprocity, and isotropic surface symmetry over all possible input/output directions has been implemented in commercial optical analysis codes. It was originally motivated by the need to fit (and possibly catalogue) measured BRDFs of everything from polished optical surfaces to rough diffuse blacks, reasonably extend in-plane only data to out-of-plane, reduce hundreds or thousands of measurement points to a relatively small number of parameters (like glass dispersion formulas), and cleanup "sloppy" data or models that violate physical constraints. However, there is no attempt to relate the BRDF to any actual surface structure or statistics (the inverse problem). As application examples, the model successfully fits several thousand measured data points on a "glossy" anodized Aluminum sample to a 100-coefficient form and several dozen measured data points on Aeroglaze Z306 diffuse black paint to a general 20-coefficient form then a simpler 2-parameter model. Variations and other general BRDF models are also proposed.

9577-10, Session 2

Optomechanical analysis of diffractive optical elements

Gregory J. Michels, Victor L. Genberg, Sigmadyne, Inc. (United States)

Diffractive optical elements are important components to many high precision optical systems. When such systems are subjected to mechanical loading these optical components yield performance degradation contributions quite different from non-diffractive optical components. It is of interest to predict by analysis such performance degradations for the purposes of development of the optomechanical design for relevant optical systems. While non-diffractive optical surfaces contribute to optical performance degradation through changes in surface shape as might be characterized by deformation normal to the surface or parallel to the optical axis of the surface, diffractive optical surfaces contribute additional optical errors due to the change in phase properties associated with deformations in directions tangent to the optical surface. Such tangent deformations cause changes in spacing on linear gratings or changes in phase profiles on more complex diffractive elements. The developments of this paper are to characterize the changes in phase due to such deformations as predicted by the finite element method and represent them in optical analysis alongside characterizations of surface shape changes.

9577-11, Session 3

Minimize polarization aberrations to use all of the photons all of the time

James B. Breckinridge, California Institute of Technology (United States) and The Univ. of Arizona (United States); Wal Sze T. Lam, College of Optical Sciences, The Univ. of Arizona (United States); Russell A. Chipman, The Univ. of Arizona (United States)

The image of the point spread function (PSF) for astronomical telescopes and instruments depends not only on geometric aberrations and scalar wave diffraction, but also on those wavefront errors introduced by the physical optics or polarization properties of reflecting and transmission surfaces within the optical system. These vector wave aberrations are called polarization aberrations and result from two sources: 1 The mirror coatings necessary to make the highly reflecting mirror surfaces and 2. The opto-mechanical packaging. Here, I discuss polarization aberrations, provide the analytical tools to calculate the PSF images and give examples of how astronomical image data may be affected.

Our findings are: 1. The image plane irradiance distribution is the linear superposition of four PSF images: One for each of the two orthogonal polarizations and one for each of two cross-product polarization terms. 2. The PSF image is brighter by 9% for one polarization component compared to its orthogonal state. 3. The image of the PSF for orthogonal polarization components are shifted with respect to each other, causing the PSF image for astronomical sources (polarized or unpolarized) to become slightly elongated (elliptical) with a centroid separation of about 0.6 masec. This is important for both astrometry and coronagraph applications. 3. The orthogonally polarized components of unpolarized sources contain different wavefront aberrations, which are separated by approximately 32 milliwaves. This implies that a wavefront correction system cannot optimally correct the aberrations for all polarizations simultaneously. 4. The polarization aberrations couple small parts of each polarization component of the light (~1E-4) into the orthogonal polarization to create highly distorted secondary, or "ghost" PSF image. 5. The radius of the spatial extent of the 90% encircled energy of this ghost PSF image is twice as large as the Airy diffraction pattern. Methods to mitigate polarization aberrations are discussed.

9577-12, Session 3

Simultaneous and independent optical impairments monitoring using singular spectrum analysis of asynchronously-sampled signal amplitudes

Latifa Guesmi, Mourad Menif, SUP'COM (Tunisia)

Fiber optic communication has been tremendous growth over the last

decade fueled mainly by the continuous and relentless demand for high capacity. Besides, transmission of high data rates over long distances is limited by the impairments in an optical fiber, like chromatic dispersion (CD), polarization mode dispersion (PMD) and optical signal-to-noise ratio (OSNR) as well as in other network components. These impairments have a significant impact of the performance of optical networks operating at data rates in excess of 40Gbps.

Thus, optical performance monitoring (OPM) is an enabling technologies for the management and maintenance of future high-speed reconfigurable optical networks. In the other hand, advanced optical modulation formats offering high spectral efficiencies have been successfully employed by analyzing the asynchronously sampled amplitude.

Based on the previous studies, this paper proposes a novel technique for independent and simultaneous multi-impairment monitoring of CD, OSNR, first-order PMD and Q-factor, where we propose the use of singular spectrum analysis (SSA) of time series analysis and prediction. It has proven their usefulness in the temporal and spatio-temporal analysis of short and noisy time series in several fields of some disciplines. This technique is based on the singular value decomposition (SVD) of a specific matrix constructed upon the time series.

The SSA forecasting method consists of two stages: decomposition and reconstruction of time series representing various optical impairments at different bit rates and modulation formats.

Numerical simulations are performed to investigate the applicability of this methods in the monitoring of phase-modulated optical signals and the prediction of OSNR, CD, PMD and Q-factor for advanced modulation formats signals at high bit rates: 100 Gbps NRZ-DP-QPSK and 160 Gbps DP-64QAM.

It is obvious from the results that the proposed technique enables large monitoring ranges. In particular, the CD monitoring ranges of 0-800 ps/nm and 0-500 ps/nm for 100 Gbps NRZ-DP-QPSK and 160 Gbps DP-64QAM systems, respectively, and also the DGD up 20 ps is monitored. We could accurately monitor the OSNR in the range of 5-30 dB with monitoring error remains less than 1 dB in the presence of large accumulated CD.

The proposed SSA-based technique proves a good monitoring accuracies of optical impairments without requiring any information about the modulation format and signals bit rates during the monitoring process.

9577-13, Session 3

Combining topology optimization and computational lithography for micro-/ nano-device design

Mingdong Zhou, Technical Univ. of Denmark (Denmark) and Dassault Systèmes Deutschland GmbH (Germany); Boyan S. Lazarov, Ole Sigmund, Technical Univ. of Denmark (Denmark)

A unified approach combining topology optimization and computational lithography is presented for the design of micro- / nano- devices fabricated by optical projection lithography. By solving a topology optimization problem and simultaneously considering the manufacturing process, it yields an effective source and a binary mask, which can be sent directly to manufacturing without additional Optical Proximity Correction (OPC). At the same time, the performance of the device, which is simulated using finite element analysis, is optimized and robust w.r.t. process variations, such as lens defocus or photo-resist / dose variations. The proposed computational framework can be applied to design micro- / nano- devices for various physical problems. A micro-compliant mechanism design example is presented to show the potential of this solution.

9577-14, Session 4

System simulation method for fiber-based homodyne multiple target interferometers using short coherence length laser sources

Maik Fox, Thorsten Beuth, Karlsruher Institut für Technologie (Germany); Andreas Streck, ELOVIS GmbH (Germany); Wilhelm Stork, Karlsruher Institut für Technologie (Germany)

Homodyne laser interferometers for velocimetry are well-known optical systems used in many applications. While the detector power output signal of such a system, using a long coherence length laser and a single target, is easily modelled using the Doppler shift, scenarios with a short coherence length source, e.g. an unstabilized semiconductor laser, and multiple weak targets demand a more elaborated approach for simulation. Especially when using fiber components, the actual setup is an important factor for system performance, as effects like return losses and multiple way propagation have to be taken into account. If the power received from the targets is in the same region as stray light created in the fiber setup, a complete system simulation becomes a necessity.

In previous work, an amplitude based signal simulation approach for interferometers based on short coherence length laser sources has been evaluated. To facilitate the use of the signal simulation, a fiber component ray tracer has since been developed that allows the creation of input files for the signal simulation environment. The software uses object oriented MATLAB code, simplifying the entry of different fiber setups and the extension of the ray tracer.

Thus, a seamless way from a system description based on arbitrarily interconnected fiber components to a signal simulation for different target scenarios has been established. The ray tracer and signal simulation are being used for the evaluation of interferometer concepts incorporating delay lines to compensate for short coherence length.

Future work will include modelling of free space optics effects in the ray tracing component.

9577-15, Session 4

Calculation of detection efficiency of the fiber-optic sensor to measure radioactive contamination using MCNP simulation

Hanyoung Joo, Arim Lee, Chan Hee Park, Rinah Kim, Joo Hyun Moon, Dongguk Univ. (Korea, Republic of)

The residual radioactivity in soil at nuclear facility site shall be measured after complete decommissioning of it. This study developed a fiber-optic sensor for measurement of gamma radiation from contaminated soil. The fiber-optic sensor consisted of Lyso scintillator, epoxy resin, and optical fiber. The epoxy resin was manufactured in trapezoid pillar shape. The small end-side of epoxy resin was connected with an optical fiber, and its other end-side was connected to a bundle of LYSO scintillator with 3 mm in diameter.

To confirm if the fiber-optic sensor has a good capability to measure gamma radiation, it was set to measure gamma radiations from Cs-137 source (1.1 ?Ci) in a disk shape for 600, 1000, and 1,800 seconds, respectively. Also, MCNP simulation was performed for the same geometry and compositions as that in the experimental setup. Comparison between measurements by the fiber-optic sensor and MCNP simulation showed that its detection efficiency was about 20%. The fiber-optic radiation sensor is expected to be useful in measuring gamma radiations from the radioactive soil at nuclear facility site.

9577-16, Session 5

Numerical investigation of the high spatial frequency gratings in photopolymer materials

Haoyu Li, Yue Qi, Ra'ed Malallah, John T. Sheridan, Univ. College Dublin (Ireland)

When a Solid-State Crystal laser source at ? nm is used for holographic recording in photopolymer materials, the maximal spatial frequency formatted theoretically is less than about 2/? nm-1 for formatting transmission gratings. To overcome the restriction of the laser wavelength achieving a higher spatial frequency, a multiply phase exposure method is introduced, by making use of the non-linear response of the photopolymer materials to the exposure intensity. By theoretical modeling, typical high spatial frequency transmission gratings are produced in an acrylamide/ polyvinyl alcohol (AA/PVA) photopolymer material, which can reach by twice previously produced maximal spatial frequency. The simulations are also carried out to calculate the holographic characterizations of the resulting high spatial frequency gratings. By doing so, the maximal holographic memory capacity for the materials can be improved.

9577-17, Session 5

Experimental study on high-brightness semiconductor laser based on spectral beam combining

Hao Tan, China Academy of Engineering Physics (China)

Based on the spectral beam combining technology, use the wavelength selection characteristic of the grating and the feedback by external cavity , to simultaneously control each element of The Diode Laser Array (DLA) to emit a different wavelength and to overlap the individual beams in the near and far fields. The spectral combined beam has the same beam quality as the beam of single element of the DLA, greatly improve the beam quality of the output beam. The conventional CM-Bar with 19 emitters is apllied, The period of the CM-Bar is 500 um and the width of emitters is 100 um .With a maximum continuous injection current of 70.00A, obtain a continuous 44.90W laser output ,The beam quality of slow and fast axes after spectral beam combining , respectively are 1.52mm * mrad and 5.00mm * mrad, spectral broadening is 3.24nm and electro-optic conversion efficiency of 36% are achieved. The output spot brightness is about 36.92MW / cm?-str.

9577-18, Session 5

Spectral beam combining of four fiber lasers based on a pair of parallel diffraction gratings

Fei Tian, Hong Yan, Gengcheng Xie, Jianmin Li, Shufeng Wang, Institute of Applied Electronics (China)

Spectral beam combining (SBC) is believed to be a feasible method to combine multiple fiber outputs with high beam quality, which attracts broad attentions in recent years. In a single diffraction grating SBC system?the requirement for laser parameters is restrict , which limits the development of high power beam combination system. In this paper, we described a theoretical and experimental investigation on the SBC of four fiber lasers based on a pair of parallel diffraction gratings. The wavelengths of the four fiber lasers are 1060 nm, 1062 nm, 1064 nm and 1066 nm, respectively, and the beam quality of each one is approximately diffraction limited. With spectral beam combining, the output power of 1.62 kW was achieved with beam quality M2 as high as 1.4, while the combining efficiency was about 92.2%. Both theoretical and experimental results illustrated that SBC based on a pair of parallel diffraction gratings could be useful for multiple fiber output combination while maintain high beam quality.

9577-19, Session 5

Temperature sensing on tapered single-mode fibre using mechanically-induced long-period fibre gratings

Sigifredo Marrujo-García, Ernesto González-Ocaña, Jesus Salvador Velazquez-Gonzalez, Fernando Martínez-Piñón, Maria Guadalupe Pulido-Navarro, Ctr. de Investigación e Innovación Tecnológica (Mexico); Daniel Enrique Ceballos-Herrera, Univ. Autónoma de Nuevo León (Mexico)

The modeling of a temperature optical fibre sensor is proposed and experimentally demonstrated in this work. The suggested structure to obtain the sensing temperature characteristics is by the use of a mechanically induced long period fiber grating on a tapered single mode optical fibre. The optical taper is made by applying heat using a butane flame burner and stretching the single mode fibre whose coating has been removed. The resulting geometry of the device is important to analyze the coupling from the core mode to the taper cladding, and this will determine whether the fibre taper is adiabatic or nonadiabatic. The sensor is tested from room temperature up to 600 0C showing high sensitivity of nearly 50 pm/0C around the resonant wavelength of 1550 nm.

9577-20, Session 5

Low-cost and high-resolution interrogation scheme for LPG temperature sensor

Venkata Reddy Mamidi, Srimannarayana Kamineni, National Institute of Technology, Warangal (India)

In this article we present a low-cost and high resolution interrogation scheme for a long-period fiber grating (LPG) temperature sensor, with adjustable temperature range. In general LPG is used as an optical edge filter to interrogate the wavelength encoded signal from sensors such as fiber Bragg grating (FBG) by converting it into intensity modulated signal. But the interrogation of LPG sensors using FBG is a bit novel and is to be studied experimentally. In this study an LPG drawn by using CO2 laser has been used as sensing element for temperature measurement over a range of 15-450°C. The sensor works based on measurement of shift in attenuation band of LPG corresponding to the temperature. The wavelength information form the LPG sensor is measured using an optical spectrum analyser (OSA). Further the bulk and expensive OSA is replaced with a low cost interrogation system employed a fiber Bragg grating (FBG), photodiode and a transimpedance amplifier (TIA). The light signal from LPG is reflected by the FBG of suitable Bragg wavelength and thus converted into an intensity modulated signal. This intensity signal is captured by a photodiode accompanied with TIA. The designed interrogation scheme made the system low-cost and fast in response, and also enhanced its resolution to 0.1°C. But the scheme has reduced the range of temperature measurement to 120°C. However this range can be shifted within 15-450°C by means of adjusting the Bragg wavelength of FBG.

Conference 9578: Current Developments in Lens Design and Optical Engineering XVI

SPIE. OPTICS+ PHOTONICS OPTICAL ENGINEERING+ APPLICATIONS

Monday - Tuesday 10–11 August 2015

Part of Proceedings of SPIE Vol. 9578 Current Developments in Lens Design and Optical Engineering XVI

9578-1, Session 1

Simulation of the optical performance of refractive elements to mimic the human eye focusing

Gerardo Diaz-Gonzalez, Agustín Santiago-Alvarado, Ángel S. Cruz-Félix, Univ. Tecnológica de la Mixteca (Mexico)

Refractive optics has evolved and incorporated new elements in optical systems every day, such as conventional lenses, tunable lenses, GRIN lenses, Fresnel lenses, diffractive lenses, intraocular lenses, etc. Some of these elements are reported in the literature together with different proposed models of the human eye. In this work, optical properties of each of these lenses will be studied, and simulations of their behavior will be done in order to analyze which one is better for imaging process. Such lenses will be incorporated in an optical system that mimics the human eye behavior. Analysis and obtained results are reported, as well as the proposed optical system. Finally, we present the conclusions of the work.

9578-2, Session 1

The point spread function in paraxial optics

Russell A. Chipman, Wai Sze T. Lam, College of Optical Sciences, The Univ. of Arizona (United States)

Paraxial optics is generally regarded as yielding ideal spherical wavefronts. These spherical wavefronts should yield ideal Point Spread Functions. But small polarization deviations from uniformly polarized input occur across the exit pupil in paraxial optics for skew rays. The cause of this polarization rotation, known as skew aberrations, is related to the Berry phase. These polarization variations yield additional cross-polarized components in the PSF. The form of these PSF components are related to the derivative of the PSF. These PSF components, which although very small, are nevertheless not zero. Since they occur within paraxial optics they are thus intrinsically interesting.

9578-3, Session 1

Fast robust non-sequential optical ray-tracing with implicit algebraic surfaces

Alan W. Greynolds, Retired (United States)

The fastest, most robust, general technique for non-sequentially ray-tracing a large class of imaging and non-imaging optical systems is by geometric modeling with algebraic (i.e. polynomial) implicit surfaces. The basic theory of these surfaces with special attention to optimizing their precise intersection with a ray (even at grazing incidence) is outlined for an admittedly limited software implementation. On a couple of “tame” examples, a 64-bit Windows 7 version is significantly faster than the fastest commercial design software (all multi-threaded). Non-sequential ray-surface interactions approaching 30M/sec are achieved on a 12-core 2.67 GHz Mac Pro desktop computer. For a more exotic example of a 6th degree Wood’s horn beam dump (light trap), a 32-bit Windows single thread version traces rays at least 3 times faster than the commercial ASAP software’s implicit algebraic surface and over 10 times faster than its equivalent NURBS surface. However, implicit surfaces don’t play well with most CAD systems and thus unfortunately, don’t easily fit into a modern workflow.

9578-4, Session 1

Mathematical modeling and analysis for self-radiation stray light of infrared imaging system

Jian Du, Beijing Simulation Ctr. (China)

Stray light is the non-imaging beam arriving at the detector. Due to its existence, detector’s SNR (Signal Noise Ratio) is depressed and the whole optical system’s detecting and recognizing ability is also affected. So the ability to suppress stray light is the key to improve the detecting ability of systems for a certain photoelectric sensor of the detector. In visible light range, optical systems only channel off the beams but not emit stray light. While the infrared optical systems shelter and absorb the incident stray light and emit thermal radiation at the same times.

In this thesis?a novel way to quantitatively analyze and calculate the near-field stray radiation of infrared system is proposed. The main contents are:

Firstly, by analyzing and researching the source and transmitted process of self-radiation stray light, it is found that the reflection and refraction are the main factors but the scattering and diffraction are subordination ones. So the self-radiation stray light is researched in deterministic way, and the result is evaluated with the distribution of radiant illumination..

Secondly, a mathematical model based on geometrical optics of self-radiation stray light is built. The coordinate of the intersection point of the light and the imaging plane is calculated with the method of certain directional differential and sequent ray tracing, and the energy distribution is exported with energy count matrix.

Thirdly, a self-radiation stray light of infrared imaging system analysis software is developed. Based on the basic principle of radiation energy and power, a detailed project of radiation source and entrance pupil sampling of self-radiation analysis is proposed, giving the calculating formula with the assistance of MATLAB.

9578-5, Session 1

Comparison of geometrical and diffraction optical transfer functions *(Invited Paper)*

Virendra N. Mahajan, College of Optical Sciences, The Univ. of Arizona (United States); José Antonio Diaz Navas, Univ. de Granada (Spain)

In an earlier paper, we reviewed and compared the geometrical and diffraction point-spread functions of an optical imaging system [V. N. Mahajan, “Comparison of geometrical and diffraction point-spread functions,” SPIE Proc. 3729, 434-445 (1999)]. In this paper, we review and compare its corresponding optical transfer functions. While the truth lies with the diffraction OTF, it is considered easier and quicker to calculate the geometrical OTF, especially for large aberrations. We describe the theory of the two OTFs, and explore the range of spatial frequencies and the magnitude of the primary aberrations over which the geometrical OTF may provide a reasonable approximation of the diffraction OTF.

9578-6, Session 2

Integration design of endoscopes with different viewing directions *(Invited Paper)*

Dewen Cheng, Yongtian Wang, Beijing Institute of Technology (China)

Endoscopic optical systems for different viewing directions of 0°, 12°, 30°, 45°, 70° and 90° are designed and fabricated. Effort is made to use a

similar set of lenses in the designs of the objectives of these endoscopes in order to reduce the fabrication cost. However, the stop surface is located at different positions for different viewing directions, as the obstruction of the light should always be avoided when different folding prisms are used. In our design results, two of the objective lenses are different, and the space distances between the objective lenses are set as zoom parameters in order to improve the imaging quality of different systems for different viewing angles. The six endoscopes are set up as a multi-configuration system and optimized as a whole. The design and prototype results show that the imaging performance of the systems are fine enough for medical usage. We further introduce freeform surfaces into the design of the endoscopic objectives, which can greatly simplify the structure of the systems.

9578-7, Session 2

Recent experience with design and manufacture of cine lenses

Michael D. Thorpe, Kristy Dalzell, Raytheon ELCAN Optical Technologies (Canada)

Modern cine lenses require a high degree of aberration correction over a large and ever expanding image size. It would be difficult if not impossible to achieve this correction in a lightweight and compact lens package without the use of aspheric surfaces and the modern glasses that have been developed in recent years. The nominal compact design using high index glass is then typically very tolerance sensitive, not least of these tolerances are the aspheric surface and aspheric surface alignment tolerances. Some assembly strategy including compensators must be selected to achieve an acceptable level of performance in a medium volume production environment. The compensation strategy is critical to the manufacturability of the lens as it defines the tolerance band for both optics and mechanics. For instance use of a decenter compensator may offer the attractive prospect of much looser element decenter and wedge tolerances.

In this paper we first review the toleranced performance characteristics of some modern cine designs both our own internal designs and from the patent literature. The critical tolerances and tolerance uncertainties are reviewed as well as the development of particular aberrations with build errors. Several potential compensation schemes are proposed and assessed with impact on tolerances. We then present some statistical data on production lens performance relative to a particular tolerance and compensation model.

9578-8, Session 2

Ultra-compact hourglass lens for integrated cameras

Mohsen Rezaei, Hooman Mohseni, Northwestern Univ. (United States)

Producing a high field of view (FOV) sub-millimeter lens for ultra-low dimensional cameras is still a considerable challenge. Here we introduced a new design for an ultra-compact lens with special frequency of ~200 cycle/mm (MTF=0.5), at FOV= ±30° . A part of our work is to produce a micro-machined assembly holder for such lens. Conventional assembly methods are not suitable for these dimensions - nor are traditional micro-processed lenses due to the high aspect ratios needed. We developed micromachining technique to make a holder with volumes below 0.6?0.6?0.6 mm3. The main goal of this work is realization of ultra-compact high-resolution optics with large FOV for ultra-thin 2D and 3D imagers. Point spread function (PSF) for this lens will be extracted using direct imaging on imager arrays with small (~1.2um) pixel pitch, as well as measurement of beam shape with costume designed scanning confocal microscopy.

9578-9, Session 2

Landsat-swath imaging spectrometer: optical design

Pantazis Mouroulis, Robert O. Green, Byron E. Van Gorp, Lori Moore, Jet Propulsion Lab. (United States)

We describe the optical design of a high-throughput pushbroom imaging spectrometer and telescope system capable of Landsat swath and resolution, while providing better than 10 nm per pixel spectral resolution. The design is based on a 3200 element x 18 ?m pixel size focal plane array, two of which are utilized to provide the full swath. At an optical speed of F/1.8, the system is the fastest proposed to date to our knowledge. The utilization of only two spectrometer modules fed from the same telescope reduces system complexity while providing a solution within reachable detector technology.

9578-10, Session 3

Testing and alignment of freeform-based multi-mirror telescopes *(Invited Paper)*

Xue-jun Zhang, Donglin Xue, Ming Li, Changchun Institute of Optics, Fine Mechanics and Physics (China)

Three Mirror Anastigmat (TMA) systems including both on-axis and off-axis configurations have been widely used in space applications. In some designs, correction for high-order aberrations and realization of large FOV, freeform surfaces are used to provide more design freedoms. This trend brings challenges to optical manufacturing and testing community. In this paper, the design principle and aberration fields of freeform-based multi-mirror telescopes are discussed. Since testing is critical to make highly accurate aspheres and freeform surfaces, the paper also addresses Computer Generated Hologram (CGH) design and implementation to measure large freeform mirrors. In particular, the design of a multifunctional CGH element simultaneously used for individual mirror testing and system alignment is introduced. Finally, CGH assisted alignment procedure for TMA telescopes are discussed in detail.

9578-11, Session 3

Tolerancing an optical freeform surface: an optical fabricator's perspective

Jessica D. Nelson, Kate Medicus, Michael P. Mandina, Optimax Systems, Inc. (United States)

Freeform optical shapes or optical surfaces that are designed with non-symmetric features are gaining popularity with lens designers and optical system integrators. Tolerances on a freeform optical design influence the optical fabrication process. Case studies and soft tolerancing limits for easier fabrication of these freeform surfaces will be discussed. Freeform optical manufacturing is similar to high departure and complex aspheres, which implies that many of the same tolerancing limits apply, such as a minimum local concave radius and maximum sag to allow for tool clearances. Measurement is also a gating item. Initial work shows that various measurement platforms correlate, but discrepancies at low orders remain. Although significant progress has been made in this area, additional research is ongoing in order to ensure the capability of fractional wave freeform surfaces. In addition to reducing freeform measurement uncertainty, questions have arisen around specifying and controlling the surface form. A few of these questions include: How is radius error separated from irregularity? How is alignment error separated from irregularity? How is wedge defined for a freeform? How is thickness measured and defined? These questions along with others regarding optical tolerancing of freeforms will be addressed in this paper.

9578-12, Session 3

Manufacture and analysis of a refractive surface with variable asphericity to model the human cornea

Ángel S. Cruz-Félix, Agustin Santiago Alvarado, Fernando Iturbide Jiménez, Univ. Tecnológica de la Mixteca (Mexico); Eduardo Tepichín-Rodríguez, Estela López-Olazagasti, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico)

The cornea contributes substantially to the performance of the human eye and obtaining the shape of the corneal surface is crucial for ophthalmic applications such as manufacture of contact lenses and visual laser correction. In this direction, there exist a large amount of theoretical models which describe the shape of the corneal surface. A previous model of the anterior corneal surface using high-order aspherics have been reported in the literature, and one of the main features of this model is that it has been shown to accurate reproduce the clinical data. In this work we design a refractive surface with variable asphericity using the model mentioned above by means of finite element software, and once the design was obtained we proceeded to manufacture the optical surface made of a polymer known as PDMS. Also an interferometric analysis with a Mach-Zehnder interferometer was performed in order to obtain its wavefront aberration function. The main application of this optical surface is to be used as a substitute of a corneal surface within an optomechanical system to mimic the performance of the human eye.

9578-13, Session 3

Research on the collimators' position method for nanometer accuracy aberration inspection with Shack-Hartmann method

Jiani Su, Zengxiong Lu, Yuejing Qi, Guangyi Liu, Qingbin Meng, Academy of Opto-Electronics (China)

The accurate position of the collimator before the sensor is one key factor for lithographic lens aberration inspection with nanometer accuracy based on the method of Shack-Hartmann.

Based on the wave-front reconstruction with Zernike polynomials, in this paper, an optical alignment method for acquiring the positional displacements of collimator is presented. The function between the Zernike coefficients and the displacements with multi-degree-of-freedom is used, a matrix in the function is obtained from the Zernike coefficients variations for collimator's different positions, and then the collimator's positional displacements were acquired. The accurate position of collimator is solved by this method.

Based on the aberration inspection with Shack-Hartmann method, an engineering model of 193nm NA 0.75 projection lens in commercial simulating software (ZEMAX) was established, analyzed the influence of measurement accuracy toward the positional displacement of collimator, and the distribution map of positional displacement was acquired.

9578-14, Session 4

The design of spherical aberration free multi-layer lenses for the K- and W-bands

Alex Orange, David Schurig, The Univ. of Utah (United States)

In the context of designing microwave and millimeter focusing optics, we explore the optimization of a multilayer lens design with arbitrary (azimuthally symmetric) surfaces and interfaces to reduce geometric aberrations and reflection over moderate bandwidth. In these wavelength ranges arbitrary surface fabrication and mating is possible with standard machining techniques. Optimizations are performed using ray optical path length, with confirmation and diffraction effects provided by FDTD simulations. Test lenses are machined from commercially available polymers and measured with a K-band and W-band free-space, scanning measurement system.

Prior work has focused on the use of power series to describe the surfaces of a lens system and eliminate a finite set of aberrations. This work provides a method to describe the final surface to be added to any lens system that compensates for all spherical aberrations. The resulting surface is the solution to a quadratic equation that satisfies the condition that all optical path lengths are the same. As such the surface is analytic. We use this formulation to specify the final surface of a multi-layered lens. Using multiple, properly chosen, layers reduces both reflections and aberrations. These extra layers are free surfaces and can be used to reduce or eliminate other aberrations (i.e. coma, astigmatism, distortion, field curvature and others of higher order). Raytracing confirms the lack of spherical aberrations. Preliminary electromagnetic simulations using FDTD have shown that this provides a focal intensity of 5.22 compared to 4.44 for a spherical surface (with a 20 wavelength aperture).

9578-15, Session 4

Rainbow station via geometric phase holograms

Jihwan Kim, North Carolina State Univ. (United States)

Wavefront control over the optical geometric phase is a completely new way of beam shaping beyond a spatial control of classical optics based on the optical path differences. Optical elements that are based on spatial control of the geometric phase have been studied but prior studies were limited by the fact there were no practical method to realize spatially varying optical elements with arbitrary polarization patterns. Here we report an effective way to generate geometric phase holograms (GPHs), which are formed as thin films of liquid crystal that can control the angle and color dispersion of lightwaves with very high efficiency. This paper shows various examples of the GPHs including recent high-tech demonstration of the elements working as a rainbow maker onto one of the Amsterdam Central Station's 45 by 25 meter roof arches. This demonstration comes courtesy of artist Daan Roosegaarde and researchers in NC State University, Leiden University, and ImagineOptix Corporation, in celebration of the 125th anniversary of the station's opening and the start of the UNESCO International Year of Light 2015.

9578-16, Session 4

Assessment of technological need and availability to use optical imaging devices in augmented reality devices for cancer detection and improved removal

Rose Ann M. Haft, MUIH (United States)

Cancerous cells are larger and smaller than normal cells, with nuclei that are either enlarged or smaller. They also emit a different wavelength than normal cells, which can be detected using optical detectors sensing between 1226 and 1370 nm with a resolution of <0.5mm that to be able to tell the difference between cancerous and noncancerous cells without having to worry about the pixel size of cameras or sensors. Current augmented reality systems have very small screens and various degrees of resolution and pixel to pixel mapping onto the surface to be used before and during surgery to help make informed decisions during procedures. An overview of the state of science and directly applicable technology is given to understand the feasibility, challenges and benefits of using optical technology combined with augmented reality to help improve the cancer detection and removal process.

9578-17, Session 4

Reducing chromatic aberrations of a multichannel multiresolution imaging system using hybrid lenses

Gebirie Y. Belay, Heidi Ottevaere, Michael Vervaeke, Jürgen Van Erps, Youri Meuret, Hugo Thienpont, Vrije Univ. Brussel (Belgium)

Conventional multichannel imaging systems comprise of many channels having similar imaging properties, namely field-of-view (FOV) and angular resolution/magnification. We demonstrated that the different channels can be designed such that each channel captures a different FOV and angular resolution compared to its neighboring channels. We designed and experimentally demonstrated a three-channel multiresolution imaging system where the first channel has the narrowest FOV (7°) and highest angular resolution (0.0096°) and the third channel has the widest FOV (80°) and lowest angular resolution (0.078°). The second channel has intermediate properties. The performance of the demonstrated three-channel imaging system however was affected by chromatic aberrations as it was designed for a single wavelength of 587.6 nm. The first channel was largely influenced by longitudinal chromatic aberration and the third channel by lateral chromatic aberration. Therefore, we have replaced the aspherical refractive lenses by hybrid lenses, which contain diffractive structures on top of their refractive surfaces, in the three-channel multiresolution imaging system to reduce its chromatic aberrations. The performance of the three channels with hybrid lenses is compared with those of the corresponding channels without hybrid lenses. The longitudinal color aberration of the first channel has been reduced from 1.7 mm to 0.2 mm; whereas the lateral color aberration of the third channel has been reduced from 250 μm to 14 μm. In conclusion, the hybrid lenses have reduced the chromatic aberrations of the three channels and extended the operating spectral range of the imaging system in the visible wavelength range.

9578-26, Session PMon

Laser-strength interference coatings at 1540-2100 nm

Vladimir V. Novopashin, Alexsandr V. Shestakov, JSC “Research Institute” POLYUS “them. M.F. Stelmaha” (Russian Federation)

The development of laser technologies defined the novel quality demands to optical interference coatings. Among various film parameters, laser strength to laser irradiation is the most importance. It is necessary to note, that laser damage at spectral range 1540-2100nm has some peculiarities in comparison with 1064 nm. We can added, that almost perfect film structure without porous must be obtained in both cases, but in range 1540-2100nm water molecule can be present in micro-porous structure. Thin-film microstructure has strongly affects on optical coatings performance in harsh environments and is complex function of arrival energy of film atoms, growth rate and temperature, surface preparation and topography, residual gases and ion bombardment [1, 2]. By no means, optical films with low losses and high laser strength can be produced by ion-beam evaporation materials or electron ion assisted beam evaporation. Advantages and deficiency of both methods will be discussed. All films in this work were produced by electron-beam evaporation with ion assistance. The effect of ion-beam influence at grate extent displayed during evaporation oxide materials. Besides, influence of active ions Ar +and O2+ and substrate temperature is considered to be the factor of densification film structure. Various regime of ion source that impact on laser strength were investigated. Ion energy from less than 100 eV to a few hundred eV is generally sufficient for surface cleaning without significant damage. Based on these technological effects experimental processes were produced. Pre-cleaning pure substrate by the ion-beam of Ar+ before the evaporation and also after each layer was important to produce mirrors for Y3Al5O12 +Ho3+ lasers in 2088 nm. Moreover, this effect revealed when oxide materials with d-electron orbital were used. To such materials can be regarded TiO2, Ta2O5, Nb2O5 which possess the possibility to have various valences of metals. For this reason the connection metal – O2 can be disturbed, and empty appear on film structure. Influence of active Ar+ +O2+ ions in this case led to formation almost perfectly surface. Anti-reflection, output and high reflection coatings were examined. High reflection mirrors at 1540 nm have laser damage 3.0 – 3.5 GW/cm2 with pulse 20ns. At 2088nm laser damage for output mirror with anti-reflection coating and high reflection mirror was 30 – 40 J/cm2 with pulse 600 μs in laser spot 2.5 mm.

Microresonator based on a polymer capillary fiber PMMA for the measurement of humidity

Duber A. Avila Padilla, Univ. Popular del Cesar (Colombia) and Univ. de Sucre (Colombia); César O. Torres Moreno, Univ. Popular del Cesar (Colombia)

In this paper the properties of a polymer fiber capillary PMMA for measuring the humidity of the environment is studied. Polymer fiber capillary has a reduced size and acts as a microresonador where the field is coupled through a fiber Taper reaching WGMS excitation of modes within the cylindrical cavity. The sensitivity of the device is measured and calculated from a simplified theoretical model being able to obtain similar results. The sensitivity of the device depends on the geometric parameters such as wall thickness and outer diameter.

9578-28, Session PMon

All-reflective zoom system based on foveae technology

Jun Chang, Ke Zhang, YiFan Huang, Jing Chen, Jian Yang, Beijing Institute of Technology (China)

Reflective zoom optical system has many advantages, such as light weighted, no influence of chromatic aberration, and high thermal stability, which can be widely used in many fields. This paper is based on the foveae principle to design a new reflective zoom system with several different mirrors, respectively presents the simulation, optimization, and image quality evaluation. Finally, through the analysis of aberration and structural performance, the new concept system was introduced to improve the balance capacity for optical aberration; we obtained the off-axis three-mirror system based on foveae concept, this kind of new systems is of good technical reference for the use of different special area.

9578-29, Session PMon

Design considerations for an unconventional infrared prism with a 90-degree ray deviation

Beyza Akarca, Goktug G. Artan, TÜBITAK SAGE (Turkey)

In this study, the optical performance of a 90 degree prism working in the mid-wave infrared region with the purpose of carrying a beam of light from one optical system to another in an unconventional way is discussed. First, a group of mirrors is considered as a design alternative to lower the overall cost of the system. However, using mirrors greatly increases the diameter of the beam due to the rays coming from wide field of view angles.

Another drawback of mirrors is that having separate mirrors requires precise alignment for the system to work at full performance which is difficult for the given application. However, these alignment issues are not valid for a single piece prism. Therefore, a single piece prism is the preferred option and has been taken into account in this study. Material selection is important, especially in the mid-wave infrared region where the index of refraction differs greatly from material to material. Silicon and Germanium are the materials preferred because of their high index of refraction and transmission characteristics. Aside from optical properties, these materials are also considered in terms of manufacturability. Also, options for the coatings to be applied to reflecting surfaces of the prism are discussed with regard to the transmission loss within the system. In order to have total internal reflection within a prism, coatings must be chosen carefully to handle transmission loss at the reflecting surfaces. All of the system parameters are examined using sequential and non-sequential modes of ZEMAX OpticStudio software.

Optical modeling with precise spatial-chromatic light distribution in phosphor-converted white LEDs

Ching-Cherng Sun, Yu-Yu Chang, Yu-Huan Wang, Ching-Yi Chen, Yi-Chien Lo, Han-Hsiang Cheng, National Central Univ. (Taiwan)

In this paper, a new modeling algorithm for use in phosphor-converted white light-emitting diodes (pcW-LEDs) is proposed, which is aimed to perform accurate simulation for color appearance. Furthermore, the algorithm can be potentially enabling optical designers to remove yellowish/bluish spots in LED lighting. The modeling process begins by conducting ray tracing of the light emissions from the active layer of a blue die. The blue light then penetrates the phosphor volume with absorption for reemitting yellow light, or redistributes through Mie scattering. The yellow light is from isotropic radiation caused by the yellow phosphor and is redistributed through Mie scattering. After verifying key parameters, namely the absorption coefficient and conversion efficiency of the phosphor, the blue and yellow light distributions can be precisely simulated. Accordingly, the proposed modeling method was applied to simulate a pcW-LED without an encapsulation lens, and subsequently, a pcW-LED with a hemispherical lens. Both simulations accurately predicted the blue and yellow light distribution. The model was further verified by applying a total internal reflector lens to the pcW-LED. In the midfield region, the blue and yellow light distribution exhibited large variations as the observation distance changed; this varying light pattern for both the blue and yellow lights can be accurately predicted using the proposed model. The developed optical model will be helpful to facilitate designing a pcW-LED that features high-quality illumination and higher color uniformity in practical.

9578-31, Session PMon

Analysis of three-element zoom systems for laser beam expanders with tunable-focus lenses

Pavel Kulmon, Antonín Mik?, Pavel Novák, Ji?í Novák, Czech Technical Univ. in Prague (Czech Republic)

Lasers are widely used in many areas of science and technology. Since a laser beam has specific optical properties, there are required special optical systems for transformation of laser beams. Common optical systems used both in classical imaging optics and laser optics are beam expanders. In case of transformation of a homocentric light beam simple telescopic systems are being used for the beam expansion. In case of a laser beam the input Gaussian beam has to be transformed into output Gaussian beam with a different waist diameter and divergence. Thus, the design of the optical system of a laser beam expander is different because of different formulas are valid for the transformation of the Gaussian laser beam. The properties of the Gaussian beam has to be considered during the design of such laser beam expanders. In practice zoom optical systems are frequently required in various applications. For the case of classical homocentric beams the problem of an analysis and design of zoom systems is described thoroughly in literature.

Our work is focused on the problem of a theoretical analysis of imaging properties and initial optical design of the three-element zoom optical system for laser beam expanders using lenses with a tunable focal length. Equations that enable to calculate basic paraxial properties and parameters of such optical systems are derived. Finally, the derived equations are applied on an example of calculation of parameters of the three-element zoom system for the laser beam expander.

9578-32, Session PMon

Recovery of objects on move with digital holographic techniques

Martin Hernández-Romo, Pedro Soto-López, Alfonso Padilla-Vivanco, Univ. Politécnica de Tulancingo (Mexico)

A digital holographic recorder setup based on off-axis interferometer is presented. The holographic recording makes use of illumination by reflection in order to get some holograms from samples with disturbance induced by mechanical vibrations. Moreover, the Gabor Wavelet transform and the impulse response technique are used to compute the numerical diffraction pattern distributions, which both are compared with the angular spectrum method. This last method allows to retrieval the phase distribution in short reconstruction distances down to zero and with flexibility in the control of image noise. Finally, the phase retrieval algorithms are completed with the two dimensional unwrapping phase method based on a reference hologram for the purpose of compensate the optical aberrations introduced by the digital holographic recorder system. On other hand, due to the samples have high scattering surfaces it is important to use a retrieval algorithm that is previously calibrated. Experimental results are presented.

9578-33, Session PMon

The fractional Fourier transform of the aperidic and fractal functions

Alfonso Padilla-Vivanco, Aldo Yuck-Franco, Univ. Politécnica de Tulancingo (Mexico)

In this work the fractional Fourier transform (FRFT) from aperiodic and fractal functions have been computed to obtain the physical properties of some optical elements. One of most promising candidates in optical imaging is the Fibonacci grid. In this paper, the diffraction patterns of Fibonacci gratings (FBG) are computed, which are typical examples of aperiodic devices. These kinds of optical devices have some novel features such as redundancy and robustness, maintaining their imaging features intact even when there is significant loss of information. FBGs also contain fractal signatures and are characterized by a fractal dimension. Our study suggests that non-periodic gratings may be better than their counterparts the fractal-based technologies. Also we can identify the characteristics that define the frequency. We investigate the analysis of a digital-optical information system based on the architecture of the Fractional Fourier transform. We describe the intensity retrieval process by Fourier-type filters. A mathematical analysis and an optical-digital setup is shown. Experimental results are shown.

Design and fabrication of a tunable solid elastic lens

Agustín Santiago-Alvarado, Univ. Tecnológica de la Mixteca (Mexico); Emilio Reyes Pérez, Univ. Technológica de la Mixteca (Mexico); Daniel Arriaga Martínez, Fernando

Iturbide Jiménez, Ángel S. Cruz Félix, Jorge González García, Enrique A. López López, Univ. Tecnológica de la Mixteca (Mexico)

The development of a tunable Solid Elastic Lens (SEL) involves the design of an electromechanical system that will be used to modify some of its geometrical parameters. The raw material used for the fabrication of the SEL is the polymer known as PDMS due to its excellent mechanical and optical properties which are desirable for a particular application. Nevertheless, the presence of air bubbles formed within the main body during the process of curing of these kinds of lenses is a recurring problem; additionally the jaws do not exert pressure or tension uniform on the lens body, extra optical aberrations are introduced to the overall optical system because of the mentioned problems. We describe in this work a new methodology to fabricate SELs made of PDMS without air bubbles and the use of a mechanical system of uniform actuation is presented in order to reduce optical aberrations.

9578-35, Session PMon

Design of an optical system that mimics the human eye image formation

Agustín Santiago-Alvarado, Cristian Á. Domínguez Osante, Ángel S. Cruz Félix, Univ. Tecnológica de la Mixteca (Mexico)

The eye is one of the most complex organs in the human body and constantly is being under study in order to fully describe its objective performance and its characteristics. Several theoretical models have been proposed to describe it and even functional models using fixed elements to describe the iris and the crystalline lens can be found in the literature, however, these result in a restricted version of the actual eye and are mainly used for educational purposes. In this work, we present the design of an optical system that mimic the optical behavior of the human eye for image formation. We include a dynamical aperture diaphragm to emulate the iris and a tunable lens is used to emulate the crystalline lens in order to achieve focus objects at different focal distances. Results and simulation analysis of the opto-mechanical performance of the proposed optical system is presented.

9578-36, Session PMon

Extending the depth-of-field for microscopic imaging by means of digital image fusion

Alfonso Padilla-Vivanco, Carina Toxqui-Quitl, Roman Hurtado-Perez, Univ. Politécnica de Tulancingo (Mexico)

In optical microscopy, the depth of field (DOF) is limited by the physical characteristics of the image-forming systems. Taking a focused picture with all the field of view can be impossible to reach in optical microscopy. So that, we have to use some digital image techniques to produce a complete focused image from all the field of view. In order to extend the DOF in an optical microscopic system, this paper propose a method based on image fusion and in the module of the gradient color planes. The procedure is to move the microscope stage in the paraxial Z-axis taking several color images to fuse them in a single composite image. The lighting technique used is by means of the bright field in reflection. Our results are obtained by using real samples and also any post-processing steps are performed to merge a final fused image. The proposed method is simple, fast and virtually free of artifacts or false color. Experimental results are presented.

9578-37, Session PMon

Optical model of optical volume diffusion plate: polycarbonate plate doped with silicon dioxide micro particle

Yeh-Wei Yu, Yu-Heng Chen, Ming Le, Ching-Cherng Sun, National Central Univ. (Taiwan); Jong-Wu Chen, Plastic Industry Development Ctr. (Taiwan); Chih-Yuan Cheng, National Central Univ. (Taiwan)

High-efficiency diffusers play important roles in modern optical industry. The applications include back-light of television, uniform lighting, glare suppression, lighting decoration, and so on. In this paper, we develop optical volume diffusion plate using polycarbonate (PC) plate doped with silicon dioxide (SiO_2) micro particle. In order to predict the optical performance of the diffuser with different particle concentration and micro particle size, we use Monte-Carlo ray-tracing with Mie-scattering model to build up the optical model. Because particles distribution is not uniform inside the volume diffusion plate, we use particle space as a tuning factor in the Mie-scattering model. Finally, we use the high speed measurement system - screen imaging synthesis (SIS) system to measure the BSDF of each diffuser and demonstrate the optical model.

9578-38, Session PMon

Coaxial fundus camera for opthalmology

Jarbas C. Castro Neto, Univ. de São Paulo (Brazil)

A Fundus Camera for ophthalmology is a high definition device which needs to meet low light illumination of the human retina, high resolution in the retina and reflection free image. Those constraints make its optical design very sophisticated, but the most difficult to comply with is the reflection free illumination and the final alignment due to the high number of non coaxial optical components in the system. The reflection of the illumination, both in the objective and at the cornea, mask the quality of the image, and a poor alignment make the sophisticated optical design useless. In this work we developed a totally axial optical system for a non-midriatic Fundus Camera. The illumination is performed by a LED ring, coaxial with the optical system and composed of IR of visible LEDs. The illumination ring is projected by the objective lens in the cornea. The Objective, LED illuminator, CCD lens are coaxial making the final alignment easily to perform. The CCD lens is a CCTV camera with autofocus and Zoom built in, making the system easily operated and very compact.

9578-18, Session 5

Temperature-dependent refractive index measurements of L-BBH2 glass for the Subaru CHARIS integral field spectrograph

Douglas B. Leviton, Leviton Metrology Solutions, Inc. (United States); Kevin H. Miller, Manuel A. Quijada, NASA Goddard Space Flight Ctr. (United States); Tyler D. Groff, Princeton Univ. (United States)

Using the Cryogenic High Accuracy Refraction Measuring System (CHARMS) at NASA's Goddard Space Flight Center, we have made the first cryogenic measurements of absolute refractive index for Ohara L-BBH2 glass to enable the design of a prism for the Coronagraphic High Angular Resolution Imaging Spectrograph (CHARIS) at the Subaru telescope. L-BBH2 is employed in CHARIS's prism design for improving the spectrograph's dispersion uniformity. Index measurements were made at temperatures from 115 to 305 K at wavelengths from 0.46 to 3.16 microns. We report absolute refractive index, dispersion, and thermo-optic coefficient for this material. We provide temperature-dependent Sellmeier coefficients based on our data to allow accurate interpolation of index to other wavelengths and temperatures. This paper also speaks of the challenges in measuring

index for a material which is not available in sufficient thickness to fabricate a typical prism for measurement in CHARMS. Under this circumstance, designing a prism which will produce accessible beam deviations, has adequately large refracting face area (which affects signal levels), and is also manufacturable with adequately accurate refracting faces is non-trivial. The tailoring of the index prism's design that allowed index measurements to be made and the remarkable results obtained from that prism for this practical infrared material are discussed. (Please see related paper on the optical design for CHARIS by Tyler Groff in session OP405.)

9578-20, Session 5

Cryogenic refractive indices of S-LAH55, S-LAH55V, S-LAH59, S-LAM3, S-NBM51, S-NPH2, S-PHM52, and S-TIH14 Glasses

Kevin H. Miller, Manuel A. Quijada, NASA Goddard Space Flight Ctr. (United States); Douglas B. Leviton, Genesis Engineering Solutions, Inc. (United States)

The Transiting Exoplanet Survey Satellite (TESS) is an explorer-class planet finder, whose principal goal is to detect small planets with bright host starts in the solar neighborhood. The TESS payload consists of four identical cameras and a Data Handling Unit (DHU) fitted with CCD detectors and associated electronics. Each camera consist of a lens assembly with seven optical elements that include various types of Ohara glass substrates. The successful implementation of a panchromatic and a thermal lens assembly design for these cameras requires a fairly accurate (up to 1e-6) knowledge of the temperature- and wavelength-dependent of the refractive index in the wavelength and temperature range of operation. Hence, this paper is devoted to report on measurements of the refractive index over the wavelength range of 0.42—1.15 um and temperature range of 110—300 K for the following Ohara glasses: S-LAH55, S-LAH55V, S-LAH59, S-LAM3, S-NBM51, S-NPH2, S-PHM52, and S-TIH14. The measurements were performed utilizing the Cryogenic High Accuracy Refraction Measuring System (CHARMS) facility at NASA's Goddard Space Flight Center. A dense coverage of the absolute refractive index for all these substrates in the aforementioned wavelength and temperature ranges was used to determine the thermo-optic coefficient (dn/dT) and dispersion relation (dn/d?) as a function of wavelength and temperature. A comparison of the measured indices with literature values, specifically the temperature-dependent refractive indices of S-PHM52 and S-TIH14 reported by Yamamuro et al. [Yamamuro et al., Opt. Eng. 45(8), 083401 (2006)], will be presented.

9578-21, Session 5

Temperature-dependent refractive index measurements of CaF2, Suprasil 3001, and S-FTM16 for the Euclid Near-Infrared Spectrometer and Photometer

Douglas B. Leviton, Leviton Metrology Solutions, Inc. (United States); Kevin H. Miller, Manuel A. Quijada, NASA Goddard Space Flight Ctr. (United States); Frank U. Grupp, Max-Planck-Institut für extraterrestrische Physik (Germany)

Using the Cryogenic High Accuracy Refraction Measuring System (CHARMS) at NASA's Goddard Space Flight Center, we measured absolute refractive indices at temperatures from 110 to 300 K at wavelengths from 0.42 to 2.72 microns for CaF2, Suprasil 3001 fused silica, and S-FTM16 glass in support of lens designs for the Near Infrared Spectrometer and Photometer (NISP) for ESA's Euclid dark energy mission. We report absolute refractive index, dispersion (dn/d?), and thermo-optic coefficient (dn/dT) for these materials. In this study, materials from different melts were procured to understand index variability in each material. Inter-melt variability study is further enabled by comparisons with our measurements of these material types for previous projects. We provide temperature-dependent Sellmeier coefficients based on our data to allow accurate interpolation of index to other wavelengths and temperatures. (Please see companion paper on the need for accurate cryo refractive indices and mechanical properties of optical materials for Euclid NISP by Frank Grupp in session OP401.)

Laser-activated remote phosphor light engine for projection applications

Martin Daniels, OSRAM GmbH (Germany)

Laser-activated remote phosphor light engine for projection applications

Recent developments in blue laser sources enable attractive solutions in projection applications using phosphors for efficient light conversion with very high luminance levels. Various commercially available projectors incorporating this technology have entered the market in the past years. Luminous flux levels are currently still comparable to lamp-based systems, while lifetime expectations of classical lamp systems are exceeded by far. OSRAM has been exploring this technology for several years now and has introduced the PHASER® brand name (Phosphor + Laser).

Various optical system design approaches and laser/phosphor architectures will be discussed. State-of-the-art is a rotating phosphor wheel to deliver the necessary primary colors either sequentially for single-imager projection engines or simultaneously for 3-panel systems. The PHASER® technology enables flux and luminance scaling, which allows for smaller imagers and therefore cost-efficient projection solutions.

The resulting overall efficiency and ANSI lumen specification at the projection screen of these systems is significantly determined by the target color gamut and the transmission of the projection system. With increasing power and flux level demand, thermal issues, especially phosphor conversion related, dominate the opto-mechanical system design requirements. These flux levels are a great challenge for all components of an SSL-projection system. OSRAM´s PHASER® light engine platform is constantly expanded to higher luminous flux levels and also to higher luminance levels for various applications. Recent experiments employ blue laser pump power of multiple 100 Watts to excite various color phosphors resulting in luminous flux levels of more than 40 klm.

Complex visible scene projection technology

Hong Yu, Beijing Simulation Ctr. (China)

The first and most essential capability a visible scene projection system must have is low background and high contrast during dynamic simulation. A complex visible scene projection system was developed to meet the above requirements. The complex visible scene projection system mainly consists of the optical fiber subsystem , LCD (Liquid Crystal Display) subsystem, multiple focal plane coupler and the collimation objective. There are three channels which represent a target and two different star field simulations in optical fiber subsystem. 9 fibers arranged in 3?3 array to display the simulated target which comes from far to near, the center fiber is lighted when the target is far, the peripheral fibers are then lighted gradually and become brighter and brighter when the target approaching. Thaler prism polarizers were used as attenuator in each of 9 fibers, motor driving one of the pair of the polarizer to change the energy timely in each of 9 fibers. In the star field simulations, two different star field patterns can be displayed. There are 7 fibers fixed in 7 holes respectively on a star board in each of two star field simulations, so a star field pattern of 7 stars at most can be simulated, and the star field patterns were determined in advanced. Polarizers were used as attenuator in each of 14 star fibers. Manually rotate one of the pair of the polarizer to change the output energy. 23 fibers in all in the optical fiber subsystem were connected with an integral sphere to obtain the uniform light. The LCD subsystem consists of illumination, LCD module and imaging objective. 1024?1024 of 1920?1080 LCD array were used to display dynamic visible scene. because the sizes of the 1024?1024 LCD array and the above star boards are different, so the imaging objective were used to project the original 1024?1024 LCD array to an image with the same size as the star board. Multiple focal plane coupler is responsible for coupling the 4 focal planes of 3?3 target fibers, two star boards and the LCD image. A prism was used as beam combination element to transmit the target fibers through and reflect the rest of three. Two star boards and the LCD image can be reflected optionally by rotating the prism to make the reflection surface facing at it. The collimation objective projects any one or two of combination of 4 focal plane to infinity. The size and weight of the whole system was confined to be suitable to mount on flight motion table.

LED collimation optics for large sources

Yasmín Berenice Alcántara-Pérez, Univ. de Guanajuato (Mexico); Ivan Moreno, Univ. Autónoma de Zacatecas (Mexico)

Trending chip-on-board (COB) and multichip LEDs are extended light sources that significantly increase flux output. However, a large light source can be a nightmare when dealing with compact and high efficiency collimation optics. Here we analyze nonimaging optics that concentrates the light of an extended source into a small cone. We discuss the foundations of nonimaging collimators, and the primary architectures that have been exploited for developing collimators with large LEDs. Considerations on collimating optics such as optical efficiency, beam divergence angle, and performance optimization are also discussed. We review some important methods and designs from the specialized literature, proposing a new design method for optimized directional lighting with large LEDs, which directly considers the extended source without beginning with a point source approximation.

9578-25, Session 6

High-performance LED luminaire for sports hall

Xuan Hao Lee, Jin-Tsung Yang, National Central Univ. (Taiwan); Wei-Ting Chien, Jung-Hsuan Chang, National Central Univ. (Taiwan) and WitsLight Technology Group (Taiwan); Yi-Chien Lo, Che-Chu Lin, Ching-Cherng Sun, National Central Univ. (Taiwan)

In this paper, we present a luminaire design with anti-glare and energy-saving effects for sports hall. Compared with traditional lamps using in a badminton court, the average illuminance on the ground of the proposed LED luminaire is enhanced about 300%. Besides, the uniformity is obviously enhanced and improved. The switch-on speed of lighting in sports hall is greatly reduced from 5-10 minutes to 1 second. The simulation analysis and the corresponding experiment results are demonstrated.

An optical filter with angular selectivity of the light transmission

Rustam S. Zakirullin, Orenburg State Univ. (Russian Federation)

Features of the application of a novel optical filter with angular selectivity of the light transmission to architectural glazing are considered. The filter consists of a sheet transparent substrate with thin-film grating layers on both surfaces. The gratings formed by directionally transmissive strips, alternating with absorptive, reflective, or scattering strips. Their relative position on the input and output surfaces provides angular selectivity of the directional light transmission – as the incidence angle changes, the proportion of radiation that passes through both gratings of the filter also changes. Chromogenic materials currently used in the laminated smart windows, providing control over the intensity and spectrum of the transmitted solar radiation, cannot achieve the selective regulation on the ranges of incidence angles. Such a regulation requires the use of additional daylight-redirecting devices, especially blinds, to dynamically adapt to the position of the sun. The grating optical filter provides angular selectivity of the light transmission of a window without such devices. The features of using this filter in the single and double glazed windows are described. A graphic-analytical calculation method is proposed for estimating the effect of geometrical and optical parameters of the filter on the angular characteristics of the light transmission. An algorithm to optimize filtering solar radiation taking into account the geographical coordinates of terrain, time of day and year and the orientation of the window to the cardinal is set. An algorithm to calculating geometrical parameters of the filter with pre-specified characteristics of the light transmission is obtained.

Design and verifications of an eye model fitted with contact lenses for wavefront measurement systems

Yuan-Chieh Cheng, National Tsing Hua Univ. (Taiwan) and Instrument Technology Research Ctr. (Taiwan); Jia-Hong Chen, Rong-Jie Chang, Chung-Yen Wang, National Tsing Hua Univ. (Taiwan); Wei-Yao Hsu, Instrument Technology Research Ctr. (Taiwan); Pei-Jen Wang, National Tsing Hua Univ. (Taiwan)

Contact lenses are measured by liquid-immersed box method due to large optical power from small anterior central curve radius (ACCR) though the Back Vertex Power of contact lenses may be small. In this study, an optical measurement system based on Shack-Hartmann wavefront principle has been established for investigation of the aberrations of soft contact lenses. By mimicking the fitting conditions, optical design of an eye model with various topographical shapes in anterior cornea are studied. Initially, it is essential to measure samples of contact lens not only by conventional method but also fitted with various topographical corneal shapes fitted on the model. In addition, optics simulation program has been employed for evaluation of sources of errors and accuracy of the system. Finally, with various Diopters of in samples of soft contact lenses, both the simulations and experiments have confirmed the controversial issues in the measurement method by eye-model fitted contact lenses. More importantly, the results have concluded aberrations of contact lenses could be measured with the proposed system.

Plenoptic camera based on a liquid crystal microlens array

Yu Lei, Huazhong Univ. of Science and Technology (China) and Shijiazhuang Tiedao Univ. (China); Qing Tong, Xinyu Zhang, Hongshi Sang, Changsheng Xie, Huazhong Univ. of Science and Technology (China)

The plenoptic camera is an innovation of photography which can acquire the three-dimensional radiance of a scene by inserting a silica microlens array between the main lens and the image sensor of the traditional camera. In this paper, we propose to substitute a liquid crystal microlens array (LCMLA) with electrically tunable focal length for the silica microlens array in the plenoptic camera to adjust the depth of field (DOF). The LCMLA we fabricated is mainly composed of an aluminum patterned silica electrode and an indium-tin-oxide coated planar silica electrode with liquid crystals injected between them. The pattern etched in the aluminum silica electrode is an array of circular holes with a diameter of 128 ?m and a hole pitch of 160 ?m. When a certain alternating current voltage signal is applied over the two electrodes, symmetrical inhomogeneous electric fields in each holes will be generated and an array of liquid crystal microlenses with gradient refractive index are formed for converging incident rays. The focal length of the microlens can be changed by adjusting the voltage signal between the electrodes. We integrated the LCMLA with an image sensor to construct a plenoptic camera prototype based on LCMLA. Several raw images are acquired using our plenoptic camera and rendered images are also presented after image processing. Our experiments proved that it is feasible to apply a LCMLA in plenoptic cameras and the DOF of the LCMLA-based plenoptic camera can be adjusted by changing the applied voltage signals.

Performance analysis of NRZ, RZ, raised cosine and Gaussian modulation formats in 32x10 Gbps WDM system with different compensation techniques

Hardeep Singh, Thapar Univ. (India); Nivedita Mishra, Thapar Univ. (India) and Thapar University, Patiala(Punjab), India (India)

In this paper, four modulation techniques are studied along with different dispersion compensation techniques namely, pre compensation, post-compensation and symmetric compensation technique. The performance of NRZ, RZ, Gaussian and Raised cosine at 10 Gb/s for 32 channel WDM optical communication system is analysed. The performance evaluation is

being done graphically in terms of maximum received Quality factor. The transmitter section consists of the data source (PBRS), electrical driver, CW laser source and Mach-Zehnder modulator. The data source is generating signal of 10 Gbps with random sequence and CW laser source generates 32 laser beams from 192.1 THz to 195.3 THz at 100 GHz spacing. After multiplexing, signals are sent onto fiber transmission link which is designed considering the fiber parameters of DCF and SSMF so that the first-order dispersion is compensated exactly (D=0). Link consists of 5 spans of standard single mode fiber (SSMF) of 50 km each and 10 km of dispersion compensating fiber whose placement depends upon type of compensation used. In the receiver the signal is demultiplexed, detected by PIN detector, passed through the filter and 3R regenerator.

We investigated pre, post-compensation and symmetrical or hybrid-compensation in the presence of fiber nonlinearities with NRZ, RZ, Raised Cosine and Gaussian modulation formats for 32x10 Gbps system in this work. Analysis is done taking Quality factor and eye diagram at receiver. The simulation results showed that for all the modulation formats as the signal input power increases up to certain limit Q value first increases and then starts decreasing. The symmetric compensation scheme performs better than pre and post compensation techniques for all type of modulation formats except in case of Gaussian format at input signal power 0 dBm. It is also found out that NRZ performs better for lower input signal power and RZ performs better at high input signal powers for symmetric compensation.

9579-28, Session PMon

Enhanced and heralded single-photon source models for quantum applications

Attia Moez, Amor Gueddana, Rihab Chatta, SUP'COM (Tunisia)

This work addresses a comparison study between two kinds of Single Photon Sources (SPS). The first SPS is an Enhanced SPS (ESPS), which consists of an association between InAs/GaAs Quantum Dot (QD) and an optical microcavity. The fundamental mode of the QD emits a single photon at 1550 nm. To exclude the other photons being on other modes, we show that the QD has to be embedded in an optical microcavity with resonant mode at 1550 nm. The resonant performances of three different optical microcavities are highlighted, they are the microdisk, the microgear and the Photonic Crystal (PC), which are all based on GaAs material. We show that the PC microcavity used with QD provides the best resonant and coupling performances, which allows to obtain a probability P1 to get a single photon at 1550 nm around 0,7. The second SPS is the Heralded SPS (HSPS) and based on active two-dimensional PC over LiNbO3. When PC is excited by a pump laser source at 980 nm, it emits two single photons at 1310 nm and 1550 nm. These photons are separated spatially using a demultiplexer. The photon at 1550 nm, called idler photon is delayed and the photon at 1310 nm, called signal photon, informs about the coming of the idler photon and triggers it's detection mechanism. According to the physical parameters of this architecture, including photons generation, photons loss and the detection process, we demonstrate that the probability to obtain a HSPS at 1550 nm is closed to 0,57. Finally, we address a comparison study between ESPS and HSPS when they are used in an application of quantum communication.

9579-29, Session PMon

Optical sensor for detection of the level of liquids or liquefied gases in tanks without the use of moving parts

Cicero L. Omegna, Jonas Fontes Garcia, Luxtec Sistemas Ópticos LTDA (Brazil); Roddy E Ramos-Gonzales, Luxtec Sistemas Ópticos LTDA (Brazil) and Luxtec Optical Systems (Brazil); Luiz C. Barbosa, Luxtec Sistemas Ópticos LTDA (Brazil)

This study aims to build a prototype of a new device for measuring by optics, the level of liquids or liquefied gases in tanks without the use of moving parts for general applications, stationary or not, industrial and chemical vehicles. There are a lot of optical devices for measuring liquid level and various settings and runs, some devices with buildings and sophisticated technologies, complicated and more simple, but none of these devices has the configuration (provision and operation), for measuring by optical means, the level of liquids in tanks and reservoirs. That is a simple, efficient and cost effective device.

9579-30, Session PMon

Chemical resistance of optical plastics and resin for level detectors

Cicero L. Omegna, Jonas Fontes Garcia, Roddy E. Ramos-Gonzales, Luiz C. Barbosa, Luxtec Sistemas Ópticos LTDA (Brazil)

A test method was developed to find the ideal optical material that supports the chemical reaction of some fuels. Optical plastics and resin were submerged for long periods of time in reservoirs of ethanol, gasoline, diesel and biodiesel. The dimensional change and weight change of the submerged samples was measured. A special resin successfully supported the chemical attack of fuels. Samples of acrylic polymer and polycarbonate were used as type of optical plastic.

9579-31, Session PMon

One-mirror and two-mirror laser scanners with variable focus lens

Petr Pokorn?, Antonín Mik?, Ji?í Novák, Pavel Novák, Czech Technical Univ. in Prague (Czech Republic)

A disadvantage of the present state of laser scanners is that their parameters cannot be continuously and adaptively changed. Active optical components such as variable focal lenses make possible to design new types of adaptive scanners. The work presents formulas for a ray tracing in the optical system of a one-mirror and two-mirror laser scanner with a variable focus lens. The procedures for modeling of one-mirror and two-mirror systems, which are used frequently in practice, are described. The result of the analysis describes a general calculation of the position of the laser beam spot in the detection plane with respect to deflection angles of scanner mirrors. Furthermore, equations for the calculation of the focal length which ensure focusing of a beam at the desired point in a detection plane are derived. The chosen vector approach is general. Thus, the application of the formulas in various configurations of the optical systems is possible. An uncertainty analysis of the position of the laser beam spot in the detection plane is performed. Using derived formulas one can calculate deflection angles of scanner mirrors and required focal length of the variable focus lens provided that the position of the focused beam in space is given with a required tolerance. Computer simulations are performed on examples of one-mirror and two mirror laser scanners with a variable focus lens.

9579-33, Session PMon

An optofluidic grism

Sergio Calixto-Carrera, Ctr. de Investigaciones en Óptica, A.C. (Mexico); Martha Rosete-Aguilar, Univ. Nacional Autónoma de México (Mexico); Guillermo Garnica, Ismael Torres-Gomez, Ctr. de Investigaciones en Óptica, A.C. (Mexico)

For some type of instrumentation transmission gratings are needed instead of reflection gratings. For example it is possible to convert cameras or telescopes into spectrographs by placing a grating in front of the lens. This

optical configuration will show an on-axis image of the light source (zero-order) and on their sides the spectrum of the source. However, if an on-axis view is necessary, for one desired wavelength, a Grism should be used. It is composed of a transmission grating placed onto the hypothenuse of a right angle prism. The light diffracted by the grating is bent back on-axis by the refracting effect of the prism. So far, developed Grisms are made mainly of glass that has a refractive index. This implies that light of a given wavelength crosses the Grism without deviation. If it is necessary that light with a different wavelength crosses without deviation then a replacement Grism should be used. To avoid this change of Grism we suggest the use of an optofluidic Grism. In the study we have developed a hollow Grism where liquids with different refractive indices can be used. Thus, it is possible to tune the Grism and choose the wavelength that will not suffer a deviation. We describe the fabrication and testing of the hollow prism and the blazed grating.

9579-34, Session PMon

Analysis and compensation of moiré effects in fiber-coupled image sensors

Salman Karbasi, Ashkan Arianpour, Nojan Motamedi, Joseph Ford, Univ. of California, San Diego (United States)

Imaging fiber bundles can relay a curved image surface to a conventional flat focal plane, effectively providing the curved image sensor needed for some high performance lenses. If the fiber bundle period or image sensor pitch are very different, the system resolution is determined by the oversampled fiber or sensor feature. But crosstalk imposes an approximately 2μm minimum waveguide pitch, and light collection and fabrication constraints imposes a limit of 1-2μm for the sensor pitch. Maximizing image information leads to some degree of aliasing, which appears in the form of moiré pattern on the raw sensed image. For example, a 30 Mpixel 120˚ field of view imager using a 1.75μm Bayer filtered CMOS focal plane with 2.5μm pitch fiber bundle yielded images with visible moiré, which was mitigated by sensor response calibration. Here we present a study of moiré effects in fiber-coupled image sensors, including a method for quantitative analysis of moiré, and experimental characterization of color and monochrome sensors with 1.1μm pixel pitch, the highest spatial resolution in commercially available focal plane arrays. We investigate the effect of temperature, angle of incidence of collimated light, and imaging lens F/# on the raw moiré pattern strength, and on the calibrated final image. We also examine the behavior of the sensor by varying exposure times, source irradiance and color. This study provides a guideline for optimization and operation of high resolution fiber-coupled imagers.

9579-1, Session 1

Nonlinear multi-photon laser wave-mixing optical detection in microarrays and microchips for ultrasensitive detection and separation of biomarkers for cancer and neurodegenerative diseases

Manna Iwabuchi, Marcel Hetu, Eric Maxwell, Sebastien Pradel, Sashary Ramos, William G. Tong, San Diego State Univ. (United States)

Multi-photon degenerate four-wave mixing is demonstrated as an ultrasensitive absorption-based optical method for detection, separation and identification of biomarker proteins in the development of early diagnostic methods for HIV-1, cancer and neurodegenerative diseases using compact, portable microarrays and capillary- or microchip-based chemical separation systems that offer high chemical specificity levels. The wave-mixing signal has a quadratic dependence on concentration, and hence, it allows more reliable monitoring of smaller changes in analyte properties. Our wave-mixing detection sensitivity is comparable or better than those of current methods including enzyme-linked immunoassay for clinical diagnostic and screening. Detection sensitivity is excellent since the wave-mixing signal is a coherent laser-like beam that can be collected with virtually 100% collection efficiency with high S/N. Our analysis time is short (1-15 minutes) for molecular weight-based protein separation as compared to that of a conventional separation technique, e.g., sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). When ultrasensitive wave-mixing detection is paired with high-resolution capillary- or microchip-based separation systems, biomarkers can be separated and identified at the zepto- and yocto-mole levels for a wide range of analytes. Specific analytes can be captured in a microchannel through the use of antibody-antigen interactions that provide better chemical specificity as compared to size-based separation alone. The technique can also be combined with immune-precipitation and a multi-channel capillary array for high-throughput analysis of more complex protein samples. Wave mixing allows the use of chromophores and absorption-modifying tags, in addition to conventional fluorophores, for online detection of immune-complexes related to cancer.

9579-2, Session 1

A compact, efficient, and lightweight laser head for CARLO: integration, performance, and benefits

Waldemar Deibel, Adrian Schneider, Univ. Basel (Switzerland); Marcello Augello, Univ. Hospital Basel (Switzerland); Alfredo E. Bruno, AOT AG (Switzerland); Philipp Jürgens, Univ. Hospital Basel (Switzerland); Philippe C. Cattin, Univ. Basel (Switzerland)

Ever since the first functional lasers were built about 50 years ago, researchers and doctors have dreamed of a medical use for such systems. Today's technology is finally advanced enough to realize these ambitions in a variety of medical fields. There are well-established laser based systems in ophthalmology, dental applications, treatment of kidney stones, and many more. The Er:YAG laser presents more than just an alternative to conventional methods for osteotomies. It offers less tissue damage, faster healing times, comparable intervention duration and in the consequence improves postoperative treatment of patients. However, there are a few factors that limit routine applications. These technical drawbacks include missing depth control and safely guiding the laser beam. But those drawbacks can be overcome. This paper presents the engineering and integration of a miniaturized laser head for a computer assisted and robot-guided laser osteotome (CARLO), which is developed in the University of Basel Spin-off AOT AG. The CARLO device ensures a safe and precise guidance of the laser beam. Such guidance also enables new opportunities and methods, e.g. free geometrical functional cuts, which have the potential to revolutionize bone surgery. The laser head is optimized for beam shaping, target conditioning, compactness and the integration of all other parts needed for the CARLO device, e.g. CCD-Camera for referencing, a visible guidance laser, etc. The beam coming out of the laser system is conditioned in shape, energy properties and working distance with an optical arrangement to achieve the desired cutting performance. Here also parameters like optical losses, operating mode, optics materials and long-term stability have are taken into account.

9579-3, Session 1

Multispectral digital holographic microscopy with applications in water quality assessment

Farnoud Kazemzadeh, Chao Jin, Iman Khodadad, Robert Amelard, Shahid A. Haider, Simarjeet S. Saini, Monica B. Emelko, Univ. of Waterloo (Canada); David A Clausi, Univ of Waterloo (Canada); Alexander Wong, Univ. of Waterloo (Canada)

Safe drinking water is essential for human health, yet over a billion people

worldwide do not have access to safe drinking water. Due to the presence and accumulation of bio-contaminates in the natural water sources, (e.g. pathogenic microorganisms, neurotoxin, hepatotoxin or cytotoxin released due to algal bloom), it is increasingly challenging to provide safe drinking water supply around the world. One of the biggest challenges in water quality assessment is the speed and accuracy of quantitative analysis at reasonable costs. Traditional laboratory methods are costly, time consuming and require well trained experts to conduct the sample analysis. It is not financially feasible and practical to monitor and quantify water quality frequently enough to identify the potential health risk due to contamination, especially in developing countries. We propose a low-cost, small-profile multispectral (MS) system based on Digital Holographic Microscopy (DHM) and investigate methods for rapidly capturing holographic data of natural water samples. We have developed a test-bed for an MSDHM instrument to produce and capture holographic data of the sample at different wavelengths in the visible and the near Infra-red spectral region, allowing for resolution improvement in the reconstructed images. Additionally, we have developed high-speed statistical signal processing and analysis techniques to facilitate rapid reconstruction and assessment of the MS holographic data being captured by the MSDHM instrument. The proposed system is used to examine cyanobacteria as well as Cryptosporidium parvum which are the main concerns in the natural water sources globally.

9579-4, Session 1

Concurrent fluorescence macro-imaging across multiple spectral regions in the visible and the near infrared

Farnoud Kazemzadeh, Shahid A. Haider, Chao Jin, David A. Clausi, Alexander Wong, Univ. of Waterloo (Canada)

Fluorescent imaging, often synonymous with microscopic imaging, is an imaging modality whereby various features of a target are observed based on assignment of chemical labels. These labels are in most cases indirect tracers of specific structures or chemical compounds which cannot be otherwise identified. The tracers are excited by an illuminating source and they in turn emit light at specific wavelengths. This light is then captured by an imaging device and represented as an indirect observation of the specific feature in the sample. The process of excitation and imaging of the emitted light is performed sequentially and is proportional to the number of tracers or fluorescence species present in the sample. We present an imaging system that can image fluorescent tracers, in the visible and the near Infra-red, simultaneously. This system is capable of illuminating the target with different excitation light sources and capture the corresponding fluorescence images in one snapshot using a series of mirrors to capture different views of the sample. The simultaneously captured image are fused using a computational reconstruction process to present a coherent multispectral fluorescence image. The system is proposed for use in applications where the rapid enumeration of fluorescent species in a large field of view is paramount as opposed to their microscopic image of in a narrow field of view. The system was tested using a controlled cocktail solution of four different types fluorescent microspheres and was able to enumerate the microspheres based on their different fluorescent signatures as captured by the system.

9579-5, Session 1

Endoscopic system for automated high dynamic range inspection of moving periodic structures

Cornelius F. Hahlweg, bbw Hochschule (Germany); Hendrik Rothe, Helmut-Schmidt Univ. (Germany)

In the current paper an advanced endoscopic system for high resolution and high dynamic range inspection of persiodic structures in rotating machines is presented. We address the system architecture, short time illumination, special optical problems, such as exclusion of the specular reflex, image processing, forward velocity prediction and metrological image processing. There are several special requirements to be met, such as the thermal stability above 100 °C, robustness of the image field, illumination in view direction and the separation of metallic surface diffuse scatter. To find a compromise between image resolution and frame rate, an external sensor system was applied for synchronization with the moving target. The system originally was intended for inspection of thermal engines, but turned out to be of a more general use. Beside the theoretical part and dimensioning issues, practical examples and measurement results are included.

9579-101,

Democratization of next-generation imaging, sensing, and diagnostics tools through computational photonics

Aydogan Ozcan, Univ. of California, Los Angeles (United States) and California NanoSystems Institute (United States)

My research focuses on the use of computation/algorithms to create new optical microscopy, sensing, and diagnostic techniques, significantly improving existing tools for probing micro- and nano-objects while also simplifying the designs of these analysis tools. In this presentation, I will introduce a new set of computational microscopes which use lens-free on-chip imaging to replace traditional lenses with holographic reconstruction algorithms. Basically, 3D images of specimens are reconstructed from their “shadows” providing considerably improved field-of-view (FOV) and depth-of-field, thus enabling large sample volumes to be rapidly imaged, even at nanoscale. These new computational microscopes routinely generate >1–2 billion pixels (giga-pixels), where even single viruses can be detected with a FOV that is >100 fold wider than other techniques. At the heart of this leapfrog performance lie self-assembled liquid nano-lenses that are computationally imaged on a chip. These self-assembled nano-lenses are stable for >1 hour at room temperature, and are composed of a biocompatible buffer that prevents nano-particle aggregation while also acting as a spatial “phase mask.” The field-of-view of these computational microscopes is equal to the active-area of the sensor-array, easily reaching, for example, >20 mm2 or >10 cm2 by employing state-of-the-art CMOS or CCD imaging chips, respectively.

In addition to this remarkable increase in throughput, another major benefit of this technology is that it lends itself to field-portable and cost-effective designs which easily integrate with smartphones to conduct giga-pixel tele-pathology and microscopy even in resource-poor and remote settings where traditional techniques are difficult to implement and sustain, thus opening the door to various telemedicine applications in global health. Some other examples of these smartphone-based biomedical tools that I will describe include imaging flow cytometers, immunochromatographic diagnostic test readers, bacteria/pathogen sensors, blood analyzers for complete blood count, and allergen detectors. Through the development of similar computational imagers, I will also report the discovery of new 3D swimming patterns observed in human and animal sperm. One of this newly discovered and extremely rare motion is in the form of “chiral ribbons” where the planar swings of the sperm head occur on an osculating plane creating in some cases a helical ribbon and in some others a twisted ribbon. Shedding light onto the statistics and biophysics of various micro-swimmers’ 3D motion, these results provide an important example of how biomedical imaging significantly benefits from emerging computational algorithms/theories, revolutionizing existing tools for observing various micro- and nano-scale phenomena in innovative, high-throughput, and yet cost-effective ways.

Restocking the optical designers’ toolbox for next-generation wearable displays

Bernard C. Kress, Google (United States)

Three years ago, industry and consumers learned that there was more to Head Mounted Displays (HMDs) than the long-lasting but steady market for defense or the market for gadget video player headsets: the first versions

of Smart Glasses were introduced to the public. Since then, most major consumer electronics companies unveiled their own versions of Connected Glasses, Smart Glasses or Smart Eyewear, AR (Augmented Reality) and VR (Virtual Reality) headsets. This rush resulted in the build-up of a formidable zoo of optical technologies, each claiming to be best suited for the task on hand. Today, the question is not so much anymore "will the Smart Glass market happen?" but rather "which optical technologies will be best fitted for the various declinations of the existing wearable display market," one of the main declination being the Smart Glasses market.

9579-6, Session 2

Development features of nuclear CCTV systems for reactors' internal surfaces surveillance

Sergei L. Pervov, Radda A. Iureva, Nadezhda K. Maltseva, Michael E. Fedosovsky, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

Special devices with high tolerance to radiation and certification for tolerance to a certain level and nature of radiation exposure are required to service an existing nuclear power plant (NPP).

Some part of system will be a subject to radiation exposure's maximum. A good solution to reduce the net cost of an element base under radiation exposure's maximum is to remove a part of camera's elements to an external unit, also located at a distance from a radiation source. This solution not only provides an opportunity to reduce an amount of components, receiving the highest dose of radiation, but also helps to reduce the size and weight of a camera and allows to simplify the design and circuit of the device operating under constant negative radiation exposure. Thus, only lens, vidicon and minimum of electronic circuits have to be located in camera unit in order to achieve maximum of radiation tolerance. The main part of electronic circuits is removed to television system remote unit located outside radiation exposure.

As for an optical part of a system, thanks to special circuit design and use of rad-tolerant vidicon as light-to-signal transducer it provides excellent image quality and sharpness in high radiation fields. All lenses are made of rad-tolerant glass, not darkening under radiation exposure.

Rad-tolerant TV camera, minimization of electronic circuits, exposed to radiation, specialized software for receiving, processing and recording images contribute to implementation of the above mentioned features and operation of rad-tolerant CCTV systems twenty four by seven.

9579-7, Session 2

Dynamic noise corrected hyperspectral radiometric calibration in the SWIR 1000-2300 nm using a supercontinuum laser

Janos C. Keresztes, Ben Aernouts, KU Leuven (Belgium); R. John Koshel, College of Optical Sciences, The Univ. of Arizona (United States); Wouter Saeys, KU Leuven (Belgium)

As line scanning short wave infrared (SWIR) hyperspectral imaging (HSI) is a growing field in the food industry, it is important to select efficient illumination designs to image contaminants with high contrast and low noise. Spectral radiometric measurements onto an illuminated lambertian target can be performed to compare SWIR light systems. Those imagers can be calibrated in spectral radiometric units using a supercontinuum laser setup. However, as those measurements can be time consuming, InGaAs based sensors being very sensitive to noise, the dark current should be sampled frequently to avoid noise time drifts. Additionally, fluctuations of the laser power can occur, which may bias the radiometric model. To correct for source fluctuations, an optical system consisting of a supercontinuum laser, a monochromator, a second order filter and a gold-coated integrating sphere (IS) setup is proposed. The input laser power is first measured using a power meter coupled with a thermal sensor. A high sensitivity photodiode and the HSI are further placed at different ports of the IS to measure synchronously the monochromatic light during calibration. For each spectral band, the radiance observed by the imager corresponding to a line is detected using image analysis, while the remainder of the image is used to sample the noise of the sensor. This approach allowed to correct for 6% of noise temporal fluctuations. A per-pixel linear radiometric model was fitted with an R? of 0.94 ±0.3, and used to measure a halogen spot light distribution with and without a diffuser using the calibrated SWIR HSI.

9579-8, Session 2

Risley prism universal pointing system

John P. Dixon, James R. Engel, Robert Vaillancourt, Craig Schwarze, Kevin Potter, OPTRA, Inc. (United States)

OPTRA is currently developing a Risley Prism Universal Pointing System (RPUPS): a highly customizable cued beamsteering system. The RPUPS consists of a visible or infrared cueing imager co-aligned with an optical beam steering system's pointing-field-of-regard. The cueing imager is used to identify a region-of-interest within its wide field-of-view, via a wireless tablet device. The tablet user can choose to manually or automatically, identify and track regions-of-interest. The optical beam steering system uses a matched pair of Risley Prisms to direct an interrogating optical system's instantaneous-field-of-view onto the identified region-of-interest. The tablet updates the user with real time information from both the cueing imager and the interrogating optical system. Risley prism material and geometry choices provide operating wavelength, aperture size, and field-of-regard flexibility for this front-end pointing component. Back-end components may be receive-only, transmit-only, or transmit/receive combinations. The flexibility of the RPUPS allows for mission specific customization where applications include but are not limited to: synthetic foveated imaging, spectroscopic probes and laser (LIDAR) ranging and tracking. This paper will focus on the design and anticipated applications of the RPUPS.

9579-9, Session 2

Further development of imaging near-field scatterometer

Denise Uebeler, Florian Dannenberg, Cornelius F. Hahlweg, bbw Hochschule (Germany)

In continuation of last years paper on the use of near field imaging, which basically is a reflective shadowgraph method, for characterization of glossy surfaces like printed matter or laminated material, further developments are discussed. Beside the identification of several types of surfaces and related features, for which the method is applicable, several refinements are introduced. First, the theory of the method is extended, based on a mixed fourier-optical and geometrical approach. Further, cross and parallel polarization techniques are applied for separation of the shadow image and the image of the near field distribution of the diffuse reflective part of the shadowing areas. Variation of plane of focus and incident angle are used for reconstruction of the surface unter test. Finally, latest measurement results and examples are included.

9579-10, Session 2

Object silhouettes and surface directions through stereo matching image processing

Akira Akiyama, Kanazawa Technical College (Japan); Hideo Kumagai, Tamagawa Seiki Co., Ltd. (Japan)

We have studied the object silhouettes and surface directions through the stereo matching image processing to recognize the occupation position, size and direction of the object.

When we work for the stereo matching image processing by using a pair of the good contrast captured images, we can only match the object component areas between a pair of image. And the extraction of the object silhouette is difficult under using a pair of the good contrast images only when the object boundary intensity is smoothly close to the other objects and the background.

We usually need the object silhouette to realize the object body as a whole. We note that the tendency of the object intensity change near the good contrast focus position is more stable than the tendency of other objects intensity change under not good contrast focus position.

Therefore we use several images near the good contrast focus position to extract the object silhouette. We can extract the object silhouette by computing the intensity change with respect to each pixel, arranging the pixel intensity change into the pixel intensity change distribution form large to small order as a half normal distribution, extending it as a whole normal distribution, computing its standard deviation and selecting the small intensity change pixel by the computed standard deviation. The group of the selected small intensity change pixel becomes the object silhouette candidate.

We use the pixel numbers of a pair of object component area and the projection cosine rule to find the surface direction followed by the stereo matching image processing.

9579-11, Session 3

Advancements in transformation optics-enabled gradient-index lens design

Sawyer D. Campbell, Donovan E. Brocker, Jogender Nagar, Pingjuan L. Werner, Douglas H. Werner, The Pennsylvania State Univ. (United States)

Transformation Optics (TO) provides the mathematical framework for representing the behavior of electromagnetic radiation in a given geometry by “transforming” it to an alternative, usually more desirable, geometry through an appropriate mapping of the constituent material parameters. Using a quasi-conformal mapping, the restrictions on the required material parameters can be relaxed allowing isotropic inhomogeneous all-dielectric materials to be employed. This approach has led to the development of a new and powerful design tool for gradient-index (GRIN) optical systems. Using TO, aspherical lenses can be transformed to simpler spherical and flat geometries or even rotationally-asymmetric shapes which result in true 3D GRIN profiles. TO can also potentially be extended to collapse an entire lens system into a representative GRIN profile thus reducing its physical dimensions while retaining the optical performance of the original system. However, dispersion effects of the constituent materials often limit the bandwidth of metamaterial and TO structures thus restricting their potential applicability. Nonetheless, with the proper pairing of GRIN profile and lens geometry to a given material system, chromatic aberrations can be minimized. To aid in the GRIN construction, we employ advanced multi-objective optimization algorithms which allow the designer to explicitly view the trade-offs between all design objectives such as RMS spot size, field-of-view (FOV), lens thickness, ?n, and focal drift due to chromatic aberrations. We present an overview of our TO-enabled GRIN lens design process and analysis techniques while demonstrating designs which minimize the presence of mono- and polychromatic aberrations and discuss their requisite material systems.

9579-12, Session 3

Simulating optical system performance with three-dimensional scenes

William J. Duncan, Jim Schwiegerling, The Univ. of Arizona (United States)

A variety of techniques with varying levels of accuracy have been developed to simulate images that are produced by optical systems. In the simplest approximation, the Point Spread Function (PSF) is assumed invariant over the field of view of the system. This leads to a simulated image which is simply the convolution of the PSF with the appropriately-scale version of the object scene. The next level of approximation samples the PSF at multiple points in the field and uses this information to interpolate the PSF at an arbitrary field point. The simulated image is then assembled from the individual PSFs. Both of these techniques inherently assume a 2D planar object. In this effort, we develop techniques for extending the image simulations to 3D scenes. In general, the PSF will now be dependent both on the location of a point in the field as well as the distance to the point is object space. We investigate the image simulation for standardized scenes and compare to similar scenes captured photographically. In addition, we examine approximations to simulating the blurred 3D scene which include assuming the scene is composed of discrete planes at different distances, as well as ignoring higher order aberrations in cases where defocus is the dominant aberration. These approximations facilitate a reduction in computation time.

9579-13, Session 3

Curved fiber bundles for monocentric lens imaging *(Invited Paper)*

Salman Karbasi, Igor Stamenov, Nojan Motamedi, Ashkan Arianpour, Univ. of California, San Diego (United States); Adam Johnson, Ron Stack, Rick Morrison, Distant Focus Corp. (United States); Ilya Agurok, Distant Focus Corp. (United States) and Univ. of California, San Diego (United States); Joseph Ford, Univ. of California, San Diego (United States)

Monocentric lenses allow high resolution panoramic imaging, where imaging fiber bundles transport the hemispherical image surface to conventional focal planes. Refraction at the curved image surface limits the field of view coupled through a single bundle of straight fibers to less than +/-34˚, even for NA 1 fibers. Previously we have demonstrated a nearly continuous 128˚ field of view using a single lens and multiple adjacent straight fiber coupled image sensors, but this imposes mechanical complexity of fiber bundle shaping and integration. However, a 3-D waveguide structure with internally curved optical fiber pathways can couple the full continuous field of view onto a single focal plane. Here we demonstrate how the 3D bundle can be formed from a tapered fiber bundle, and show that it can be used for relaying a 128° field of view from a curved input to the planar output face. We numerically show the coupling efficiency of light to the tapered bundle for different field of views depends on the taper ratio of the bundle as well as center of the curvature chosen for polishing of the fiber bundle facet. We characterize a tapered fiber bundle by measuring the angle dependent impulse response and the divergence angle of the light propagating from the output end of the fiber. Finally, we demonstrate wide-field imaging using a monocentric lens and the curved fiber bundle.

9579-14, Session 4

Optical transfer function optimization based on linear expansions

Jim Schwiegerling, The Univ. of Arizona (United States)

The Optical Transfer Function (OTF) and its modulus the Modulation Transfer Function (MTF) are metrics of optical system performance. However in system optimization, calculation times for the OTF are often substantially longer than more traditional optimization targets such as wavefront error or transverse ray error. The OTF is typically calculated as either the autocorrelation of the complex pupil function or as the Fourier transform of the Point Spread Function. We recently demonstrated that the on-axis OTF can be represented as a linear combination of analytical functions where the weighting terms are directly related to the wavefront error coefficients and apodization of the complex pupil function. Here, we extend this technique to the off-axis case. Strategies for fast and stable calculation of the expansion terms, as well as examples of OTF optimization of traditional imaging systems and extended depth of focus systems will

be illustrated. The expansion technique offers a potential for accelerating OTF optimization in lens design, as well as insight into the interaction of aberrations with components of the OTF.

9579-15, Session 4

Illumination design using computer experiments

Janos C. Keresztes, Bart De Ketelaere, Jan Audenaert, KU Leuven (Belgium); R. John Koshel, College of Optical Sciences, The Univ. of Arizona (United States); Wouter Saeys, KU Leuven (Belgium)

Illumination design becomes crucial when designing cost-effective machine vision systems. Local optimization methods, such as the down hill simplex optimization (simplex), often result in an optimal solution that is influenced by the starting point by converging to a local minima, especially when dealing with high dimensional designs or nonlinear merit spaces. This work suggests a novel non-linear optimization approach, based on computer experiments. The methodology is first illustrated with a 2D case study on four lights symmetrically positioned along a fixed arc in order to obtain optimal irradiance uniformity on a flat Lambertian reflecting target. The first step consists to choose angular positions with no overlap between sources using a fast flexible space filling design. Ray tracing simulations are then performed at the found design space points and a merit function is used for each configuration to quantify the homogeneity of the irradiance at the target. The screening points and their response are further used as input to a Gaussian kriging model (GKM), which models the merit space. Global optimization is performed on the GKM providing an estimate optimum. Next, the light positioning case study is further investigated by varying the radius of the arc, and by adding two spots symmetrically positioned along an arc diametrically opposed to the first one. The added value of computer experiments with regard to the performance in convergence is compared to simplex. Experimental validation is performed using a short-wavelength infrared (SWIR) hyperspectral imager monitoring a Spectralon panel illuminated by tungsten halogen sources.

9579-16, Session 4

Comparative analysis of optimization with freeform orthogonal polynomials for rectangular apertures

Milena I. Nikolic, Univ. Polítecnica de Madrid (Spain); Pablo Benítez, Juan Carlos Miñano, Univ. Politécnica de Madrid (Spain) and Light Prescriptions Innovators, LLC (United States); Jiayao Liu, Dejan Grabovickic, Bharathwaj Narasimhan, Marina Buljan, Univ. Politécnica de Madrid (Spain)

Interest in optical systems that use freeform surfaces is rapidly increasing with the development of new manufacturing techniques. With the investigation of novel applications new issues constantly appear. Since freeform surfaces tend to be used in a non-conventional optical systems, like off-axis systems or high aspect ratio systems, a study of non-circular apertures is of potential relevance.

First non-circular aperture shape that one can be interested in due to tessellation or various folds system is the rectangular one. This paper covers the comparative analysis of a simple local optimization of one design example using different orthogonalized representations of our freeform surface for the rectangular aperture.

A very simple single surface off-axis mirror is chosen as a starting system. The surface is fitted to the desired polynomial representation, and the whole system is then optimized with the only constraint being the effective focal length. The process is repeated for different surface representations, amongst which there are some defined inside a circle, like Zernike or Forbes polynomials, and others that can be defined inside a rectangle like Legendre and new calculated Legendre type polynomials orthogonal in the gradient.

It can be observed that with Legendre or this new calculated polynomial type there is a faster convergence to a deeper minimum compared to defined-inside-a-circle polynomials. The average MTF values across 17 field points also show clear benefits in using the polynomials that adapted more accurately to the aperture used in the system.

9579-17, Session 4

Design of three freeform mirror aplanats

Bharathwaj Narasimhan, Pablo Benitez, Dejan Grabovickic, Juan C. Miñano, Milena Nikolic, Jose Infante, Univ. Politécnica de Madrid (Spain)

Freeform optical surfaces have been in much demand recently due to improved techniques in their manufacturability and design methodology, and the degrees of freedom it gives the designers. Specifically in the case of off-axis mirror systems, freeforms can considerably reduce the number of surfaces and compensate for some of the higher order aberrations as well, which improves the overall system performance.

In this paper, we explore the design of freeform surfaces to obtain full aplanatic mirror system, i.e, free of spherical aberration and circular coma of all orders. It is well know that such a system must be stigmatic and satisfy the Abbe sine condition. This problem is well known (Schwartlitz, 1906) to be solvable with two aspherics when the system has rotational symmetry. Here we prove that a rigorous solution to the general non-symmetric problem needs at least three free form surfaces, which are solutions of a system of partial differential equations.

We present here that the three mirror solutions of said system of PDE can be found using optimization. The merit function for such an optimization includes the spatial and angular deviation of the rays sampled in the pupil from the aplanatic condition. Therefore, the value of the merit function at the exact solution will be zero. The examples considered have one plane of symmetry, where a consistent 2D solution is used as boundary condition for the 3D problem. We have used the x-y polynomial representations for all the surfaces, and the optimization has shown fast convergence.

9579-18, Session 4

A method to improve the image reconstruction quality in a coded aperture compressive imaging system

Ouyang Yao, Jing Chen, Beijing Institute of Technology (China)

Compressive imaging is one of the emerging novel research areas based on compressive sensing theory. The first successful compressive imaging application is the single pixel camera designed by Rice University which used only one detector for image sensing. Another promising compressive imaging device is based on a coded aperture system called coded aperture compressive imaging designed by Duke University which embodied its advantages in reducing imaging time compared with single pixel camera. To make coded aperture compressive imaging method become a practical imaging system, several optical system parameters have to been considered and optimized. Therefore in this paper we simulated a coded aperture compressive imaging system using optical simulation software and described an optimized design of coded aperture mask to improve the performance of reconstructed image.

The contribution of this paper includes three parts. First, we simulated a coded aperture compressive imaging system by utilizing ZEMAX and quantified the relationship between the image reconstruction error and optical parameters, such as defocus distance, F number of lens, mask position and fill-factor of mask. Second, for coded aperture compressive imaging system the projection matrix was generated from the coded aperture mask. According to compressive sensing theory, the sparse dictionary and projection matrix have a great influence on the quality of reconstructed image. Therefore we used an optimization method that based

on equiangular tight frame (ETF) design to minimize the mutual coherence between projection matrix and sparse dictionary. From this optimized projection matrix, we derived a better coded aperture mask pattern. Experimental results show that the mutual coherence coefficient between projection matrix and the sparse basis was reduced more than 15% and the retrieved image error was decreased significantly.

9579-19, Session 5

120-view autostereoscopic display

Junejei Huang, Yuchang Wang, Delta Electronics, Inc. (Taiwan)

A 120-view autostereoscopic display using angle-magnifying screen is proposed. The angle-magnifying screen comprises a double-lenticular main part and a micro-deflector attaching part. With the micro-deflector, small angles eixting from the aperture of the projection lens is deflected into four angle ranges. With the double-lenticular, four ranges of small angles incident into the screen are magnified into a large field of view for the observer. The scanning angles are realized by the vibration of Galvo-mirror that synchronizing with the frame rate of the DMD and reflecting the laser illuminator to the scanning angles. For one cycle of vibration of Galvo-mirror, 8 and 7steps of reflections happen on going and returning paths. A frame is divided into two viewing frames of odd or even lines. For each viewing position, 48 viewing frames with odd or even lines per second are provided. Two aperture-relay lenses are used to double the aperture of the projection lens and viewing frame of of odd or even lines is selected for each aperture. On the exit pupil, a scanning 30 spots of light source is realized. The double-lenticular is covered with two micro-deflector sheets of (+1,-1) and (+2,-2) deflecting angles. The defecting directions of two sheets are perpendicular to each other. Each elements of the micro-deflector are aligned with the pixels that imaged on the screen. When a scanning of 30 spots passes different deflecting elements of 4 pixels, the scanning is deflected to four angle ranges and 120 viewing zones are formed after the screen magnification.

9579-20, Session 5

Color and brightness uniformity compensation of a multi-projection 3D display

Jin-Ho Lee, Juyong Park, Dongkyung Nam, Du-Sik Park, SAMSUNG Electronics Co., Ltd. (Korea, Republic of)

Light-field displays are good candidates in the field of glasses-free 3D display for showing real 3D images without decreasing the image resolution. To acquire a large number of light-field rays, the projector arrays could be used. But, in the multi-projection display system, the compensation is very critical due to slightly different characteristics and arrangement positions of the projectors. In this paper, we present an enhanced 55-inch, 100-Mpixel multi-projection 3D display consisting of 96 micro projectors for immersive natural 3D viewing in medical and educational applications. To achieve enhanced image quality, color and brightness uniformity compensation method are utilized along with an improved projector configuration design and a real-time calibration process of projector alignment. In the color compensation method, the reference images from each projector are captured by a camera arranged in front of the screen, and then a number of pixels depending on color intensities of the captured images are calculated, and the distributions of the RGB colors are corrected based on a maximum value of the color intensity. In the brightness compensation method, each light-field ray emitted from a screen pixel is modeled by a radial basis function, and then compensating weights of each screen pixel are calculated for the desired uniformity distribution. Compensating weights are transferred to the projection images by the mapping relationship between the screen and projector coordinates. Finally, brightness compensated images are rendered for each projector. Consequently, the display shows improved color and brightness uniformity, and consistent, exceptional 3D image quality.

9579-21, Session 5

3M miniature projection optical system design

Zhisheng Yun, Andrew Ouderkirk, Stephen J. Willett, 3M Co. (United States)

This paper describes the pros and cons of designing a miniature projection system with the emphasis on efficiency (lm/w) with respect to maximum brightness (lm) on screen. In particular, this paper will discuss how to design a miniature optical system to achieve high efficiency and how to design the optical system to get maximum brightness on screen. This paper will present a couple of optical system design examples to explain the findings by the authors.

9579-22, Session 5

Convertible 2D-3D display using an edge-lit light guide plate based on integral imaging

Zi Wang, An-Ting Wang, Chun Gu, Lixin Xu, Hai Ming, Univ. of Science and Technology of China (China)

A thin and lensless two-dimensional (2D) to three-dimensional (3D) convertible display based on integral imaging using an edge-lit light guide plate (LGP) is proposed with improved optical efficiency. The proposed system is composed of a general flat backlight and an edge-lit LGP which is commonly used in the backlight of LCD and a LC panel. The edge-lit LGP is a waveguide (an acrylic sheet) that is drilled by laser to form a diffuser dot array at the bottom and edge illuminated with LEDs. Light from the LEDs is channeled through the waveguide to the opposite side except where it encounters the diffuser dots, which scatter light and cause bright spots to appear. A point light source array for 3D mode is created then. A general flat backlight behind the transparent LGP is turned on for 2D mode meanwhile edge-lit light is turned off. The 2D and the 3D display modes can be simply modulated by turning on different light source. The explanation of the proposed system is provided and the experimental results are also presented.

9580-23, Session PMon

A liquid lens actuated using dielectric polymer

Boya Jin, Jihyeon Lee, Zuowei Zhou, Sangwoo Park, Changwoon Nah, Hongwen Ren, Chonbuk National Univ. (Korea, Republic of)

Adaptive liquid lenses have been studied intensively in the past decades. They have potential applications in machine vision, target tracking, image surveillance systems, and portable electronic devices. Owing to the optical isotropy, these liquid lenses can obtain the highest optical performances. Various approaches, such as mechanical actuation, stimuli-responsive hydrogel, ferrofluidic, acoustic, electrowetting, dielectrophoretic effect, and dielectric polymer (DEP) actuation were demonstrated. Each approach has its own strengths and limitations. In contrast to other approaches, a liquid lens based on DEP owns the advantages of scalable lens aperture, a large focus power change, and voltage actuation. The major challenge of the demonstrated DEP lenses is the bulky system.

In this report, an adaptive liquid lens actuated using a DEP film is demonstrated. Different from previous method, we integrate a DEP film and a liquid droplet to form a lens system. Therefore, our lens system is very compact. The DEP film has a circular hole, and the liquid droplet is fixed in the hole. The droplet has a lens character. When a DC voltage is applied to the DEP film, the aperture of the DEP hole is changed due to the pressure of the generated Maxwell force. The changed aperture can cause the surface profile of the droplet to vary. As a result, the focal length of the liquid lens has to change. In this work, we demonstrated a DEP liquid lens with a miniature aperture size, the focal length of the lens is measured and the optical performances of the lens are evaluated. Our lens can present a high performance with a large dynamic range for imaging. Our DEP liquid lens has potential applications in image processing, machine vision, biotechnology, and other lab-on-a-chip devices.

9580-1, Session 1

Challenges of designing a zoom lens for planetarium projection *(Invited Paper)*

Marco Hanft, Dirk Döring, Carl Zeiss AG (Germany)

The optical design of zoom lenses for projection applications is a task which has to take many different aspects into consideration. The optical designer has to achieve a demanding specification with respect to monochromatic and polychromatic aberrations across a significant magnification range.

Besides the requirements on image quality there are usually numerous constraints deriving from fixed mechanical interfaces that already have an impact in the very early design stages of the paraxial and monochromatic design.

It has been proven essential to also include cost targets in the figure of merit during the design work.

This paper will outline a systematic process for projection zoom lenses design.

A solid specification of the design task in terms of magnification range, image quality therein, mechanical and cost requirements is necessary as starting point.

Paraxial considerations are helpful to gain insight into the design problem and choose the appropriate zoom design type for further design work.

Intermediate designs, which are only monochromatically corrected, proofed invaluable while considering mechanical design requirements.

As soon the basic design requirements are fulfilled it makes sense to correct chromatic aberrations.

Outstanding color correction requires extensive use of expensive glasses for secondary color correction.

In order to find an ideal compromise between potential cost of an optical design and image quality achieved therewith, we employ tools to identify cost drivers as well as tools to simulate the perceived imaging performance.

Together these tools also enable us to efficiently discuss specifications that drive cost without aiding perceived image quality.

9580-2, Session 1

"Perfect Zoom System" which enables both a zoom ratio of 25:1 and a high-resolution in stereo microscope *(Invited Paper)*

Norio Miyake, Masahiro Mizuta, Nobuhiro Shinada, Hiroaki Nakayama, Yumiko Ohuchi, Nikon Corp. (Japan)

A stereo microscope can stereoscopically observe an object with protrusions and recesses as if the object is viewed by both eyes. In such a stereo microscope, an optical system of the luminous flux entering left and right eyes is at least partially separated to cause the optical axes to intersect over the surface of the object to obtain a parallax for stereoscopically observing the object. Enlarged images of the object viewed from different directions are created, and the images are observed through an eyepiece to stereoscopically view a minute object. Each of the observation optical systems usually includes a variable magnification mechanism which will be called a zoom lens system.

In recent years, a demand for a stereo microscope capable of observing a wide variable magnification range by one microscope is increasing along with the diversification of applications.

However, there are no stereo microscope zoom lenses with high resolution and large zoom ratio. We developed Perfect Zoom System, which can reduce the light flux diameter going through the objective lens in the low-power state. In the Perfect Zoom System, the zoom lens groups move along not only the optical axes but also perpendicular to the axes. Therefore, it made the objective lens smaller by decentering both the second group lens G2 and the third lens group G3 in zoom lens group. We achieved a high resolution and a zoom ratio of 25:1.

9580-3, Session 1

Understanding how entrance and exit pupils have determined the evolution of the modern zoom lens design *(Invited Paper)*

Ellis Betensky, Consultant (Canada)

Stated simply, a zoom lens is an imaging device that allows for a continuously variable image scale without the need to refocus. Usually a zoom lens is further defined according the zoom ratio (range of magnification change), the size of the object covered, the image size, and the relative aperture. However, while the details of the entrance and exit pupils, particularly their locations and stability during zooming, have always played an important role in the design, they are rarely mentioned in the description of the lens. In this tutorial the position of the aperture stop, rather than the number of moving groups, will be used as a means of examining the design characteristics, and explaining how new designs have evolved. In addition to lens diameters, as determined by paraxial locations and the effects of aberration of the pupils, the position of the pupils, and their shapes as a function of zooming will be examined. The primary objective of the tutorial is to provide insight and a better understanding of zoom lens fundamentals, towards the selection of a design starting point; whether from an existing design, or from basic principles.

9580-4, Session 2

Toward a paraxial pre-design of zoom lenses *(Invited Paper)*

Thomas Milde, Carl Zeiss AG (Germany)

Optimizing the power distribution of fixed and moved lens groups as well as the motions of the latter, is typically a challenging part of the whole zoom lens optical design task. Once, the merit function is formulated to optimize an initial approach, the paraxial moving equations are solved implicitly in local optima. Hence, finding local optima becomes an ill posed problem when these equations cannot be solved uniquely for certain zoom configurations. Furthermore, an inappropriate initial power distribution can lead to large overall lengths, sensitive lens groups, small zoom ranges, induced aberrations and much more disadvantageous effects. From these reasons it appears as a logical consequence to first consider a paraxial pre-design of the zoom lens. This paper shows how first order aberrations, centering sensitivities as well as all common paraxial requirements can be analyzed and formulated as a merit function for finding power distributions and (zooming) air spaces. In particular, the benefit of formulating zoom invariants as constraints in order to apply the Sequential Quadratic Programming (SQP) is shown. Based on a variation approach, an optimizable characteristic is introduced for control of the uniqueness of the moving equations. Global optimization methods like e.g. Differential Evolution can be used to obtain an initial paraxial approach. This approach can be improved using the SQP or the Damped Least Squares (DLS) method. Finally, the generation of an initial real lens system is described.

9580-5, Session 2

New tools for finding first-order zoom lens solutions and the analysis of zoom lenses during the design process

Anthony J. Yee, Gustavo A. Gandara-Montano, Daniel J. L. Williams, Peter McCarthy, Julie Bentley, Duncan T. Moore, Univ. of Rochester (United States)

We developed software design tools in MATLAB that are compatible with CodeV for supporting the process of designing zoom lenses. These tools simplify the process of finding paraxial solutions and evaluating intermediary design steps. Paraxial solutions are found through a partially random search for four group zoom systems with moving second and third groups. It requires several user-specified system parameters and then randomly assigns powers to each group. This process of randomly assigning powers is done a set number of times and only the valid solutions where no lenses crash are considered for further use. The valid designs are plotted over different design criteria and can then be selected to retrieve the first order design parameters. For the intermediate design process, the software displays lens specifications and diagnostic results across zoom for the entire lens as well as the individual groups. Systematic evaluation of the intermediate design steps is useful in determining how to proceed and improve the design. The design process is described for two different zoom lenses to show the efficiency and utility of these tools. The two zoom lenses are a 16x surveillance camera zoom lens working in the visible and a 3x zoom lens working in the visible and short wave infrared. The design procedure for these lenses covers finding the paraxial solutions to evaluating the lens for further improvement.

9580-6, Session 2

Modular optical design for flexible beam expansion

Ulrike Fuchs, Sven Wickenhagen, asphericon GmbH (Germany)

In complex laser systems, such as those for material processing, and in basically all laboratory applications passive optical components are indispensable. Matching beam diameters is a common task, where Galileo type telescopes are preferred for beam expansion. Nevertheless, researches and customers have found various limitations when using these systems. Some of them are complicated adjustment, very small diameter for the incoming beam (1/e?), fixed and non-modifiable magnifications. Above that, diffraction-limited performance is often only assured within the optical design. Additionally, one often would like to have a system that can be adapted to the wavelength used without varying the magnification.

A monolithic solution, which is based on the usage of only one aspheric component, will be presented. Systems are designed for four basic wavelengths (532, 632, 780 1064nm) and allow for a remarkable input aperture of up to 14.7mm. If various magnification levels (1.5x, 1.75x, 2.0x) are combined with each other in a cascade, one can achieve 230 possible overall enlargements. Experimental data on the performance of cascades with up to five monolithic elements with diffraction-limited wavefronts will be shown. Additionally, we present an add-on element, which allows for wavelength tuning and adaption of divergence of the incoming beam without changing the beam diameter. This allows for the usage of the monolithic beam expanders over the complete wavelength range from 500nm up to 1600nm. Furthermore, another module – a zoom lens - is introduced. Adding this element overcomes the discreet incrementation and allows for continuous enlargement from 1x to 32x.

9580-7, Session 2

Zoom lens design for tilted objects

Robert M. Malone, Daniel K. Frayer, Morris I. Kaufman, Heather R. Leffler, Alfred Meidinger, National Security Technologies, LLC (United States)

When a zoom lens views a tilted finite conjugate object, its image plane is both tilted and distorted depending on magnification. Our image plane design has six degrees of freedom; only one moving doublet lens is required to change magnification. Two lens design models were analyzed. The first required the optical and mechanical axes to be collinear, resulting in a tilted stop. The second allowed the optical axis to be tilted from the lens mechanical axis with an untilted stop moving along the mechanical axis. Both designs produced useful zoom lenses with excellent resolution for a distorted image. For both lens designs, the stop was anchored to the moving doublet and its diameter is unchanged throughout magnification changes. This unusual outcome allows the light level at each camera pixel to remain constant, independent of magnification. As-built tolerance analysis is used to compare both optical models.

The design application is for proton radiography. At the end of an accelerator, protons exit an aluminum vacuum window producing a shadowgraph image onto an LYSO (lutetium yttrium orthosilicate) scintillator. The 5? square scintillator emission reflects off a pellicle and is collected by the zoom lenses located 24? away. Four zoom lenses will view the same pellicle at different alpha and beta angles. Blue emission from the scintillator is viewed at an alpha angle of –14° or –23° and beta angles of ±9° or ±25°. The pellicle directs the light backwards to a zone where adequate shielding of the cameras can be achieved against radiation scattered from the aluminum window.

9580-8, Session 2

Compensator selection considerations for a zoom lens

John R. Rogers, Synopsys, Inc. (United States)

The selection of compensators for a cam-driven zoom lens is more complex than for a prime lens, because tolerances cause the back focal distance to shift by different amounts in different zoom positions, i.e, the system loses parfocality. Adjustment of the back focal distance can bring one, but not all, of the zoom positions back into focus. Furthermore, compensator selection is more complex because it is usually desirable to avoid adjustments within the moving groups. If moving groups are to be adjusted, it is often desirable to restrict the adjustments to shifting entire groups rather than changing

spacings within the moving groups.

In this paper, we examine the effects of tolerances and compensators on a photographic-format zoom lens. We begin by assigning reasonable tolerances to all surfaces, materials, and groups, and then examine in detail how these tolerances affect the image quality. We determine the relative amount of degradation caused by transverse tolerances (decenters and tilts) compared to rotationally symmetric tolerances (power, index, thicknesses and spacings). For the rotationally symmetric tolerances, we examine the efficacy of the following compensators (which we list approximately in order of decreasing desirability): shifting the detector, shifting the fixed groups, respacing elements within the fixed groups, shifting the moving groups relative to their zoom pins, and respacing elements within the moving groups. Similarly, for the transverse tolerances, we examine the efficacy of implementing decenter compensators within the fixed groups, and then examine the additional performance gain achieved by implementing decenter compensators inside the moving groups.

9580-9, Session 2

To zoom or not to zoom: do we have enough pixels?

Richard N. Youngworth, Riyo LLC (United States); Eric Herman, The Aerospace Corp. (United States)

Common lexicon in imaging systems includes the commonly used term digital zoom. Of course this term is a complete misnomer as there is no zooming in such systems. Instead, digital zoom is a term describing the illusion of zoom that comes with an image rewriting or reprinting that is more accurately described cropping and enlarging an image (a pixel remapping) for viewing or printing. The essential question, pondered and manipulated since the advent of digital image science, really becomes “do we have enough pixels to not zoom.” This paper will summarize known imaging factors in detail, most notably resolution considerations. The paper includes examples and information useful to the greater consumer, technical, and business community who all have an interest in understanding the key technical details that have driven the amazing technology and development of zoom lenses.

—

Ideas on nice things to possibly include:

- Space mapping out for zoom versus resolution (needs more thought)
- Examples will include cases where zoom MUST be used
- Another way to look at it: “Justifying zoom”
- Pixels are useful for other purposes – good point to make. Should any pixels be used to avoid zoom?
- Include zooming up and down types of cases
- Ask basic yet useful question here and provide a good summary of something that is not always understood by even technical people and certainly not the public
- Focus factors
- Pupil size changes

9580-10, Session 3

Increasing dual band infrared zoom ranges *(Invited Paper)*

Jay N. Vizgaitis, Arthur Hastings Jr., optX imaging system (United States)

Complexity in infrared zoom lenses is increased with the broadening of the spectral band. Trying to find ways to increase the zoom range for multi-spectral infrared systems without the overburdening of the optical train with significantly more elements or reduced performance can involve applying a combination of known methods. Traditionally zoom lenses generally take one of two forms...continuous zoom or discrete zoom. Continuous zoom lenses are generally built as all refractive solutions which require multiple moving groups to achieve good performance over large magnification ranges. Discrete zoom lenses can be built in a similar method, be all reflective, or utilize combined reflective/refractive approaches for larger magnification ranges. Scaling pixel sizes for any given focal length also effectively zoom a lens by changing its instantaneous field of view. The concept and performance impact of combining all these concepts into a single zoom lens to significantly increase the zoom range of a dual band infrared system is explored in this paper.

9580-11, Session 3

Optical design study and prototyping of a dual-field zoom lens imaging in the 1-5 micron infrared waveband

Dmitry Reshidko, The Univ. of Arizona (United States); Pavel Reshidko, Ran Carmeli, RP Optical Lab. Ltd. (Israel); Jose Sasian, The Univ. of Arizona (United States)

Some optical systems can benefit from simultaneous imaging in several spectral bands. A new generation of focal plane arrays allow detection in more than one spectral region. The design of a refractive imaging lens for such detector is particularly challenging: the aberrations should be balanced over the wide range of wavelengths. On the other hand, the selection of available optical materials and coatings is limited.

We show a dual-field zoom lens designed for a cooled detector sensing from short-wave infra-red (SWIR) to mid-wave infra-red (MWIR) spectral bands (continuous imaging for 1-5 micron). The zoom lens has 75 mm focal length in the wide mode (horizontal field-of-view (HFOV) of 7.6 degrees) and 250mm focal length in the narrow mode (HFOV of 2.22 degrees), operating at f/4.7. The lens is designed to work in thermal environments from -20C to +70C. We present the optical design methodology, discuss the selection of materials and coatings for the optical elements, and analyze the transmission of the lens and optical performance. A prototype system has been manufactured and assembled. We validate our design with the experimental data.

9580-12, Session 3

Optical design study of a VIS-SWIR 3X zoom lens

Rebecca E. Berman, James A. Corsetti, Keija Fang, Eryn Fennig, Peter McCarthy, Greg R. Schmidt, Anthony J. Visconti, Daniel J. L. Williams, Anthony J. Yee, Yang Zhao, Julie Bentley, Duncan T. Moore, Univ. of Rochester (United States); Craig Olson, L-3 Communications (United States)

A design study is compiled for a VIS-SWIR dual band 3x zoom lens. The initial first order design study investigated zoom motion, power in each lens group, and aperture stop location. All designs were constrained to have both the first and last lens groups fixed, with two middle moving groups. The first order solutions were filtered based on zoom motion, performance, and size constraints, and were then modified to thick lens solutions for the SWIR spectrum. Successful solutions in the SWIR were next extended to the VIS-SWIR. The resulting nine solutions are all nearly diffraction limited using either PNNP or PNPZ (“Z” indicating the fourth group has a near-zero power) design forms with two moving groups. Solutions were found with the aperture stop in each of the four lens groups. Fixed f-number solutions exist when the aperture stop is located at the first and last lens groups, while varying f-number solutions occur when it is placed at either of the middle moving groups. Design exploration included trade-offs between parameters such as diameter, overall length, back focal length, number of elements, materials, and performance.

9580-13, Session 3

Chromatic correction for a VIS-SWIR zoom lens using optical glasses

Yang Zhao, Daniel J. L. Williams, Peter McCarthy, Anthony J. Visconti, Julie L. Bentley, Duncan T. Moore, Univ. of Rochester (United States)

With the advancement in sensors, hyperspectral imaging in short wave infrared (SWIR 0.9 ?m to 1.7 ?m) now has wide applications, including night vision, haze-penetrating imaging etc. Most conventional optical glasses can be material candidates for designing in the SWIR as they transmit up to 2.2 ?m. However, since SWIR is in the middle of the glasses' major absorption wavebands in UV and IR, the flint glasses in SWIR are less dispersive than in the visible spectrum. As a result, the glass map in the SWIR is highly compressed, with crowns and flints all clustering together. Thus correcting for chromatic aberration is more challenging in the SWIR, since the Abbe number ratio of the same glass combination is reduced. Conventionally, fluorides, such as CaF2 and BaF2, are widely used in designing SWIR system due to their unique dispersion properties, even though they are notorious for poor manufacturability or even high toxicity. For lens elements in a zoom system, the ray bundle samples different sections of the each lens aperture as the lens zooms. This creates extra uncertainty in correcting chromatic aberrations. This paper focuses on using only commercially available optical glasses to color-correct a 3X dual-band zoom lens system in the VIS-SWIR. The design tools and techniques are detailed in terms of material selections to minimize the chromatic aberrations in such a large spectrum band and all zoom positions. Examples are discussed for designs with different aperture stop locations, which considerably affect the material choices.

9580-14, Session 4

Cine-servo lens technology for 4K broadcast and cinematography *(Invited Paper)*

Ryuji Nurishi, Tsuyoshi Wakazono, Fumiaki Usui, Canon Inc. (Japan)

Along with the rapid evolution of 4K image capturing technology in the past few years, usage of large-format cameras with Super35mm Single Sensors has increased in TV production for diverse shows such as dramas, documentaries, wildlife, and sports. While large format image capturing has been the standard in the cinema world for a long time, the recent trend seen in the broadcast industry has revealed various differences in the requirements of large format lenses as compared to the cinema industry. A typical requirement for a broadcast lens is higher zoom ratio in order to avoid changing lenses in the middle of a live event, which is mostly not the case for traditional cinema productions. Another example would be the need for compact size, light weight and servo operability for a single camera operator shooting in a shoulder-mount ENG style. On the other hand, there are new requirements that are common to both worlds, such as smooth and seamless change in angle of view throughout the long zoom range, which could lead to a new image expression that never existed in the past.

This paper will discuss the requirements from both industries, cinema and broadcast, while at the same time introducing the new technologies and new optical design concepts applied to our latest "CINE-SERVO" lens series which consists of the two models, CN7x17KAS-H and CN20x50IAS-H.

It will further explain how Canon has realized 4K optical performance and fast servo control while achieving compact size, light weight and high zoom ratio at the same time, by referring to patent-pending technologies such as the optical power layout, lens construction, and glass material combinations.

9580-15, Session 4

Extreme retrofocus zoom lens for single-shot single-lens HDR photography and video

Anthony Vella, Julie L. Bentley, Univ. of Rochester (United States)

Traditional high dynamic range (HDR) photography is performed by capturing multiple images of the same scene with different exposure times, which are then digitally combined to produce an image with great detail in both its light and dark areas. However, this method is not viable for moving subjects since the multiple exposures are not captured simultaneously. Recently an alternative method has been developed in which beamsplitters are utilized to simultaneously record the same image on three identical sensors at different illumination levels. This process enables single-shot HDR photography as well as continuous HDR video. This paper describes the design of a 2.5x zoom lens for use in this application. The design satisfies the challenging working distance and ray angle constraints imposed by the placement of two beamsplitters between the lens and the image plane. The particular importance of first-order layout when designing a retrofocus zoom lens is also discussed.

9580-16, Session 4

All-reflective optical power zoom objectives *(Invited Paper)*

Jens Knobbe, Heinrich Grueger, Fraunhofer-Institut für Photonische Mikrosysteme (Germany); Kristof Seidl, Fraunhofer-Institut für Photonische Mikorsysteme (Germany)

Over the past decades zoom lenses have become an important type of objective. Due to their ability to dynamically change magnification or field angle they are being used in many fields of application. Most zoom lenses consist of a number of lenses or lens groups. The magnification can be changed by axially shifting some of these lens groups with a more or less complicated moving function.

However, in principle it should be possible to construct zoom lenses that do not rely on the movement of some of their components. Instead, the change in magnification is achieved by changing the optical power of at least two lenses within the system (optical power zoom (OPZ)). Moreover, for broadband applications it is highly favourable to use mirrors instead of lenses due to the absence of chromatic aberrations.

Based on a "Schiefspiegler" approach a 3x reflective OPZ objective consisting of four mirrors has been designed. Two mirrors are assumed to have a variable radius of curvature for changing optical power. During aberration correction special consideration has been given to the reduction of field curvature, since the optical power change strongly influences field curvature for different zoom positions. The simulation shows adequate image quality for photographic applications over the whole zooming range.

For the realization of such a OPZ objective deformable mirrors with a comparatively large stroke are needed. Before starting a complex development of such devices three setups with different fixed focal lengths were built as a prove of concept.

9580-17, Session 4

Design of a zoom lens with a large field-of-view and better solutions with asphere

Takanori Yamanashi, Theta Optical LLC (United States)

It is known that a wide angle zoom lens can include "wild asphere". It must be interesting to know how aspheres are influenced by aberration correction. Even if there are zoom lenses of positive lead and negative lead,

the latter one is commonly used for the wide angle zoom lens. In this paper different types of zoom lens are introduced and discussed, in terms of the optical design with the same specifications. Then possible ways on how to modify the asphere is suggested. In comparison a solution of all spherical version is also described.

9580-18, Session 5

Change of optical design thought about focusing of zoom lens *(Invited Paper)*

Hitoshi Hagimori, Panasonic Corp. (Japan)

Zoom lens has accomplished most various evolution as interchangeable lens attached to single-lens camera system to be differentiation from a fixed focal lens.

The interchangeable lens with zoom function put up a first cry around 1960 and so far many lenses with various specifications , from standard type to high zoom ratio type, has been sent out in the market by the innovation of optics type to change focal length continually.

When I move the eye to a camera body of single-lens system ,it may be said that the evolution of camera's function has been the history of the automation. most especially the auto focus alignment function evolved in by an appearance of phase difference AF method dramatically.

In late years contrast AF method with the imaging sensor comes up in digitization and auto focusing came to be made in the case of not only still image but also movie.

On the other hand, in the zoom lens for interchangeable system, new and original design thought about zooming and focusing that matched each AF method of this camera body was brought about and led to the development of the zoom lens.

In this report I introduce the design thought of optics about zooming and focusing of interchangeable zoom lens that evolved to the change of camera body AF method mentioned above. Also I say associated technique such as actuator and lens control, in addition introduce one end about directionality of the evolution of the future zoom lens.

9580-19, Session 5

Multi-channel compact optical zoom module by using microlenses

Wei-Hsiang Liao, Guo-Dung Su, National Taiwan Univ. (Taiwan)

Nowadays mobile cell phones are a few millimeters thickness. It becomes challenging to achieve optical zoom function in such a small device. In this paper, we propose a multi-channel imaging system which combines the principles of insect's compound eyes and optical zoom. The proposed optical system could reduce the total track length of optical zoom imaging device and has potential for compact mobile phone. The optical zoom is achieved by adjusting distance between two aspherical lenses to change effective focal length of the optical zoom system and insect's compound eye (multi-channel structure) is made by a curved hexgonal microlens array. By the curved hexgonal microlens array, we can get the same effect when using the lens group to make our system thinner. The thickness is about 8 mm and the zoom ratio is about 2X.

9580-20, Session 5

Design study for a 16x zoom lens system for visible surveillance camera

Anthony Vella, Heng Li, Yang Zhao, Isaac Trumper, Gustavo A. Gandara-Montano, Di Xu, Daniel K. Nikolov, Changchen Chen, Andres Guevara-Torres, Nicolas S. Brown, Hae Won Jung, Jacob Reimers, Julie L. Bentley, Univ. of Rochester (United States)

High zoom ratio zoom lenses have extensive applications in broadcasting, cinema and surveillance. Here, we present a design study on a 16x zoom lens with 4 groups (including two internal moving groups), designed for, but not limited to, a visible spectrum surveillance camera. Fifteen different solutions were discovered with nearly diffraction limited performance, using PNPX or PNNP design forms with the stop located in either the third or fourth group. Some interesting patterns and trends in the summarized results include the following: (a) in designs with such a large zoom ratio, the potential of locating the aperture stop in the front half of the system is limited, with ray height variations through zoom necessitating a very large lens diameter; (b) in many cases, the lens zoom motion has significant freedom to vary due to near zero total power in the middle two groups; and (c) we discuss the trade-offs between zoom configuration, stop location, packaging factors, and zoom group aberration sensitivity.

9580-21, Session 5

Novel optical system for very thin zoom lenses

Akira Yabe, Consultant (Japan)

In this report a novel optical system for very thin zoom lenses is shown. This system is expected to be used in the mobile phone camera.

This system has a prism or a mirror as the first element to bend the optical axis 90 degrees. The key point of this system is the use of the intermediate image. The system consists of 3 lens groups with the positive optical power. The first group makes the intermediate image. The second group is put around the intermediate image to reduce the height of rays from the off-axis object points. The third group relays the intermediate image to the image plane.

The possibility of the zooming and focusing types is investigated, as well as the possibility of the power distribution of 3 lens groups. If all the groups are moved for the zooming, this has the largest freedom of the design. By fixing one group or connecting two groups, the system is simplified. 6 different zooming types can realize the good performance.

Finally the procedure to realize such an unprecedented optical system is shown. The thin lens model with the intrinsic aberration coefficients is used to construct the zooming system. Then thin lenses are replaced to real lenses. This is the starting point of the optimization with the real ray trace. Global optimization is applied and the best solution is chosen.

9580-22, Session 5

Optical design of optical zoom optics with intermediate image

Yi-Chin Fang, National Kaohsiung First Univ. of Science and Technology (Taiwan)

This study designs a 6x zoom lens which is compounded by two groups of lens with 6x zoom ratio and another fixed focal optics. A real image (e.g., intermediate image) is shown between two zoom lens groups. The effect of the intermediate image makes the power of two group of lens independently, which can assign a lower power in the front lens group to alleviate the diameter of lens elements. The traditional zoom ratio is defined by Mtotal = ftele/fwid, where fwid is the effective focal length (EFL) with wide-angle and ftele is the EFL for telescope. Figure 1 illustrates the total zoom ratio for intermediate image.

The specification of the proposal is shown in Table 1. The CCD size is 1/2.7" and its diagonal distance is 6.592mm. Since the proposed zoom lens is symmetrical, the half diagonal distance of CCD size (that is 3.296mm) is used to evaluate the performance in Code V.

9581-1, Session 1

Self-healing of light beams: a wave-optics approach *(Invited Paper)*

Andrea Aiello, Max-Planck-Institut für die Physik des Lichts (Germany); Girish S. Agarwal, Oklahoma State Univ. (United States)

Contrarily to common beliefs, almost all beams of light possesses somehow the ability to "reconstruct themselves" after hitting an obstacle [1-3]. The celebrated Arago spot phenomenon is nothing but a manifestation of this property. In this work we analyze the self-healing mechanism from a wave-optics point of view [4]. This leads to a novel expression for the minimum reconstruction distance, which is valid for any kind of beam, including Gaussian ones [5]. Finally, a witness function that quantifies the self-reconstruction capability of a beam is proposed and tested. Our results represent a step forward in the understanding of the physics underlying self-healing mechanism in optical beams.

Angular accelerating white light

Angela Dudley, CSIR National Laser Ctr. (South Africa); Christian Vetter, Alexander Szameit, Friedrich-Schiller-Univ. Jena (Germany); Andrew Forbes, Univ. of the Witwatersrand (South Africa)

Significant interest has been devoted to tailoring optical fields that transversely accelerate during propagation in the form of Airy, Weber and Mathieu beams. In this work, we introduce a new type of optical field that exhibits controlled angular acceleration during propagation which is achieved by superpositions of Bessel beams with non-canonical phase functions. We demonstrate these angular accelerating fields by modulating the phase and amplitude of a supercontinuum source with the use of a phase-only spatial light modulator (SLM). We illustrate that by considering only the first diffraction order when the SLM is encoded with a blazed grating, the SLM is capable of tailoring the spatial profile of broadband sources without any wavelength dependence. By digitally simulating free-space propagation on the SLM, we compare the effects of real and digital propagation on the angular rotation rates of the resulting optical fields for various wavelengths. The development of controlled angular accelerating optical fields will be useful in areas such as particle manipulation, plasma control, material processing and non-linear optics.

9581-3, Session 1

Self-healing of Hermite-Gauss and Ince-Gauss beams

Dilia Aguirre-Olivas, Gabriel Mellado-Villaseñor, Victor Arrizón, Sabino Chávez-Cerda, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico)

An optical beam that is subject to a partial obstruction propagates showing certain degree of self-reconstruction in the obstruction domain. This phenomenon is known as self-healing (SH) of the beam. The SH has been widely studied in propagation invariant beams like Bessel, Airy, Mathieu and Weber.

Nevertheless, there is a family of beams whose transverse profile remains invariant under propagation, changing only the scale. This beams are solution of the paraxial wave equation in three different coordinate systems, Hermite-gauss (HG) beam in rectangular coordinates, Ince-gauss (IG) beam in elliptical-cylindrical coordinates and Laguerre-gauss (LG) beam in cylindrical coordinates.

In this work we report numerically and experimentally the SH effect in HG and IG beams with an opaque obstruction.

First, a semi-analytical analysis is made by means of a figure of merit named signal to noise intensity ratio. This figure of merit is based on analytical diffraction formulas and is explicitly dependent on the features of the beam and the obstruction applied to it.

We demonstrate the SH effect by numerical simulation and experimentally. Numerical simulations were made with analytic expression for HG and IG beams. Experimental generation of the beams under test we employ amplitude computer-generated holograms (CGHs), displayed in a twisted nematic liquid crystal (TNLC) spatial light modulator (SLM). A significant detail is that the holograms were designed including the obstruction as a feature of the generated fields.

Finally, as a complement of the semi-analytical analysis, a quantitative evaluation of the SH effect in HG and IG beams was made employing the Root Mean Square deviation and the similarity function.

This phenomenon is known as self-healing (SH) of the beam. The SH has been widely studied in propagation invariant beams like Bessel, Airy, Mathieu and Weber.

Classical entanglement of vector vortex beams

Melanie McLaren, Univ. of the Witwatersrand (South Africa); Thomas Konrad, Univ. of KwaZulu-Natal (South Africa); Andrew Forbes, Univ. of the Witwatersrand (South Africa) and CSIR National Laser Ctr. (South Africa)

Vector beams are defined by spatially inhomogeneous states of polarization, that is, the spatial distribution and polarization state of the beam are non-separable. These beams have found interest in a variety of optical fields such as microscopy, interferometry and optical tweezing. It is therefore important to determine the degree to which these beams are non-separable or to determine the "vectorness" of such beams. We show that the non-

separability of vector beams is analogous to that of entangled quantum states and as such, we use traditionally quantum techniques such as a Bell inequality, to determine the vectorness of our generated vector vortex beams.

9581-5, Session 1

Generating non-diffraction beams using DMD

Yongdong Wang, Nanyang Technological Univ. (Singapore); Yilei Zhang, Nanyang Technological Univ (Singapore)

Non-diffraction beams, such as the Airy beam and the Bessel beam, have attracted more and more attension due to their unique properties, such as non-diffraction, self-healing. Digital Micromirror Device (DMD) is a powerful tool using microfabricated mirrors to control light reflection, which could be used for laser beam shaping. Well designed holographic or structural patterns could be loaded in DMD to control micromirror reflection and generated desired non-diffraction beams. Wavefronts of the generated non-diffraction beams are measured using a Mach-Zehnder interferometer method. Both wavefront and profile of the generated beams agree with theoretical calculation, which proof the successful construction of the non-diffraction beams. This powerful and straightforward DMD based method could also be applied to generate other beams for engineering and biological applications.

9581-6, Session 2

2 um intra- and extra-cavity beam shaping *(Invited Paper)*

Igor A. Litvin, Council for Scientific and Industrial Research (South Africa); Hencharl Strauss, Gary King, CSIR National Laser Ctr. (South Africa)

In this work, the new techniques for intra– and extra–cavity laser beam shaping were proposed and tested. The intra-cavity beam shaping techniques was implemented to Tm:YLF slab laser. The method based on DOE and cylindrical lenses retransformation of intra–cavity oscillation field to fit rectangular like pump beam. The method allows the increasing of output laser brightness dramatically. Moreover we propose a new technique for extra–cavity laser beam shaping namely the reshaping of the laser beam into a desirable beam profile by the use of a laser amplifier with a pump beam that has a modified intensity profile. One the advantages of this method are the ability to reshape multimode beams as the method relies only on the transverse intensity of the beams. All techniques were verified experimentally for 2 μm lasers and laser beams.

9581-7, Session 2

High-brightness fiber-coupled laser-diode beam-shaping design based on right-angle prism array

Junhong Yu, Haitian (China)

A new beam shaping technique that twists the emitters of laser-diode bar and rearranges the twisted emitters abutted against each other is proposed considering a right-angle prism array and a distributed cylinder-lens stack. By using this innovative beam shaping technique, the coupling of 12 mini-bars to a fiber with a 100 ?m core diameter and 0.15 NA is is demonstrated both by simulation and experiment . The proposed coupling system is very effective and compact for coupling the laser-diode into fibers. The simulation and experiment results indicate that the right-angle prism stack and the distributed cylinder-lens stack successfully eliminate the lightless area and equalize the beam quality of the mini-bar. With the availability of output power above 400 watts and high brightness above 71.5 MW/ (cm2•sr?, much wider applications of fiber-coupled laser-diode are anticipated.

9581-8, Session 2

Intracavity beam shaping using an SLM

Liesl Burger, Council for Scientific and Industrial Research (South Africa) and Stellenbosch Univ. (South Africa); Igor Litvin, Sandile Ngcobo, Council for Scientific and Industrial Research (South Africa); Andrew Forbes, CSIR National Laser Ctr. (South Africa)

Spatial light modulators (SLMs) are phase-modulating liquid crystal display devices, and are widely used for beam-shaping of laser beam for applications like micro-machining, advanced microscopy, and the creation of novel beams. Coherent light is modulated by passing through reflectively-coated electrically-addressed liquid crystal (LC) cells, which are each programmed by means of a grey-scale bitmap displayed on the LCD screen. In standard operation incident light is reflected once off the SLM, but we replace the back reflector of a simple folded resonator with a SLM in order to exploit its phase modulating properties. In this configuration the light circulating in the resonator is subject on each pass to a phase modulation which is calculated to produce a specific desired laser beam profile using known techniques.

A prototype system revealed that although SLMs are said to be phase-only, that SLMs containing twisted nematic LCs have a small degree of amplitude modulation together with the expected phase modulation. This effect, although small and negligible in the traditional single-reflection configuration, is amplified when the SLM is in the intracavity configuration. We show that as a result, a phase-only SLM behaves as a phase modulating element inside the resonator. An investigation of LC properties predicts that the new generation of SLMs containing parallel aligned LCs have a negligibly small amplitude modulation, which is confirmed by experiment, and which allows these SLMs to function as per our original idea.

A number of chosen laser beam profiles produced by our two prototypes are shown to illustrate the versatility of the system.

9581-9, Session 2

Selective excitation and detection of higher-order doughnut laser modes as an incoherent superposition of two petals modes in a digital laser resonator

Sandile S. Ngcobo, Igor Litvin, Council for Scientific and Industrial Research (South Africa); Darryl Naidoo, CSIR National Laser Ctr. (South Africa); Kamel Ait-Ameur, Ecole Nationale Supérieure d'Ingenieurs de Caen et Ctr. de Recherche (France); Andrew Forbes, CSIR National Laser Ctr. (South Africa)

Higher-order Laguerre–Gaussian beams with zero radial index and nonzero azimuthal index are known to carry orbital angular momentum (OAM), and they are routinely created external to laser cavities. Previous reports on the generation of such modes from laser cavities suffer from inconclusive evidence of the real electromagnetic field. In this paper we demonstrate a simple method of selectively generating higher-order doughnut modes using a digital laser and we show that an observed doughnut beam from a laser cavity may not be a pure Laguerre–Gaussian azimuthal mode but can be an incoherent sum of petal modes, which do not carry OAM. We also demonstrate a method that could be used for future analysis of such fields from laser resonators.

9581-10, Session 3

C-shaped structured electron beams: design and experimental production

Michael Mousley, Jun Yuan, Mohamed Babiker, Gnanavel Thirunavukkarasu, The Univ. of York (United Kingdom)

Computer generated holograms (CGHs) have been designed to create structured illumination with a C shape. The structured illumination is based on a vortex state, however the inclusion of radial phase gradients leads to non integer topological charge and a redistribution of intensity in the far field diffraction pattern. By analysing the phase gradients present in the wavefunction the structured illumination pattern can be predicted and independent control of the radius and opening angle is possible. C shaped illumination is experimentally produced in an electron microscope showing two different opening angles , using two different CGH mask types an amplitude mask and a phase mask. C-shaped structured illumination offers interesting particle interactions and trapping possibilities with the ability to control the size of the gap between trapped particles at the ends of the intensity curve. A spatial light modulator would allow for the real time opening and closing of the C shape whilst interacting with particles. C shaped illumination promises potential applications both in the optical and electron beam lithography of metamaterials which utilise split ring structures and dimensions as small as nanometres can be achieved in the electron beam case.

9581-11, Session 3

Shaping sinusoidal phase contrast holograms (SPCH) for highly-efficient electron vortex beams

Gnanavel Thirunavukkarasu, Michael Mousley, Mohamed Barbiker, Jun Yuan, The Univ. of York (United Kingdom)

Generation of electron vortex (EV) beams with high efficiency is a much discussed topic following the experimental realizations of EV beams in a TEM. The initial realization was based on searching graphite flakes in a randomly stacked graphite thin films sheet to locate a staircase like spiral structure which produces the required 2ϖ phase variation around their point of intersection [1]. Shaping the wave function using this method is very difficult; nonetheless, it initiated the search for alternative, more efficient ways of producing electron vortex beams in a reasonably controlled manner. Consequently, a well-known optical computer generated hologram (CGH) method is adopted and successfully demonstrated for the production of EV beams [2,3]. Using this binarized CGH method one can easily realize EV beams, however, half of the beams incident intensity is blocked by the relatively thick binarized hologram grating and half of the remaining 50% is concentrated on the center beams that possess no angular momentum. Thus there is 25% left for the orders containing angular momentum limiting each first orders to a maximum of close to 10% of the total intensity incident on the hologram.

Increasing the efficiency of a particular order of this CGH generated beams is beneficial for future EV applications. Here, we demonstrate a way of increasing the efficiency of first order beams by tuning the thickness profile. The phase variation between the thicker and thinner regions of the hologram gratings follows a sinusoidal variation with the number of forks endowed at its center representing the topological charge of the beams. By manipulating the phase in this way, we experimentally demonstrate a transmitted diffraction efficiency (intensity of the first order beam divided by the transmitted intensity) of the first order vortex beams ($l = \pm1$) of 30% for a sinusoidal phase variation between 0 and 1.2ϖ. Theoretically a phase variation of 0 to 1.18ϖ is required to obtain the maximum diffraction efficiency of 33.8% for the $l = \pm1$ beams of this SPCH. The absolute diffraction efficiency, (intensity of the first order beam divided by the incident beam intensity), of this SPCH is calculated to be 11.6% using electron energy loss spectroscopy (EELS). The deviation of absolute efficiency from its theoretical maximum diffraction efficiency is mainly attributed to the loss of intensity by inelastic scattering due to the thick support films.

9581-12, Session 3

Electronically-controlled optical tweezing using space-time-wavelength mapping

Shah Rahman, Rasul Torun, Qiancheng Zhao, Tuva Atasever, Ozdal Boyraz, University of California, Irvine (United States)

We propose electronically controlled optical tweezing based on time-space-wavelength mapping technology. Space-time-wavelength mapping technology has been proven to be useful in arbitrary waveform generation in RF photonics and wide-field real time imaging in microscopy. Here we show that the same technology can be applied to optical tweezing. By using time-domain modulation, the location and the polarity of force hot-spots created by Lorentz force (gradient force) can be controlled. In this preliminary study we use 150 fs optical pulses that are dispersed in time and space to achieve a focused elliptical beam that is ~30 ?m long and ~2 ?m wide. We use an electro-optic modulator to modulate power spectral distribution of the femtosecond beam after temporal dispersion and hence change the intensity gradient along the beam at the focal spot. The results show that we can achieve ±200 pN forces on nano objects (~100 nm) without mechanical beam steering. The intensity of wavelengths along the spectrum can be manipulated by using different RF waveforms to create a desired intensity gradient profile at the focal plane. By choosing the appropriate RF waveform, it is possible to create force fields for cell stretching and compression as well as multiple hot spots for attractive or repulsive forces. 2D space-time-wavelength mapping can also be utilized to create tunable 2D force field distributions.

9581-13, Session 3

Encoding information using Laguerre Gaussian modes

Abderrahmen Trichili, SUP'COM (Tunisia); Angela Dudley, CSIR National Laser Ctr. (South Africa); Mourad Zghal, SUP'COM (Tunisia); Andrew Forbes, CSIR National Laser Ctr. (South Africa)

Over the last few years, there has been considerable interest in mode division multiplexing for data transmission in optical fibers and free space optical links. Using the spatial modes of light increases the overall capacity of the communication systems by several orders of magnitude.

In this context, we experimentally demonstrate an information encoding protocol using Laguerre Gaussian modes having different radial and azimuthal components. A detailed method, based on digital holography, for information encoding and decoding using different data transmission scenarios is presented. The effects of the atmospheric turbulence introduced in free space communication is discussed as well. We are convinced that this technique will find uses in the commercial free space communication systems and in mode de-multiplexers in optical fibers.

9581-14, Session 4

Experimental generation of Hermite-Gauss and Ince-Gauss beams through kinoform phase holograms

Gabriel Mellado-Villaseñor, Dilia Aguirre-Olivas, David Sánchez-de-la-Llave, Victor Arrizón, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico)

Hermite-Gauss (HG) and Ince-Gauss (IG) functions are exact solutions of the scalar paraxial wave equation in cartesian and in elliptic cylindrical coordinates, respectively. Each of them forms a complete orthogonal basis under which any function can be represented. Both of them, together with the Laguerre-Gauss functions, which are exact solutions to the paraxial wave equation in free space in circular cylindrical coordinates, can be classified in the family of structurally stable optical fields. Consequently, they are also self-transforming fields under the Fourier transform operation. Recently, the Kinoform Phase Hologram (KPH) codification technique was reported in the generation of Laguerre-Gauss beams. However, the KPH has not been investigated for the efficient and accurate generation of HG and IG beams. In this work, we propose to employ KPHs to efficiently and accurately synthesize the structurally stable Hermite-Gauss and Ince-Gauss beams. Also, we review the mathematical description of the Hermite-Gauss and Ince-Gauss functions and define the KPH transmittance. The KPH codification technique consists on taking the phase of the field to be synthesized as the hologram transmittance. We give an explanation for the high efficiency and accuracy of the kinoform technique for synthesizing these fields. In order to provide a quantitative evaluation of the performance of the KPHs, we employed the root mean square deviation. We described the experimental setup, which contains a reflective phase-only spatial light modulator for codifying the KPHs transmittance. Experimental and numerical results are presented and compared.

9581-15, Session 4

New approach for laser beam formation by means of deformable mirrors

Alexis V. Kudryashov, Julia Sheldakova, Anna Lylova, Vadim Samarkin, Active Optics Night N Ltd. (Russian Federation)

No Abstract Available

9581-16, Session 4

Polarization design of high-efficiency diffractive optics

Michael A. Golub, Tel Aviv Univ. (Israel)

Polarization shaping of laser beams can be performed with subwavelength structures based on effective index technique at zero diffraction order. Resorting to different diffraction orders of diffractive structures provides further degrees of freedom in the polarization control, albeit shows cumbersome coupling to power distribution between diffraction orders. We showed that in high-efficiency surface relief diffractive elements, polarization control is uncoupled from inter-order power distributions. We proposed an effective grating method for transformation of light beam polarization in the first diffraction order of dense transmission binary surface-relief diffractive elements with 80-100% efficiency.

We resorted to a combination of rigorous vector diffraction approaches for periodic medium and surface relief gratings, to derive analytical closed form “effective grating” equations that generalize effective index. A polarization of a diffracted beam, under general three-dimensional angles of incidence, was related to a complete set of incident beam and grating parameters in the resonance domain of diffraction. It was shown that in two-wave diffraction regime, when incident beam essentially converts to the diffracted one, incident polarization states will be straightforwardly coupled to polarization of the 1st order diffracted wave. Also shown that generalized TE and TM polarizations are uncoupled in both wave equations and boundary conditions and differ from those of classical diffraction. Pure, either TE or TM, polarizations provide up to 100% diffraction efficiency, whereas mixed TE and TM polarizations cannot reach such.

A powerful tool for rigorous design of polarization controlling diffractive beam shapers with spectroscopic scale periods is now enabled.

9581-17, Session 4

Closed-loop adaptive optics system for laser beam shaping

Javier Garces, Pedro Escarate, Mario Castro, Sebastian Zuniga, Univ. Técnica Federico Santa María (Chile); Andres Guesalaga, Pontificia Univ. Católica de Chile (Chile)

Adaptive Optics systems are rapidly becoming the norm on high-level astronomical installations. New technology development has allowed for deformable mirrors and related instruments which can allow higher precision and resolution on astronomical measurements. However, the performance of the AO system is highly dependent on the calibration process.

In order to correct the light distortion caused by the atmosphere, a wavefront reference is required by the AO system. Often, bright stars are used for this purpose, however, these are not available in all parts of the sky, and so artificial stars created through the use of laser beams are used instead. Since the laser beam is subject to atmospheric distortion on the way up, a beam shaping concept is introduced to counteract this distortion, improving the quality of the laser guide stars, and as such, improving the system’s performance.

The beam shaping process is based on an optical setup with two deformable mirrors through which the laser beam is introduced before launch. The phase distortions to be applied by each deformable mirror are estimated through a phase retrieval method. The first mirror’s purpose is to correct the amplitude distortions during propagation in the near-field, while the second mirror corrects phase aberrations.

A closed-loop control approach for the deformable mirrors’ arrangement is investigated, based on a model for the optical setup elements and evaluation for different control techniques. The purpose for this approach is to obtain a faster and more robust response for the system regarding the open loop results, which have been previously investigated and presented.

The system’s performance is examined through simulations, in order to obtain graphical results of amplitude and phase correction, compare the benefits of different control techniques, observe improvements regarding the open loop approach, and analyze different parameters’ influence on the system (such as distance and size of the beam shaping system’s elements). Following this analysis, the method is implemented on a laboratory bench, adjusting the system for the specific instruments on the optical set-up, and obtaining graphical results with comparison purposes regarding the simulated results.

9581-18, Session 4

Square shaped flat-top beam in refractive beam shapers

Alexander V. Laskin, Vadim V. Laskin, AdlOptica Optical Systems GmbH (Germany); Aleksei B. Ostrun, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

Lossless transformation of round Gaussian to square shaped flat-top collimated beam is important in building high-power solid state laser systems to improve optical pumping or amplification. There are industrial micromachining applications like scribing, display repair, which performance is improved when a square shaped spot with uniform intensity is created.

Proved beam shaping solutions to these techniques are refractive field mapping beam shapers having some important features: flatness of output phase front, small output divergence, high transmittance, extended depth of field, operation with TEM00 and multimode lasers.

Usual approach to design refractive beam shapers implies that input and output beams have round cross-section, therefore the only way to create a square shaped output beam is using a square mask, which leads to essential losses. When polarized input laser beam it is suggested to generate square shaped flat-top output by applying beam shaper lenses from birefringent materials or by using additional birefringent components. Due to birefringence there is introduced phase retardation in beam parts and is realized a square shaped interference pattern at the beam shaper output. Realization of this approach requires small phase retardation, therefore weak birefringence effect is enough and birefringent optical components, operating in convergent or divergent beams, can be made from refractive materials, which crystal optical axis is parallel to optical axis of entire beam shaper optical system.

There will be considered design features of beam shapers creating square shaped flat-top beams. Examples of real implementations and experimental results will be presented as well.

9581-19, Session 4

Beam shaping concepts with aspheric surfaces

Ulrike Fuchs, asphericon GmbH (Germany)

Employing aspherical lenses to reduce aberrations to improve focusing qualities is a well-known concept. But the potpourri of aspheric surfaces offers way more possibilities, even the chance for flexible beam shaping setups. Since these are refractive optical elements the beam shaping is robust with respect to wavelength changes.

Being able to generate ring shaped light distributions is interesting for various applications. Here the most uncommon aspheric surface – an axicon – is utilized. Axicons are glass cones, which convert the incoming light into Bessel beams. Those are characterized by their concentric ring structure and long depth of focus, which makes them very interesting for material processing. Above that, combining such an axicon with a focusing lens leads to a ring focus. Its size is not only determined by the choice of the axicon angle and the lens properties, but also through the diameter of the incoming beam. Thus, for optimal usage a flexible beam expander, which leaves the beam quality unaltered is mandatory. The remarkable properties of these beam shaping set-ups are shown in theory and experimentally. Furthermore, a configuration consisting of two axicons and interchangeable focusing lenses is presented. For one thing, this set-up allows for tuning of the working distance in any required way for optimal material processing. For another thing, the induced chromatic focal shift of the focusing lens that occurs by a change of wavelength can be compensated for by adapting the distance of the axicons and leaving the working distance unchanged.

9581-20, Session PMon

A new error compensation strategy on laser displacement sensor in freeform surface measurement

Bin Sun, Bing Li, Xi'an Jiaotong Univ. (China)

The Laser Displacement Sensor (LDS) is designed according to the principle of laser triangulation. It is a precise geometric measurement sensor, and it is characterized by non-contact, large measuring range and high measuring efficiency. Therefore it is widely used in the field of industrial inspection and reverse engineering. However, the measurement accuracy of the LDS is easy to be influenced by other factors, such as the workpiece surface color, roughness and the inclination angle of the surface, especially for free-form surface, the incidence angle has greater impact on measurement accuracy and the research is relatively less. The paper proposes a new error compensation strategy, this strategy is an approximate mathematical model which can be quantified. By inclination error compensation, it can effectively improve the measurement accuracy of free-form surfaces.

The paper analyzes the geometry of the laser light path system in detail according to the principle of direct laser triangulation measurement. The study found that the change of laser light path leads to the change of light centroid, thus producing non-linear relationship between object and image. Depending on the cause inclination error generated, a quantifiable approximate mathematical model is deduced. Subsequently, the paper verifies the correctness and reliability of the error model by using high precision Renishaw XL-80 Laser Interferometer and Sine Gauge.

By measuring the aero-engine blade surfaces, the appropriate measurement path is planned in accordance with the characteristics of the blade, and the calculation method of measuring point inclination angle is presented. After the measurement data of the blade are compensated with error model proposed, the experiment indicated that the measurement accuracy is less than 10?m. The result shows that the proposed inclination angle error compensation method can effectively improve the measurement accuracy of the LDS, and the model has certain popularize and use value in engineering applications.

Scanning in the optical vortex microscope

Agnieszka Popio?ek-Masajada, ?ukasz P?ócienniczak, Jan Masajada, S?awomir Drobczy?ski, Wroclaw Univ. of Technology (Poland)

We propose a microscopic system in which the Gaussian beam with embedded optical vortex is used. The special helical phase plate is illuminated by the Gaussian beam and then focused by the microscope objective into the sample plane. Such a beam carries the optical vortex – the zero intensity point around which the phase gradient becomes infinitely large. By moving the phase plate within the Gaussian beam, the singular point in the sample plane can be moved and such configuration can be used for scanning the sample. We found in our previous works that moving the phase plate along a straight line causes a movement of the optical vortex also along straight line. The angle of the vortex trajectory however depends on the observation plane position. There is a plane in which the trajectory is perpendicular to the phase plate shift. In this plane the core region of a vortex beam is extremely sensitive to any phase imperfections introduced into the beam. The analytical formula for the complex amplitude of the focused spot with off-axis vortex was calculated in order to calibrate the microscopic system. In this presentation the theoretical fundamentals of microscope are discussed. The conclusions are verified experimentally

9581-22, Session PMon

Orbital angular momentum mode coupling in fibers

Bienvenu I. Ndagano, Melanie McLaren, Univ. of the Witwatersrand (South Africa); Andrew Forbes, Univ. of the Witwatersrand (South Africa) and CSIR National Laser Ctr. (South Africa)

Orbital angular momentum (OAM) of light has become, over the years, the focus of intensive research worldwide. We are particularly interested in the additional degrees of freedom OAM provides for optical communication. To this end, we built an optical setup to generate and detect OAM modes. To overcome the issue of turbulence, which is detrimental to the formation and propagation of OAM modes, we propagated the generated OAM modes through an optical fibre. We demonstrate that using spatial light modulators we can not only generate specific beams carrying OAM but also decompose them in terms of orthogonal azimuthal functions characteristic of OAM modes. This decomposition technique, referred to as mode decomposition or spatial correlation, can be used to detect OAM modes. Using our optical setup we show that OAM is maintained as the modes propagate through the fibre. We first perform our analysis using scalar Laguerre – Gaussian (LG) and linearly polarised (LP) modes, where the latter approximates the natural fibre modes. We repeated the analysis using the true fibre modes,

the cylindrical vector (CV) modes which exhibit azimuthal symmetry of field distribution and polarisation. We demonstrate a novel method of generating CV modes using a q-plate and show that CV modes are better suited to carry OAM through fibres as opposed to LG and LP modes.

9581-23, Session PMon

Practical implementation of propagation-invariant laser beams

Michael G. Soskind, Rose Soskind, Rutgers, The State Univ. of New Jersey (United States); Yakov Soskind, DHPC Technologies (United States)

Due to their several unique properties, propagation invariant laser beams are playing an increasingly important role in several photonics applications. This paper describes several practical aspects of producing propagation invariant laser beams with different symmetries and structured light field distributions. Both intra-cavity and extra-cavity schemes are discussed. In the case of extra-cavity implementations, we show several practical layouts of anamorphic optical systems for shaping propagation-invariant laser beams based on the size and waist locations of the input laser beams.

The influence of components' misalignments and optical imperfections on the spatial characteristics of the produced output beams is presented as well.

9581-24, Session PMon

Fabrication and characterization of a non-zero dispersion-shifted mechanically-induced long-period grating for optical fiber sensing

Eloisa Gallegos-Arellano, Ruth I. Mata-Chavez, Eduardo H. Huerta-Mascotte, Julian M. Estudillo-Ayala, Ana D. Guzman-Chavez, Everardo Vargas-Rodriguez, Juan M. Sierra-Hernandez, Roberto Rojas-Laguna, Igor Guryev, Univ. de Guanajuato (Mexico)

We present the fabrication and characterization of a mechanically induced long period grating (MILPG) using a grating period of 400 μm and 1m of NZ-DSF. Pressure is gradually applied up to 120 Lb at different angles like 0, 30, 45 and 60 degrees. An attenuation band is observed centered at a wavelength around 1064nm using a fiber position of 30 degrees with respect to the grating´s metal plate and a maximum pressure of 145 Lb. The loss band presents a maximum depth of 22dB and a bandwidth of approximately 10nm. Torsion and curvature characterizations did not change the output spectrum of the optical grating. However, temperature characterization depicted a small shifting which could be insignificant for some applications. Still, there is a 10dB attenuation as temperature increases in a range from room temperature up to 200˚C. These preliminary studies show that this 1064 nm centered wavelength MILPG might be used in a very low dynamic range with temperature as a temperature sensor.

9581-25, Session PMon

Closed-Loop control for tip-tilt compensation

Mario A. Castro R., Pedro Escárate, Javier Garcés, Sebastián Zuñiga, Univ. Técnica Federico Santa María (Chile); Andrés Guesalaga, Pontificia Univ. Católica de Chile (Chile)

Adaptive optics (AO) is a well-known technology that compensates image distortions induced by atmospheric turbulences and low frequency vibrations. Currently the vast majority of 8 meters class telescopes are now equipped with adaptive optics systems and will be an integral component in the next generation of telescopes and astronomical instruments.

Despite the significant advances in astronomical instrumentation and adaptive optics, some problems still persist during the operations. In particular, achieving a satisfactory performance in front of mechanical vibrations progressively more important.

The vibrations effects, acting in the propagation of the science light, strongly affects the performance of the AO systems, often producing an additional image jitter. These perturbations mainly affect lower aberration modes (Piston, Tip, Tilt, Defocus), but possibly higher modes (e.g.: Coma). Also, these perturbations can corrupt the Wavefront Sensor (WFS) path or generate jitter in the laser projection system beacons on the sky, producing the AO system to correct for disturbances that actually have no effect on the science path. Moreover, vibration often occurs at frequency near or beyond the AO Bandwidth, and thus, may be poorly corrected.

This work presents a laboratory validation of a vibration mitigation system of tip-tilt modes using closed-loop control, inducing vibrations on the test bench by a motor with controllable frequency, in order to simulate the mechanical vibrations mentioned above. The tip-tilt aberrations were measured using the centroid position of laser spot. The control action is carried out by a Fast Steering Mirror (FSM).

Finally, we conclude discussing the technological limitations and possible improvements of the demonstration and its implementation on a telescope.

9581-26, Session PMon

Low-loss selective excitation of higher-order modes in a diode-pumped solid-state digital laser

Sandile Ngcobo, Teboho J. Bell, CSIR National Laser Ctr. (South Africa); Kamel Ait-Ameur, Ecole Nationale Supérieure d'Ingenieurs de Caen et Ctr. de Recherche (France); Andrew Forbes, CSIR National Laser Ctr. (South Africa)

In this paper we experimentally demonstrate intra-cavity selective excitation of Higher-Order Laguerre–Gaussian modes with nonzero radial index and zero azimuthal index using a simple absorbing ring implemented on a digital laser. We show selective excitation of modes with radial order of zero to five using a non-segment absorbing rings. We then reduce the losses associated with the absorbing ring by cutting it into segments and then experimentally demonstrate that excited modes using segmented absorbing rings have a lower threshold compared to using a full ring while at the same time maintaining mode volume, purity and slope efficient of the laser.

Conference 9582: Optical System Alignment, Tolerancing, and Verification IX

SPIE. OPTICS+ PHOTONICS OPTICAL ENGINEERING+ APPLICATIONS

Part of Proceedings of SPIE Vol. 9582 Optical System Alignment, Tolerancing, and Verification IX

9582-1, Session 1

New freeform standard in ISO 10110

Sven R. Kiontke, aspericon GmbH (Germany)

For 10 years there has been the asphere as one of the new products to be accepted by the market. All parts of the chain design, production and measurement needed to lear how to treat the asphere and what it is helpful for. The aspherical optical element now is established and accepted as an equal optical element between other as a fast growing part of all the optical elements.

Now we are focusing onto the next new element with a lot of potential, the optical freeform surface. First manufacturing has been show successfully and the ISO 10110 will soon launch four standards helping the industry.

A big part of the ISO results will be shown. There under for instance the description of freeform surfaces, as well as their tolerancing like centration, surface form deviation (irregularity, slope, Zernike, pv, pvr). Furthermore how to analyze the measurement results including some data handling and many more.

9582-2, Session 1

Scanning pupil approach to aspheric surface slope error tolerancing in head-up display optics

Viktor P. Sivokon, Raytheon ELCAN Optical Technologies (Canada)

We present a novel approach to tolerancing slope errors of aspheric surfaces in relay optics of typical avionics head-up displays (HUD). In these systems about 5mm diameter light beam entering the pilot eye occupies only a tiny fraction of HUD entrance pupil/eyebox with typical diameter of 125mm. Consequently the beam footprint on any HUD optical surface is a small fraction of its clear aperture. This presents challenges to HUD tolerancing which is typically based on parallax (angular difference in line of sight between left and right eyes) analysis. Aspheric surfaces manufactured by sub-aperture grinding/polishing techniques inherently have structured residual artifacts and add another source of errors – surface slope errors. This type of error can not only degrade image quality of observed HUD symbology but lead to “waviness” and “floating” especially noticeable when the pilot moves his head within the HUD eyebox. The suggested approach allows tolerancing of aspheric surface slope errors and guarantees acceptable level of symbology “waviness”. Narrow light beam is traced from certain pilot eye position backwards through HUD optics until it hits the light source plane. Due to small beam size slope error of aspheric surface acts primarily as overall tilt/wedge that deviates the beam and causes it to shift. Slope error is acceptable when this shift is less that certain fraction of symbol linewidth. Eye is scanned over entire eyebox and field of view and slope error tolerance is established for several zones in aspheric surface clear aperture. Procedure is then repeated for each aspheric surface.

9582-3, Session 1

The need for fiducials on freeform optical surfaces

Kate Medicus, Jessica D. Nelson, Matthew Brunelle, Optimax Systems, Inc. (United States)

The evolution from spherical, to aspheric, to freeform optics is quickly progressing towards more complex freeform surfaces. Freeform surfaces typically have little to no symmetry making the alignment of the surfaces difficult. The alignment of such freeform surfaces relative to the other features on the optic has been little considered. A typical alignment specification like wedge (edge thickness difference) is not well defined for freeform optics, nor is the wedge measurement. We show that by using fiducials during the manufacturing of freeform surfaces, the alignment and locating of the freeform surface can be specified and measured.

Fiducials are features on the optic that can be accessed during the measurement, manufacturing, and alignment processes. Fiducials can be optical or mechanical features such as flats, spheres, or diameters. Fiducial design and placement must be considered early in the design process to permit fiducial usage during the full manufacturing process. Depending on customer need, the fiducials could be removed after manufacturing is complete or they could remain on the part to assist in the alignment process.

We will show examples of freeform parts made with fiducials that demonstrate the wedge measurement and a measurement of locating two freeform surfaces relative to each other that is not feasible without fiducials. In addition, we will show how using the fiducials will allow us to separate center thickness errors and radius errors of freeform surfaces, which is not feasible without fiducials.

9582-4, Session 1

Tolerancing aspheric surfaces in optical design

Ulrike Fuchs, aspericon GmbH (Germany)

Aspheres are becoming more and more popular in optical design of lens systems. This trend is caused by the demand for reducing size and weight or even novel optical performance, which cannot be obtained with spherical designs only. This demand leads to innovative manufacturing processes for serial production of aspherical surfaces of high quality. Unfortunately, due to the type of surface form deviation introduced by CNC based grinding and polishing processes, tolerancing an optical system with aspherical surfaces becomes very complicated. Especially for serial production it is critical to know just how “good” an asphere has to be in order to guarantee the optical performance needed without overdoing it. Later one is a delicate issue to cost.

Due to the full contact polishing process spheres have surface form deviations, which can be described well with low order Zernike polynomials. Thus, common optical design software can simulate manufacturing tolerances by adding these terms to the optical surface and analyze the change in performance. Polishing aspherical surfaces is always a local process and therefore introduces a whole new type of surface form deviation, which cannot be modeled properly for tolerancing process in common optical design software.

Additionally, tolerancing of aspheres involves a complete new type of surface form deviation – slope errors. As one can imagine, depending on the slope errors introduced, this can make all the difference in performance, especially when wavefront quality is a criteria. It will be demonstrated how to overcome this limitation up to a certain level.

9582-5, Session 2

Slope sensitivities for optical surfaces

John R. Rogers, Synopsys, Inc. (United States)

Setting a tolerance for the slope errors of an optical surface (e.g., surface form errors of the “mid-spatial-frequencies”) requires some knowledge of how those surface errors affect the final image of the system. While excellent tools exist for simulating those effects on a surface-by-surface basis, considerable insight may be gained by examining, for each surface, a simple sensitivity parameter that relates the slope error on the surface to the ray displacement at the final image plane.

Snell’s law gives a relationship between the slope errors of a surface and

the angular deviations of the rays emerging from the surface. For a singlet or a thin doublet acting by itself, these angular deviations are related to ray deviations at the image plane by the focal length of the lens. However, for optical surfaces inside an optical system having a substantial axial extent, the focal length of the system is not the correct multiplier, as the sensitivity is influenced by the optical surfaces that follow.

In this paper, a simple expression is derived that relates the slope errors at an arbitrary optical surface to the ray deviation at the image plane. This expression is experimentally verified by comparison to a real-ray perturbation analysis. The sensitivity parameter relates the RMS slope errors to the RMS spot radius, and also relates the peak slope error to the 100% spot radius, and may be used to create an RSS error budget for slope error. Application to various types of system are shown and discussed.

9582-6, Session 2

Tolerance analysis of optical systems using the Nijboer-Zernike approach *(Invited Paper)*

Marco Hanft, Carl Zeiss AG (Germany)

Optical systems are designed to provide a specific functionality. The system is defined by the characteristic and location of its surfaces. Based on ray tracing and analysis routines (e.g. PSF or MTF) we know the performance of an optical system. But an built optical system will show some deviation from the nominal performance. Every component and assembling them will deviate from the original description. Tolerances are defined to control deviations caused by manufacturing process. The sensitivity analysis considers the influence of each tolerance to the performance of the optical system. In many cases the wave front itself can be used to describe the system performance. This talk will demonstrate the tolerance process using Nijboer-Zernike polynomials as expression for wave front aberrations. Nijboer-Zernike polynomials are a special form of well-known circle polynomials developed by Zernike. They are orthogonal and have an automatic balancing of aberrations of various orders. The degradation of the Strehl Ratio can be estimated very easily for every single aberration using the value of the specific coefficient. This property is very beneficial for the definition of a tolerance budget. Furthermore a sensitivity analysis with Nijboer-Zernike approach is a very clear basis to choose compensators for the alignment.

The talk will show the following steps on exemplary systems:

- Analysis with initial tolerances,
- Choice of compensators,
- Relaxation or tightening of tolerances,
- Final error budget and adjustment proposal.

9582-7, Session 2

Design and tolerance analysis of a transmission sphere by interferometer model

Wei-Jei Peng, Cheng-Fong Ho, Wen-Lung Lin, Zong-Ru Yu, Chien-Yao Huang, Wei-Yao Hsu, Instrument Technology Research Ctr. (Taiwan)

The design of a 6-in, f/2.2 transmission sphere for Fizeau interferometry is presented. To predict the actual performance during design phase, we build an interferometer model combined with tolerance analysis in Zemax. The transmission sphere belongs to double-pass system, it's not enough to only evaluate focus imaging. Thus, we study the interferometer model that includes system error, wavefronts reflected from reference surface and tested surface. Firstly, we generate a deformation map of the tested surface. Because of multiple configurations in Zemax, we can get the test wavefront and the reference wavefront reflected from the tested spherical surface and reference surface of transmission sphere respectively. According to the theory of interferometry, we subtract both wavefront to acquire the phase of tested surface. Zernike polynomial is applied to transfer the map from phase to sag and to remove piston, tilt and power. The result is the same as original map; because of no system error exists. Secondly, tolerances including fabrication of lenses and assembly are considered. The system error occurs because the test and reference beam are no longer common path perfectly . The calculated map is inaccurate while the system error is added. Although the system error can be subtracted by calibration, it should be controlled within a small range to avoid calibration error. Generally the system error of 6-in transmission sphere is measured within peak-to-valley (PV) 0.1? (?=0.6328 um), which is not easy to approach. Consequently, it's necessary and worth to evaluate the system error before fabrication. Finally, a prototype is developed and tested by a reference spherical surface with PV less than 0.1? irregularity.

9582-8, Session 3

Characterization of cryo-vacuum chamber windows for NIRCam instrument alignment and testing

Paul F. Schweiger, Torben B. Andersen, Lockheed Martin Space Systems Co. (United States)

The Near Infrared Camera (NIRCam) instrument used to align and obtain science data for NASA's James Webb Space Telescope (JWST) was tested at the module level at flight-like cryogenic temperature. This paper explains the innovative techniques used to measure the precise location and orientation of the modules. A laser tracker was used to precision locate the instrument, using a flat reference mirror/reticle surface on the modules inside a chamber through its port windows. This technique established 5 degrees of freedom of position and orientation. The accuracy achieved was on the order of 20 microns in position and 5 arc-seconds in angular orientation.

9582-9, Session 3

Measuring NIRCam's position and orientation in 6 DOF using one reference mirror surface inside an environmental chamber

Paul F. Schweiger, Torben B. Andersen, Lockheed Martin Space Systems Co. (United States)

The Near Infrared Camera (NIRCam) instrument used to align and obtain science data for NASA's James Webb Space Telescope (JWST) was tested at the module level at flight-like cryogenic temperature. This paper explains the background that created the innovative techniques used to measure NIRCam's modules alignments in 6 degrees of freedom (DOF) inside a thermal vacuum chamber. All 6 DOF were measured remotely, through a single chamber window port, using only a flat reference mirror/reticle surface mounted on each module. This measured orientation was then used to determine the optical input axis and entrance pupil for each module. The accuracy achieved was on the order of 20 microns in position and 5 arc seconds in angular orientation.

9582-10, Session 3

Dynamic alignment, tolerances, and metrology fundamentals at the nano and micro scales *(Invited Paper)*

Donn M. Silberman, PI (Physik Instrumente) L.P. (United States)

Although the terms "micropositioning" and "nanopositioning" refer to different classes of positioning systems, "nanopositioning" is often used mistakenly to describe micropositioning systems. Micropositioning systems

are typically motor-driven stages with travel ranges of a few millimeters up to a few hundred millimeters. Because the guiding systems in such stages — usually bearings of some kind — generate frictional forces, their resolution and repeatability are typically limited to 0.1 μm. The guiding system working principle also adds errors that are typically in the micrometer range. Nanopositioning systems are typically based on frictionless drives and guiding systems such as piezo actuators and flexures. These systems can achieve resolutions and guiding accuracies down to the sub-nanometer level.

Both of these classes of precision positioning and motion systems are used extensively in precision optical and photonic systems to achieve desired performance specifications of instruments and experimental research projects. Currently, many precision positioning and motion systems have been design and implemented to cross over from the micro to the nano ranges with excellent results. This paper will describe some of the fundamental performance parameters and tolerances typical of these systems, some of the metrology used to confirm specifications and a few high end applications of general interest.

9582-11, Session 3

1um adjustment-tolerance for high-precision helical laser drilling

Frank Zibner, Christian Fornaroli, Arnold Gillner, Jens Holtkamp, Fraunhofer-Institut für Lasertechnik (Germany)

High-precision micro laser drilling with high aspect ratios requires laser imaging effects such as optical double rotation. Optical double rotation is an effect where the laser beam is guided through any optical elements with a total amount of reflections that remains uneven. Those optical elements need to be mounted in a rotary stage that spins the elements with a certain velocity. In an ideal case the optical axis is identically with the rotational axis. Few optical elements such as the Dove-prism show the effect that the beam is rotated in itself while it is moving on a helical path. That offers an independency of the beam profile. However the Dove-prism alone can not be adjusted in a way that the two axis match. This is based on geometrical errors of the Dove-prism due to manufacturing technologies. Certain deviation in length and angle lead to a helical error. Additional optical elements can compensate this effect. Alignment that only takes place in one 2D plane (e.g. the focal plane) leads most likely to a cross-over of both axes (x-alignment) in that one plane. In order to match both axes the alignment needs to be done at least in two 2D planes. That requires the opportunity to both influence the optical angle and the optical position (parallel shift) in both planes. The highly complex optical alignment method as well as the mechanical storage of the optical elements will be shown in this paper. Additionally an alternative system based on a Smidt-Pechan-prism will be presented where its alignment requires precise placement of the prisms to each other.

9582-13, Session 4

State estimation in optical system alignment using monochromatic beam imaging

Joyce Fang, Dmitry Savransky, Cornell Univ. (United States)

Automated alignment of optical systems saves the time and energy needed for manual alignment and is required in cases where manual intervention is impossible. This research discusses the state estimation of the misalignment of a reimaging system using a focal plane sensor. We control multiple moving lenses and achieve high precision alignments by feeding back state estimates calculated from images from a CCD camera. A batch estimator and a Kalman filter are used to estimate the misalignment of the lenses, and we describe a closed-loop control experiment with monochromatic laser light to demonstrate the performance of the state estimation process. The result of using a Kalman filter converges to the misalignment parameters obtained from a batch estimator. The efficiency and accuracy of both methods is compared and discussed. Moving the lenses independently allows us to break degeneracies in the effects of misalignments of two lenses. The automated alignment technique can be extended to reconfigurable systems with multiple lenses and other optical components.

9582-14, Session 4

Alignment estimation performance analysis of new MDCO algorithm for a TMA optical system

Hyukmo Kang, Yonsei Univ. (Korea, Republic of); Eunsong Oh, Korea Institute of Ocean Science & Technology (Korea, Republic of); Sug-Whan Kim, Yonsei Univ. (Korea, Republic of)

In this study, we studied alignment state estimation simulations and compared the performance between two CAA algorithms i.e. 'Merit function regression (MFR)' and 'Multiple design configuration optimization (MDCO).' The former minimizes the merit function using multi-field wavefront error measurements from single configuration, while the latter minimizes the merit function using single-field wavefront error measurements from multi configurations. The target optical system used is an unobscured three-mirror anastigmat (TMA) optical system of 70mm in diameter, and F/5.0 designed for an unmanned aerial vehicle for coastal water remote sensing. The TMA consists of two aspherical mirrors (concave primary mirror, M1, and convex secondary mirror, M2), and one spherical mirror (tertiary mirror, M3) designated as the compensator. Because of its spherical mirror characteristic of M3, we used two degrees of freedom of M3 (tilt X, tilt Y) to compensate wavefront error. For the simulation, we defined deliberate misalignment to M3 (decenter X, Y: 0.1mm, tilt X, Y: 0.06mrad), and it is five times larger than the assembly tolerance of 0.02mm in decenter X, Y, and 0.12mrad in tilt X, Y. After one alignment simulation step, both algorithms can meet the alignment requirement (1/15? RMS wavefront error at 633nm) without further iteration. Both algorithms are similar in terms of alignment state estimation performance. However, MDCO is more practical than MFR as it requires for single-field wavefront error measurements only. Using MDCO, we then investigated how the misalignments of M1 and M2, the surface fabrication error, the wavefront measurement uncertainty, and the control uncertainty can affect alignment estimation performance. The computational details and simulation results are presented together with implications.

9582-15, Session 4

Alignment state estimation performance of Merit Function Regression(MFR) method under mirror fabrication error

Dongok Ryu, Sug-Whan Kim, Yonsei Univ. (Korea, Republic of)

We report alignment state estimation of compact and high performance optical instrument that is disturbed by fabrication uncertainty; i.e. power, astigmatism and other low-order fabrication errors. Even high-order terms are likely to cause uncertainty in tight error budget condition. In this study, we simulated alignment state estimation for a hypothetic 3 mirror F/10 Korch-type telescope with 800mm aperture. The Merit Function Regression (MFR) method determined alignment state estimation for 2 cases of fabrication statements. The first is designed condition which denoted no fabrication error. The case 2 used increasing surface errors up to 1/10 lambda with randomly generated Zernike polynomials which terms from 4th to 37th. The 1000 times statistic result calculations of alignment state estimation are represented and compared with no error case. The detailed progress, simulations and implications are presented together with input fabrication errors and alignment state estimation solutions.

9582-20, Session 4

Disruptive advancement in precision lens mounting

Frédéric Lamontagne, Nichola Desnoyers, Michel Doucet, Patrice Côté, Jonny Gauvin, Geneviève Anctil, INO (Canada)

No Abstract Available

9582-16, Session PMon

Analysis of alignment tolerance of focal plane assembly of a telescope

Shenq-Tsong Chang, Yu-Chuan Lin, Ming-Ying Hsu, Ting-Ming Huang, Fong-Zhi Chen, Instrument Technology Research Ctr. (Taiwan)

Focal plane assembly (FPA) is an important component for modern remote sensing instruments. Array or linear CCD or CMOS detectors are usually applied. Linear detectors are often used in the space project to have a wider swath. In a remote-sensing project, five spectral ranges are desired. The spectral ranges are designated to be Panchromatic (450-700 nm), B1 (455-515 nm), B2 (525-595 nm), B3 (630-690 nm), and B4 (765-900 nm). Pixel size of the Panchromatic band (Pan) is 10 ?m, and those for B1~B4 (multi-spectral, MS) are 20 ?m. Pixel numbers are 12000 and 6000 for Pan band and MS bands, respectively. The FPA is consisted of a filter with five stripe band-pass thin films, filter mask and a five-line detector. The arrangement of the detector is B1, B2, Pan, B3 and B4 from the top to the bottom. In order to give the alignment tolerance, an analysis of the parameters of each component in FPA has been performed. Ray tracing method has been applied to have a image projection onto the plane where thin films are located. Spread sheet computation was adopted to simulate the situations when the design parameters were changed. According to the analysis, some supplement wideness to the stripe thin films has to be added to have a satisfied alignment tolerance.

9582-17, Session PMon

An optomechanical tolerance simulation for a four-group zoom lens

Chen-Chin Cheng, Industrial Technology Research Institute (Taiwan); John D. Griffith, Moondog Optics, Inc. (United States)

The zoom lens is a typical optical system. In general, opto-mechanical design plays as important role as optical design does in the optical system design. The results of optical tolerance analysis of a zoom lens carried out by optical design software usually consist of the tolerance budgets of lens tilt, lens decenter, lens position, group tilt, group decenter, grout position and image sensor tilt. However, in real world these tolerance budgets are achieved by lens fabrication process, mechanical design, mechanical manufacturing process, and assembly sequence. Mechanical engineer must consider the capabilities of a real manufacturing process and variations caused by the tolerances of optical and mechanical components that occur in the assembly process. Only when the components and assembly variations are calculated and simulated, can the performance of a zoom lens be predicted. In this study, an opto-mechanical tolerance simulation was implemented by VSA-3D? software to calculate the tilt, decenter and despace of the lens elements and groups of a four-group zoom lens. The simulation was carried out by Monte Carlo method and the results were conducted by descriptive statistics. The results indicate that the tolerance budgets of a zoom lens requested by optical designer can be verified through the manufacturing variations of lenses, mechanical parts, and assembly method. As a result, the performance of a zoom lens system can be predicted before mass production.

9582-18, Session PMon

Development of a FSMP mirror assembly

Jihun Kim, Young-Soo Kim, Je Heon Song, Korea Astronomy and Space Science Institute (Korea, Republic of); Myung Cho, National Optical Astronomy Observatory (United States); Ho-Soon Yang, Joohyung Lee, Korea Research Institute of Standards and Science (Korea, Republic of); Ho-Sang Kim, Kyoung-Don Lee, Institute for Advanced Engineering (Korea, Republic of); Won Hyun Park, National Optical Astronomy Observatory (United States) and The Univ. of Arizona (United States); Byeong-Gon Park, Korea Astronomy and Space Science Institute (Korea, Republic of)

Fast-steering Secondary Mirror Prototype (FSMP) of the Giant Magellan Telescope (GMT) has been developed by the consortium consisting of institutes in Korea and the US. In 2014 we have finalized the FSMP project by combining two sub-systems, the mirror fabricated by Korea Research Institute of Standards and Science (KRISS) and the mirror cell with tip-tilt controlling system developed by Institute for Advanced Engineering (IAE), in the KRISS facility. We have developed an assembly procedure in which we have identified potential difficulties such as handling without contacting mirror surface, optimizing bonding process, and elsewhere. As the solutions of the difficulties we developed supporting jigs and optimized bonding procedures. The assembled FSMP system was installed in the test tower in KRISS, and we confirmed the stability of the system. For the future works, the performance of FSMP system will be evaluated in static and dynamic environments for the validation of the FSMP system operation.

9582-19, Session PMon

Multiple sensor fusion into a single optical instrument

Oren Aharon, Duma Optronics Ltd. (Israel); Itai Vishnia, PLX Inc. (United States)

The reality of accurate optical measurements is that instruments are tailored to specific applications, resulting in the need for multiple devices in order to perform a system characterization. Many applications require the use of multiple optical elements in combination with laser beams and optical axis orientations. These applications dictate a need for a better integrative measurement tool. For example, the Electronic Autocollimator is a high precision angle measurement instrument, capable of measuring angle deviations with sub arc second accuracies. However it lacks the capability of measuring optical axis deviations, as well as comparing angle deviations from laser beam directions. This article presents a sensor fusion technology that combines the power of accurate electronics and optics into a measuring instrument. This allows performing electronic auto-collimation, laser beam characterization, laser alignment to mechanical and optical axis, and many more. Specifically, by providing the new instrument with a cooperative reflective target, additional characteristics are feasible, such as optical line deviation measurement, distances to target and remote examination of parts. An integral part of the process is the integration of Monolithic Optical Structure Technology, which allows for much greater stability, resulting in greater accuracy. This new fusion sensor technology substantially increases lab measurement capabilities, offering intricate measurements to be performed on lasers, high-power laser beams, mechanical datum stability and alignment with one single instrument.

Conference 9583: An Optical Believe It or Not: Key Lessons Learned IV

Monday 10–10 August 2015

Part of Proceedings of SPIE Vol. 9583 An Optical Believe It or Not: Key Lessons Learned IV

9583-1, Session 1

Why most strategic plans don't work

Robert W. Bradford, Ctr. for Simplified Strategic Planning, Inc. (United States)

Are you thinking strategically – or just going through the motions? Robert will discuss where he has seen plans go awry and how you can get more out of your planning process.

9583-2, Session 1

Acquisitions: 8 steps to success

Denise A Harrison, Spex, Inc.; Strategic Planning and Execution (United States)

Often companies try and grow from within – when should you look outside? What are some pitfalls that can be prevented as you look to the outside to complement your company's internal capabilities?

9583-3, Session 1

Everyone knows execution is important: so why do we fail to execute?

Robert W. Bradford, Ctr. for Simplified Strategic Planning, Inc. (United States); Denise A. Harrison, Spex, Inc. (United States)

Developing the strategy comes first. Implementing it in the organization is the real challenge. What causes execution train wrecks and how can you prevent them? Robert and Denise will present their findings based on their experience working with hundreds of companies.

9583-4, Session 1

Lessons learned in aligning an organization: two-way communication is key

Denise A Harrison, Strategic Planning and Execution; Spex, Inc. (United States)

Do you ever have the feeling that you aren't getting through to your employees? Listen to how this CEO found that she wasn't communicating to her employees and how she turned the situation around.

9583-5, Session 2

They never said anything about this in school: lessons from the engineering front line

Jonathan W. Arenberg, Northrop Grumman Aerospace Systems (United States)

Engineering cutting edge systems is simultaneously, a fulfilling intellectual endeavor and a contact team sport. Creating and managing a fun and successful career requires more than simply course work. This talk will present the top missing lessons learned by the author, gleaned from several decades of experience learning it the hard way.

9583-6, Session 2

Root cause analysis: shutting down the alligator farm

Anthony J. DeMarinis, Consultant (United States)

Many companies realize the importance or root cause analysis and correcting problems. However, there is still much confusion and many problems continue to recur.

Inadequate Failure Investigation, Recurring Problems and Inadequate Documentation are often cited by auditors, and many presentations focus on the regulatory requirements and how to do and document these investigations. However, few focus on the environmental and cultural factors that prevent people from seeing and addressing the true root cause in the systems that enable and spawn these problems. This presentation addresses those barriers to real root cause analysis and enables the participant to see and overcome these barriers during their investigation activities. We will use thoughtful discussion and humorous analogies to distinguish between the true root cause and other common imposters. Emphasis will be placed on realizing system interactions and the cultural environment that often lies at the root of the problem and prevents true root cause analysis, and we will include concepts and practical advice on how to identify cultural and environmental obstacles to root cause analysis and organizational improvement. It will also review the basic tools and analytical methods needed to objectively identify the true root cause and prevent recurrence.

9583-20, Session 2

What do you do when your critical to quality features (CTQs) turn into what the flig (is happening)!? (WTFs) *(Invited Paper)*

Lance B Coleman, Full Moon Consulting (United States)

At the heart of every lean, six sigma and continuous improvement project is one thing – root cause analysis. Root cause analysis can be used to determine why a process is not performing as expected, or to determine significant factors that may lead to process improvement. Conversely, faulty root cause analysis is often the reason why problems keep occurring over and over again and why continuous improvement sometimes seems an elusive concept at best. This session will teach attendees how to accurately determine root cause as a first step in implementing effective improvement initiatives, capturing lessons learned and mitigating risk.

When analyzing complex processes, potential root causes can be identified through root cause analysis (RCA) and then Design of Experiments (DOE) or General Linear Modeling (GLM) can be used to determine the truly significant input factors to a process. Alternatively, once a significant factor has been determined through use of DOE or GLM, then RCA can be performed to help determine why the factor is significant. Whether you utilize RCA before or after DOE or GLM, the offshoot of the RCA process is to use the information discovered to create effective preventative, corrective, and/or improvement actions.

Key takeaways are:

- Learning how RCA is interconnected with both continuous improvement and risk management
- Determining root cause – tools and methods – 5WHYs, Ishikawa Diagrams, IS/IS NOT
- Effective RCA training methods
- Using root cause analysis to capture lessons learned
- Understanding the root cause analysis and corrective action process

9583-7, Session 3

Lessons learned over the last thirty years

Richard C. Juergens, Raytheon Missile Systems (United States)

This talk discusses some mistakes, goofs, and misjudgments I have come across over the last thirty years, and the lessons learned from them. The experiences cover several different disciplines, including optical design and engineering, stray light, and polarization issues, and includes both design and hardware examples.

9583-8, Session 3

Lessons not to make light of (when designing optical systems for space)

Stephen E. Kendrick, Consultant (United States)

There is a range of lessons learned when taking an optical system from design through deployment in space. I will summarize some key lessons and observations related to both airborne and spaceborne optical systems with an emphasis on lightweighted optics and space telescopes. Areas discussed encompass 1) the initial architecture and system trades as constrained by system error budgets, 2) manufacturing considerations, 3) testing implications, and 4) real and perceived cost impacts.

9583-9, Session 3

Requirements management lessons learned: fuzzy “most likely” versus clean shaven “not to exceed”

Paul A. Lightsey, Ball Aerospace & Technologies Corp. (United States)

Mission objectives often have a level of imprecision that lends itself to a fuzzy logic approach, even though the more traditional approach is to flow down bimodal pass/fail “not to exceed” type of requirements. Examples will be given for large astronomical telescope applications involving optical performance, active wave front and control, and radiometric/stray light controls demonstrating the pros and cons of the two contrasting strategies.

9583-11, Session 3

How to raise a teenage instrument: building and flying the Orbiting Carbon Observatory-2 (OCO-2)

David Crisp, Jet Propulsion Lab. (United States)

The NASA Orbiting Carbon Observatory-2 carries a 3-channel imaging grating spectrometer that was designed to make space based measurements of atmospheric carbon dioxide with unprecedented precision, accuracy, resolution, and coverage. When embarking on the development of a high performance flight instrument of this kind, it is always best practice to limit risk, to the extent possible, by adopting (and freezing) a conservative design based on high heritage parts, with ample cost, schedule, and performance margins. What happens when those practices encounter the reality of a highly competitive, cost-capped opportunity embedded in a rapidly evolving programmatic environment characterized by funding delays, team changes, delivery delays, performance shortfalls, and obsolescence of “high heritage” parts, and ever growing expectations for the instrument’s performance from your customers in the science community and beyond? Is it possible to deliver and operate an instrument, 14 years after it was conceived, which still exceeds its requirements and redefines the state of the art in spite of a few quirks and idiosyncratic features? Somehow, we managed to surmount these and other hurdles and deliver and launch OCO-2, a NASA Earth Science mission that is now collecting hundreds of thousands of precise carbon dioxide measurements over the sunlit hemisphere of the Earth each day. Here, I will summarize a few of the key technical challenges, frustrations, and surprises encountered on this long odyssey, and try to remember how we got through it all.

9583-12, Session 3

The beam rotation that almost was in the National Ignition Facility

R. Edward English Jr., L-3/Cincinnati Electronics (United States) and REE Optical Systems, LLC (United States)

How might an optical design change in the final optics assembly couple with the spherical geometry required for beam delivery to the target chamber to cause the 40 cm beam to be rotated by more than several design teams had thought, and not be discovered until the final design stage for the beam enclosure and structures?

9583-13, Session 3

Four big mistakes in developing photonics-enabled medical devices

David Hill, Krista McEuen, Zygo Corporation (United States)

Photonics components have become key enablers in the design and development of next-generation medical devices and diagnostics. This trend has its roots in mature imaging technologies like optical microscopy and endoscopy/colonoscopy, and is poised to accelerate through emerging applications such as optogenetics, laser ablation therapy, and optical coherence tomography (OCT), among many others. This white paper identifies four of the most common mistakes we see medical device manufacturers make when attempting to incorporate optics and photonics into their designs — and how to avoid them.

9583-10, Session 4

The art of planning for optical systems integration and alignment

Joseph F. Sullivan, Ball Aerospace & Technologies Corp. (United States)

This will address Lessons Learned on the approaches that worked or did not work over various programs when integrating and aligning elements into fairly complex optical systems. The appropriate planning can prevent many unnecessary headaches and achieve the desired optical performance while optimizing integration efficiency.

9583-15, Session 4

Trials and tribulations of optical manufacturing: asphere edition *(Invited Paper)*

Gregory Frisch, Kate Medicus, Mark E. Schickler, Brandon B. Light, Jessica DeGroote Nelson, Optimax Systems, Inc. (United States)

With the ongoing advancements in aspheric manufacturing and metrology, companies have to overcome processing challenges and from time to time learn costly lessons along the way. Optimax Systems, Inc., a leader in quick delivery prototype optics, has been manufacturing aspheric lenses for over

20 years. Along the way, we have learned many lessons, some the hard way. In this paper, I will share a few stories of how aspheres have humbled us, how we overcame the problem, and provide takeaways for other manufactures and designers.

9583-16, Session 4

Polarimeter calibration error gets far out of control

Russell A. Chipman, College of Optical Sciences, The Univ. of Arizona (United States)

This is a sad story about a polarization calibration error gone amuck. A simple laboratory mistake was mistaken for a new phenomena. Aggressive management did their job and sold the fictitious idea very effectively and substantial funding followed. Questions were raised and a Government lab tried to recreate the breakthrough. The results were unpleasant and the field developed a bad reputation for several years.

9583-17, Session 4

A quintuple of painful lessons from surface inspection to high-speed imaging

Cornelius F. Hahlweg, bbw Hochschule (Germany); Cornelia Weyer, G&S Gesundheit für Betriebe GmbH (Germany)

The paper delivers interesting short stories from about two decades of research and development in the field of surface inspection, hyper spectral imaging, high speed techniques and endoscopy. The papers covers problems with an import restricted SWIR sensor, which turned out to be creatively calibrated, the repeatedly ignored need for IR filters, the self-sustaining diffraction order, if you don't understand it ... shoot it - visualization plans which ended up at the Shooting range, and the desire for substituting filament bulbs in colorimetry. From todays point of view a set tirivialities, at their time thwarting factors of monstrous dimension, the problems discussed are squezed into short chapters, which hopefully will be good for some fun without unnecessary lengthy elaboration. The presentation will contain exemplary footage and visualization.

9583-18, Session 4

From SDI to tactical battlefield lasers: myths, legends, and facts. Reflections of a "Star Warrior"

James A. Horkovich, Schafer Corp. (United States)

This talk presents a history of missile defense and the "Star Wars" program and its' evolution to today's tactical battlefield laser systems, marking the 30th anniversary of President Ronald Reagan's "Star Wars" speech. Since Archimedes' "Burning Glass" at the siege of Syracuse 212 B.C. through the development of the LASER man has been fascinated with the idea of using directed energy weapons. But nothing did more to focus this effort than the threat posed by Mutually Assured Destruction. Under Reagan's "Star Wars" plan years and billions of dollars were invested in making high energy laser systems a reality. This presentation reviews the fundamentals of laser physics and traces the development of these systems in the USA, the USSR, and across the world from the Gas Dynamic LASER laboratory in the 1960s and the USAF Airborne Laser Laboratory of 1981 through the SDI era and up to today. In reflecting on the effort invested in developing this technology, this interdisciplinary talk addresses the role that this technology played in changing the geopolitical state of the cold war and continues to play in international defense efforts today.

9583-19, Session 5

The sage on the stage - and the audience is texting

Judith F. Donnelly, Three Rivers Community College (United States)

As it is, the professors give too many lectures and the students listen to too many. Or pretend to; really they do not listen, however attentive and orderly they may be. ... They reproduce the lecture in recitations like the phonograph, mechanically and faithfully, but with the tempo and timbre so changed that the speaker would like to disown his remarks if he could. (Slossen, 1910)

Conference 9584: Ultrafast Nonlinear Imaging and Spectroscopy III

SPIE. OPTICS+ PHOTONICS OPTICAL ENGINEERING+ APPLICATIONS

Sunday - Monday 9 –10 August 2015

Part of Proceedings of SPIE Vol. 9584 Ultrafast Nonlinear Imaging and Spectroscopy III

9584-1, Session 1

A beamline for attosecond pump-probe experiments: Mapping ultrafast electron dynamics in atoms and molecules

Emma R. Simpson, Simon E. E. Hutchinson, Thomas Siegel, Zsolt Diveki, Alvaro Sanchez-Gonzalez, Christian S. Struber, Lukas Miseikis, Dane R. Austin, Jon P. Marangos, Imperial College London (United Kingdom)

We present a versatile beamline for attosecond pump-probe experiments using the techniques of attosecond transient absorption spectroscopy (ATAS) and extreme ultra-violet (XUV) initiated high harmonic generation (XiHHG) to probe ultrafast electron dynamics on the attosecond timescale. Utilising a non-colinear geometry we split our incident beam into two arms, one of which generates high harmonics that can act as either the pump or the probe. A controllable delay is introduced between the two arms using a voltage-controlled piezo. The non-colinear pump-probe arrangement enables individual control over the parameters of each arm such as intensity, polarisation and ellipticity allowing these variables to be scanned as functions of delay. The recombined pump and probe arms are re-imaged in an interaction chamber using a toroidal mirror before a flat-field spectrometer with micro-channel plate (MCP) and camera assembly to detect and record the resultant harmonics.

Preliminary results from ATAS in laser dressed helium indicate we can achieve a temporal resolution better than 250as between the pump and probe arms through the use of post-processing temporal correction to account for long-term thermal drifts in the system. Delay-dependent modulations in the absorption for both the above and below ionisation potential (Ip) harmonics at even multiples of the driving field wavelength have been observed and the results are in the process of being analysed. Using a commercial optical parametric amplifier (OPA) we are extending our driving wavelength to access higher ponderomotive energy in order to look for XiHHG and ATAS from 3d ionisation in Krypton (around 93eV).

9584-2, Session 1

Ultrafast electron diffraction from laser-aligned carbon disulfide molecules *(Invited Paper)*

Jie Yang, Martin Centurion, Univ. of Nebraska-Lincoln (United States)

In conventional gas-phase electron diffraction (GED), only one-dimensional structural information can be accessed due to the random orientation of molecules in the gas phase. The method ultrafast electron diffraction from laser-aligned molecules (UEDAM) can resolve the three-dimensional molecular structure with atomic resolution. Previously, we have used this method to image the structure of the ground state of the CF3I molecule. In this work, we use UEDAM to investigate the dynamics of carbon disulfide (CS2) molecules following the interaction with an intense femtosecond IR laser pulse. Two-dimensional molecular images with atomic resolution are recorded under different laser intensities. An upper limit of degree of alignment is found with the increase of laser intensity. At higher intensity, structural deformation and dissociation are observed. We have found a diffraction-difference method that allows us to access only the 3% most aligned molecules. With this method, we're able to measure the atomic positions in transient state structures with 0.03Å precision and 1ps temporal resolution. This proof-of-principle work demonstrates the capability of studying molecular dynamics with high spatial and temporal resolution using UEDAM.

9584-3, Session 1

Imaging molecules with sub-angstrom resolution using femtosecond electron pulses *(Invited Paper)*

Omid Zandi, Univ. of Nebraska-Lincoln (United States); Alice DeSimone, Kyle Wilkin, Jie Yang, Martin Centurion, Univ. of Nebraska-Lincoln (United States)

Ultrafast electron diffraction can provide time resolved images of molecules with atomic resolution. In this talk, we will present recent results on ultrafast imaging of molecules and describe recent improvements in sources and new experimental setups designed to reach femtosecond temporal resolution. In particular, a photoelectron gun coupled with an RF cavity has been implemented to compress 100 keV electron pulses. The duration of the electron pulses is measured in-situ using a streak camera that can reach a resolution of 200 fs. Even with short electron pulses, the resolution in gas phase experiments can be degraded by the fact that laser and electron pulse traverse the sample with different velocities. We use a tilted laser pulse to match the velocity of the sub-relativistic electrons as they traverse the sample. Other approaches to achieve femtosecond resolution are to use relativistic electron pulses with MeV energy that minimize the effect of velocity mismatch. These can be generated with RF electron guns or with laser-accelerated electrons.

9584-4, Session 1

Transient chromatic aberrations at discrete energies in ultrafast electron microscopy *(Invited Paper)*

David J. Flannigan, Dayne A. Plemmons, Univ. of Minnesota, Twin Cities (United States)

In ultrafast electron microscopy (UEM), extension of the capabilities of transmission electron microscopy to the ultrafast domain allows for visualization of non-equilibrium structural and electronic phenomena. The operating principle of UEM requires spatiotemporal overlap of the fs photon pulse and electron packet at the specimen. At time zero, photon absorption by the electrons occurs, and peaks at integer multiples of the photon energy can be observed in electron-energy spectra. In this talk, I will discuss considerations for isolating inherent artifacts of the highly non-linear near-field interactions from the actual packet characteristics. Using theory developed to describe these interactions, I will discuss how temporal cross sections of peaks in the electron-energy spectra corresponding to high-order transitions are expected to exhibit the true temporal behavior of the electron packets. The portion of the pump laser pulse capable of initiating such transitions results in temporal widths converging to the electron packet duration. Additionally, photon absorption by electrons focused on the edge of a nanostructure suggests the resulting energy distribution may produce well-defined chromatic aberrations in bright-field images arising from the velocity dependence of the Lorentz force. I will discuss the prospect for detecting these discrete aberrations and their potential as a means of determining the UEM instrument response without the need for a spectrometer. Appropriate interpretation of observed spectroscopic and image features should in principle enable systematic temporal and spatial deconvolution allowing for a more accurate depiction of intrinsic ultrafast dynamics, especially as UEM capabilities advance toward angstrom-scale, real-space fs imaging.

9584-5, Session 1

Ultrafast probe using femtosecond electron pulses *(Invited Paper)*

Jianming Cao, Florida State Univ. (United States)

In recent years, femtosecond electron pulses have emerged as a powerful tool to probe ultrafast dynamics in matter. They have been used in ultrafast diffraction to reveal the atomic-detail structural dynamics in real time, covering a wide range of applications such as monitoring phase transitions in physics and materials science, and examining dynamics of reactions in chemistry and biology. They have also been used in ultrafast electron shadow imaging and deflection measurement to monitor the transient electron field and plasma dynamics. In this talk, I will focus on the development of ultrafast electron probe and its application in our research group. The topics will cover the mechanism of coherent phonon generation, ultrafast photo-induced demagnetization in ferromagnetic materials, photo-induced phase transition in correlated electron materials and the dynamics of warm dense matter.

9584-6, Session 1

MeV ultrafast electron diffraction and imaging at SLAC *(Invited Paper)*

Xijie Wang, SLAC National Accelerator Lab. (United States)

The SLAC UED&UEM facility will take advantage of the recent developments in high-brightness ultrafast electron sources, high-field magnets and electron detection. It will provide direct access to atomic coordinates with temporal resolution down to 100 fs and even below in the diffraction (UED) mode. The ultrafast imaging capabilities of the SLAC UEM will represent a paradigm shift compared to present day facilities, and it can achieve 10-nanometer and 10-picosecond resolution in single-shot mode. To realize high temporal resolution required for the SLAC UED&UEM facility, a MeV high-brightness electron beam generated by a photocathode RF gun will be employed. This allows more electrons to be packed into each bunch, offering single-shot capabilities similar to those of x-rays from LCLS. A further important advantage of relativistic beams is that they eliminate the velocity mismatch between the electromagnetic pump pulses and the electron probe beam. This mismatch limits the time resolution of ultrafast dynamics for dilute samples, such as gas and liquid samples. In addition to the higher temporal resolution, MeV electrons can penetrate thicker samples. Finally, the higher electron beam energy leads to a larger elastic scattering cross section and a decrease in the inelastic scattering cross sections, increasing the diffraction signal and reducing inelastic scattering.

9584-7, Session 2

True surface spectra from sum-frequency vibrational spectroscopy of nonpolar media *(Invited Paper)*

Chuanshan Tian, Fudan Univ. (China)

In the past decades, sum-frequency vibrational spectroscopy (SFVS) has been well established as a powerful technique for surface studies. It is based on the idea that under the electric dipole (ED) approximation, SF generation originates only from the surface or interface where the inversion symmetry is broken. There is, however, always a lingering doubt that the electric-quadrupole (EQ) bulk contribution to surface SF generation may not be negligible. The problem is particularly important for SFVS application to media that do not have a surface layer of strongly polar-oriented molecules, although it has been largely ignored by many practitioners of SFVS. Despite many theoretical and experimental studies in the past, a comprehensive picture supported by experiment is still missing.

Following our theoretical understanding, we designed an experiment and used benzene as an example to show that for the first time, we can separately obtain EQ bulk spectra and surface spectra from SFVS of a medium composed of nonpolar (symmetric) molecules. The true bulk spectra with no contribution from the surface were directly measured by transmission SFVS, and the true surface spectra with no bulk contribution was deduced from reflection SFVS through proper spectral analysis. The results also provide guidelines for evaluation of the importance of bulk contribution to SFVS when applied to media of polar molecules.

This work is supported by NSFC and NCET.

9584-8, Session 2

Chiral sum frequency generation microscopy by using polarization manipulation *(Invited Paper)*

Ziheng Ji, Peking Univ. (China); Kebin Shi, Peking Univ. (China) and State Key Lab. for Mesoscopic Physics (China) and Collaborative Innovation Ctr. of Quantum Matter (China)

Chiral sum-frequency generation (C-SFG) is an electric-dipole allowed non-degenerate second order nonlinear process which could be used to probe the chiral component of second order nonlinear susceptibility in chiral interface and chiral bulk media. Being chemical and chiral selective, C-SFG imaging and spectroscopy technique are capable for label-free, achiral background free, in situ and realtime characterization of biomolecule and bioengineering sample. Due to the sub-micron dimension of bio-functional structure, C-SFG microscopic and micro-spectroscopic toolsare often needed. Efforts have been made to adapt the classical non-paraxial configuration directly into a microscopic configuration. In this paper, we propose a new microscopic setup to manipulate the polarization state of the laser beam in order to avoid the non-paraxial arrangement. As a result, higher resolution and larger effective imaging area can be achieved. Our results also show the capabilities to combine the proposed approach with confocal microscopy or other existed imaging technique.Simulation is performed by using vector diffraction theory and Green's function formulation to calculate the structure of focal field, the generation and the propagation of C-SFG signal.The results indicate the feasibility and promising application of polarization manipulated C-SFG microscopy in practical bioengineering and biomedical research.

9584-9, Session 2

Bond models of linear and nonlinear optics *(Invited Paper)*

David E. Aspnes, North Carolina State Univ. (United States)

Bond models have a long history in optics, originating with the largely forgotten Ewald-Oseen Extinction Theorem of linear optics (Ewald, 1912; Oseen, 1915) and being used in the 1960's and early 1970's to calculate nonlinear-optical (NLO) susceptibilities in the static limit. Interest revived with the recent work of Powell et al., who showed that an anisotropic version enormously simplified the interpretation of second-harmonic-generation (SHG) data for Si-SiO2 interfaces. These models are based on fundamental physics instead of phenomenology, and describe optical responses in terms of processes that occur on the atomic scale, in real time. Also, since crystal structure is incorporated at the atomic level, tensor components emerge automatically. For linear optics, the four steps involved constitute a difficult problem in self-consistency, but for NLO, where the emerging radiation is orders of magnitude weaker and occurs at a different wavelength, all four steps can be treated independently and calculations are straightforward.

I discuss the use of bond models to identify the four basic contributions to SHG: bond anharmonicity, spatial dispersion, retardation, and magnetism, all of which can be understood in this framework in simple physical terms. I then discuss various applications, including surface and interface analysis by SHG. Other applications include third- and fourth-harmonic generation (THG, FHG), dipole-forbidden NLO processes in the bulk of amorphous

materials and crystals with inversion symmetry, and following the surface chemistry of Si oxidation under uniaxial strain.

9584-10, Session 3

Leveraging higher-order nonlinearities in optical transient absorption for microscopic imaging contrast *(Invited Paper)*

Jesse W. Wilson, Jong Kang Park, Miguel Anderson, Martin C. Fischer, Warren S. Warren, Duke Univ. (United States)

The transient absorption response of melanin is a promising optically-accessible biomarker for distinguishing malignant melanoma from benign pigmented lesions, as demonstrated by earlier experiments on thin sections from biopsied tissue. The technique has also been demonstrated in vivo, but the higher optical intensity required for detecting these signals from backscattered light introduces higher-order nonlinearities in the transient response of melanin. These components that are quadratic with respect to the pump or the probe introduce intensity-dependent changes to the overall response that complicate data analysis. However, our data also suggest these nonlinearities might be advantageous to in vivo imaging, in that different types of melanins have different nonlinear responses. Therefore, methods to separate linear from nonlinear components in transient absorption measurements might provide additional information to aid in the diagnosis of melanoma.

We will discuss numerical methods for analyzing the various nonlinear contributions to pump-probe signals, and our progress toward realtime analysis with digital signal processing techniques. To that end, we have replaced the lock-in amplifier in our pump-probe microscope with a high-speed data acquisition board, and reprogrammed the coprocessor field-programmable gate array (FPGA) to perform lock-in detection. The FPGA lock-in offers better performance than the commercial instrument, in terms of both signal to noise ratio and speed. In addition, the flexibility of the digital signal processing approach enables demodulation of more complicated waveforms, such as spread-spectrum sequences, which has the potential to accelerate microscopy methods that rely on slow relaxation phenomena, such as photothermal and phosphorescence lifetime imaging.

9584-11, Session 3

Optimization of mid-IR photothermal imaging for tissue analysis *(Invited Paper)*

Atcha Totachawattana, Shyamsunder Erramilli, Michelle Y. Sander, Boston Univ. (United States)

Photothermal imaging in the mid-infrared allows highly sensitive, label-free microscopy by relying on bond-specific material characterization of the samples. In a pump-probe configuration, the mid-IR pump laser is tuned to characteristic vibrational molecular modes and thermally induces changes in the refractive index. The shorter wavelength probe scatter can be detected with lock-in technology, utilizing highly sensitive detectors at telecommunication wavelengths. This mitigates the need of complex detector technology as required for traditional infrared spectroscopy/ Fourier Transform infrared spectroscopy.

Our system features a high brightness quantum cascade laser that can be tuned continuously over a spectrum of interest. This is combined with fiber laser technology for the probe laser which features a compact footprint, robust performance metrics and reduced sensitivity to environmental perturbations compared to free-space laser configurations. In systematic spectroscopy studies where the probe laser parameters were modified, we demonstrate that the signal-to-noise ratio can be significantly increased by utilizing a mode-locked laser configuration instead of a continuous-wave laser.

With a raster-scanning approach, the photothermal spectroscopy system can be extended to a label-free mid-infrared microscope. By tuning the pump laser to the amide-I absorption band around 1650cm-1 in biological tissue samples, whose spectral characteristics can provide insight into the secondary structure of proteins (e.g. amyloid plaques; alpha-helix, beta-sheet), we can combine spectral content with localized sample details. We will present the versatility of the mid-IR photothermal system for analyzing histopathological tissue sections of e.g. cancerous tissue in a non-contact, non-destructive approach with good sensitivity.

9584-12, Session 3

Multifunctional diagnostic, nanothermometer, and photothermal nano-devices *(Invited Paper)*

Shuang Fang Lim, Kory Green, Janina Wirth M.D., North Carolina State Univ. (United States)

In this study, the known therapeutic capabilities of gold nanorods (AuNRs) have been combined with the diagnostic and nanothermometer abilities of upconversion nanoparticles (UCNPs) to develop a system for simultaneous biological imaging, photothermal therapy, and nanothermal sensing. Both the excitation of UCNPs and the finely tuned longitudinal surface plasmon resonance (LSPR) mode of AuNRs lay in a window of relatively high light penetration of tissue in the infra-red. The nanothermometer property of the UCNPs allows direct quantification of the localized temperature of the photothermally heated AuNRs chemically adsorbed to their surface and is free from the bleaching problems inherent in dye thermal sensing systems, especially at high laser fluences required to kill tissue. Spectroscopy on single particles, verified by transmission electron microscopy (TEM), has been performed at varying temperatures to confirm 1) the thermal sensing properties of UCNPs and 2) to finely tune their upconversion enhancement arising from the LSPR coupling of the AuNRs. Simultaneously measurement of the emission of two thermally coupled states in the UCNP Erbium ions, enables quantification of the localized temperature of photothermally heated AuNRs. HeLa cell viability studies have also been performed to ensure that cell death accompanying particle incubation at various concentrations and fluence dosing are the direct result of the photothermally heated AuNRs and not a result of cytotoxicity of the particle composites or absorptive properties of the medium itself.

9584-13, Session 3

Multiscale diffusion of single molecules in crowded environments *(Invited Paper)*

Ahmed A. Heikal, Univ. of Minnesota, Duluth (United States)

Living cells are crowded with organelles, biomembranes, and macromolecules such as proteins, DNA, RNA, and actin filaments. Such macromolecular crowding is believed to influence biomolecular diffusion, protein-protein interactions, protein-substrate interaction, and protein folding. In this project, we elucidate crowding effects on the diffusion of a rhodamine green (RhG), nonspecific binding and the heterogeneity of microviscosity in a crowded environment of macromolecules. For biomimetic crowding, Ficoll-70, BSA, and ovalbumin were used as crowding agents at biologically relevant concentrations and compared with glycerol-rich solutions as a continuum. The rotational (ps-ns) and translational (ms-s) diffusion of RhG was investigated using time-resolved fluorescence anisotropy (TRA) and fluorescence correlation spectroscopy (FCS), respectively, as a function of crowding. Our results suggest that the multi-scale diffusion of RhG can be described using the Stokes-Einstein model only in a continuum (e.g., glycerol) environment. Rotational diffusion measurements indicate non-specific binding between RhG and proteins (BSA and Ovalbumin), which explains the deviation from the Stokes-Einstein model in a protein-crowded environment. The equilibrium constant and changes in standard free energy of such non-specific binding were calculated using TRA results. The local microviscosity experienced during the rotational and translational diffusion of RhG agrees with the bulk viscosity over the 1-20 cP range. In Ficoll-70, BSA, and ovalbumin-crowded environments, however, the microviscosity differs from the corresponding

bulk viscosity depending on the nature (i.e., proteins versus polymers) and concentration of crowding agents. Our findings provide a foundation for multi-scale diffusion studies of biomolecules in the crowded milieu of living cells using fluorescence spectroscopy.

9584-14, Session 3

Optical imaging for digital biosensing *(Invited Paper)*

Zhenyu Li, The George Washington Univ. (United States)

Digital biosensors enable absolute counting of individual target biomolecules in a given sample without a calibration curve. Such sensing modalities with single molecule resolution has proved powerful in both ultrasensitive medical diagnostics and fundamental biological research. A variety of optical imaging techniques are particularly suited for digital biosensing. In the talk, I will discuss the general requirements for digital biosensing and how a number of optical imaging techniques can provide such capabilities, in some cases with low cost setup and small system foot print.

9584-15, Session 4

Adaptive control of waveguide modes in a few-mode fiber network *(Invited Paper)*

Yong Xu, Peng Lu, Matthew Shipton, Brennan Thews, Anbo Wang, Virginia Polytechnic Institute and State Univ. (United States)

We report an adaptive optics (AO) method that can be used to control the form of optical waves in a few-mode fiber (FMF) network. Our method relies on the incorporation of fiber Bragg gratings (FBGs) within the FMF network for model control. Since different guided modes possess different propagation constants, a typical FBG should produce different transmission / reflection responses for different guided modes. Therefore, by using optical signals reflected / transmitted by the FBG as feedback, we can utilize a simple AO algorithm to control the form of optical waves at the FBG location. This feasibility of this approach is confirmed through direct comparison with guided wave profiles captured by a CCD camera. By incorporating multiple FBGs in the FMF network, we should be able to achieve mode control in the FMF network in a quasi-distributed manner.

9584-16, Session 4

Transmission of femtosecond pulses through multimode fibers *(Invited Paper)*

Demetri Psaltis, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Multimode fibers have been investigated recently for imaging and communications. In this presentation we will explore how femtosecond pulse propagate through multi-mode fibers and discuss applications.

9584-17, Session 4

Delivery of ultrashort spatially focused pulses through a multimode fiber *(Invited Paper)*

Christophe Moser, Edgar E. Morales, Demetri Psaltis, Salma Farahi, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Multimode optical fibers potentially allow the transmission of larger amounts of information than their single mode counterparts because of their high number of supported modes. However, propagation of a light pulse through a multimode optical fiber suffers from spatial distortions due to superposition of the various exited modes and from time broadening due to modal dispersion.

We present a method to selectively excite specific optical fiber modes in a multimode fiber that follow similar optical paths as they travel through the fiber. In this way, they can interfere constructively at the fiber output generating an ultrashort spatially focused pulse. The excitation of a limited number of modes following similar optical paths limits modal dispersion, allowing the transmission of the ultrashort pulse. Digital scanning of the spatially focused pulse without movable elements is shown.

We also demonstrate that the intensity of the pulse delivered as a focused spot on the other end of the fiber is enough to excite two-photon fluorescence of a fluorescent dye whose spectral absorption peak occurs at half the wavelength of the delivered pulse.

We have experimentally demonstrated the delivery of a focused pulse through a 30 cm , 200 micrometer core multimode fiber with a duration of approximately 500 fs. This study adds two-photon imaging capability for endoscopy using commercial multimode fibers.

9584-18, Session 5

Effects of quantum confinement and environment on exciton dynamics of monolayer and few-layers molybdenum disulphide *(Invited Paper)*

Hongyan Shi, Harbin Institute of Technology (China) and Key Lab. of Micro-Optics and Photonic Technology (China); Xuan Li, Ruihuan Tian, Yan Ling, Harbin Institute of Technology (China); Xiudong Sun, Harbin Institute of Technology (China) and Key Lab. of Micro-Optics and Photonic Technology (China)

Two-dimension transition metal dichalcogenide monolayer and few-layers, i. e. MoS2, are emerging as promising potential for exploring 2D semiconductor optoelectronic devices. How exactly quantum confinement and surrounding environment affect excitonic properties of monolayer MoS2 is still currently under heated debate. We perform laser scanning transient absorption microscopy (TAM) to study optical properties and exciton dynamics in monolayer and few-layers MoS2 supported on different substrates. The novel laser scanning TAM setup allows the direct tracking of excitation propagation in space and time with ultrafast temporal resolution and sub-diffraction limited spatial resolution by scanning the probe beam relative to the pump at the focus of a microscope with a galvanometer scanner. The resulting time-dependent dynamics reveals the influence of quantum confinement and surrounding environment on exciton resonance and energy relaxation related to many-body interactions and screening due to dielectric screening of Coulomb interactions.

9584-19, Session 5

Lithography-free super absorbing metasurfaces for surface enhanced nonlinear optics *(Invited Paper)*

Kai Liu, Tianmu Zhang, Dengxin Ji, Joseph Murphy, Haomin Song, Tim Thomay, Univ. at Buffalo (United States); Kebin Shi, Peking Univ. (China); Qiaoqiang Gan, Alexander Cartwright, Univ. at Buffalo (United States)

Nanoplasmonic metamaterials are effective platforms to create ultra-compact on-chip optical devices through deep-subwavelength concentration of electromagnetic fields. These strongly localized fields are particularly promising to enhance inherently weak nonlinear optical responses of materials. Recently, lithography-fabricated periodic plasmonic/

metamaterial structures were employed to enhance nonlinear optical responses, yet imposing a cost barrier for practical applications. Here we will employ a lithography-fee low-cost metasurface to demonstrate its application on surface enhanced second harmonic generation (SHG). The proposed metasurface absorber consists of a monolayer of silver (Ag) nanoparticles (NPs), a SiO2 spacer layer and an optically thick Ag ground plate. A super absorption peak of 68% was achieved in the metasurface at the wavelength of 830 nm which was aligned well with our pump wavelength at 800 nm. Only ~25% absorption peaks was observed in the control sample (i.e. AgNPs on a glass substrate with no nanocavity enhancement). Simulation results revealed a strongly confined electric field between the Ag ground plate and the AgNP, contributing to the enhanced nonlinear optical response of those metal NPs. SHG measurement results show an obvious signal at the wavelength of 400 nm generated from the designed metasurface absorber, while no substantial SHG signal was observed from the control sample even under higher pump power conditions. Compared with previously reported lithography-fabricated matematerials for enhanced nonlinear optics processes, our lithography-free metasurface is low-cost, large-area and amenable to develop practical applications.

9584-20, Session 5

Ultrafast pump-probe spectroscopy with force detection *(Invited Paper)*

Eric O. Potma, Univ. of California, Irvine (United States)

A very important class of nonlinear optical techniques is pump-probe spectroscopy, in which the sample is optically excited by a pump pulse and the ensuing excitation dynamics is followed by a time-delayed probe pulse. As pump-probe techniques, which were originally developed for macroscopic ensemble measurements, are finding their way into single molecule applications, proper descriptions are required to interpret the pump-probe signal at the spatial scales relevant to individual molecules. In this presentation, we will discuss the pump-probe interaction in the near-field in various excita- tion geometries, and how the near-field interaction is manifested in the far-field. Based on a general description of the pump-probe signal, we examine two detection strategies of the light-matter interaction: optical detection and force detection. We will show that, besides the more conventional optical detection approach, non-optical methods such as force detection offer a viable route towards exploring ultrafast single molecule dynamics at the nanoscale.

9584-21, Session 5

An exciton's transformation in a semiconducting polymer: How absorption and emission relate in an anisotropic solid *(Invited Paper)*

Kenan Gundogdu, Bhoj Gautham, Harald W. Ade, North Carolina State Univ. (United States); Natalie Stingelin, Imperial College London (United Kingdom); Robert Younts, North Carolina State Univ. (United States); Christoph Hellmann, Imperial College London (United Kingdom)

Due to the heterogeneity of the solid-state structure of semiconducting polymers, the understanding of their electronic and opto-electronic characteristics continues to be incomplete - despite extensive investigations and considerable technological potential of these materials. As isolated chains, the one-dimensional optoelectronic structure of the conjugated backbone can be considered molecular in character. In the complex solid state, H- or J-like coupling of certain polymer segments ('chromophores') can occur, which imparts an anisotropic 2D opto-electronic character (with the third dimension being inactive) and significantly modifies the absorption and emission spectrum compared to the molecularly isolated state. Despite the effective 2D nature of the materials, the fluorescence state with lifetimes of 100s of ps following the much faster absorption is currently thought to be a result of the continuous evolution of the same quantum mechanical state. Through spectroscopic studies of the ubiquitous semiconductor poly(3-hexylthiophene) (P3HT), whose H- and J-coupling has been manipulated, we show that even in cases where the absorption spectrum exhibits intrachain excitonic line shapes (J-like), intramonomer repulsive forces and the anisotropic coupling along and transverse to the polymer chains drive formation of interchain excitons, which radiatively recombine to generate H-like emission spectra. Our time resolved studies show that this transformation is discontinuous and that photogenerated excitons seem to first form an intermediate dark polaron-pair prior to forming an interchain exciton.

9584-22, Session 5

Nano-imaging and spectroscopy with optical antennas *(Invited Paper)*

Joanna M. Atkin, Univ. of Colorado at Boulder (United States) and The Univ. of North Carolina at Chapel Hill (United States)

Many materials classes show some of mesoscale spatial heterogeneity that is important for functional properties, ranging from biological structure-function relations to domain formation in strongly correlated electron materials. Optical and IR spectroscopic techniques are important for accessing electronic and vibrational properties, but these approaches are diffraction limited and therefore have low spatial resolution.

The use of ultrasharp scanning probe tips as optical antennas provides a means to overcome the diffraction limit and extend optical spectroscopy to the nanoscale, in order to investigate the causes and effects of spatial heterogeneities. This approach is compatible with a broad range of optical modalities, including ultrafast and nonlinear implementations, enabling the study of sub-ensemble and sub-domain behavior. I will discuss several of our recent results in ultrafast scattering scanning near-field optical microscopy (s-SNOM) that have demonstrated an unprecedented degree of specificity, sensitivity, and selectivity in probing nanoscale systems. With femtosecond vibrational s-SNOM spectroscopy we can directly access homogeneous sub-ensemble dynamics within polymer systems, revealing novel coherence behavior. Pump-probe implementations allow us to investigate the impact of defects and localized strain in even nominally homogeneous microcrystal structures, while nonlinear approaches such as second-harmonic generation and four-wave mixing enable us to resolve nanometer-scale crystallographic and ferroic domain structures, with modified near-field selection rules. I will also discuss novel antenna concepts for background-free nanometer spatial and femtosecond temporal control.

9584-23, Session 6

Raman sensing in microresonators

Corey Janisch, Alexander Cocking, The Pennsylvania State Univ. (United States); Lan Yang, Washington Univ. in St. Louis (United States); Zhiwen Liu, The Pennsylvania State Univ. (United States)

High-quality whispering-gallery-mode optical resonators have garnered interest in particle sensing for a variety of applications. By utilizing high quality cavity modes to enhance the light-matter interaction between the resonant mode and the particle, several microresonator based approaches have been developed for single-particle detection by monitoring changes to the resonant mode. Here, we further explore the idea of using ultra-high quality microresonators to enhance single-particle detection and identification by monitoring the Raman scattering from a particle adhered to a silica micro-sphere. A tunable diode laser is critically coupled into a resonant mode of the micro-sphere resonator, allowing circulating power to build up within the cavity for enhanced interaction with the attached particle. Experimental results of single particle Raman scattering in high-Q microsphere resonators will be presented.

9584-24, Session 6

UV resonance Raman signatures of phonon-allowed absorptions and phonon-driven bubble formation *(Invited Paper)*

Hans D. Hallen, North Carolina State Univ. (United States); Adam H. Willitsford, Johns Hopkins Univ. Applied Physics Lab., LLC (United States); Reagan Weeks, C. Russell Philbrick, North Carolina State Univ. (United States)

We have measured UV resonance Raman near and at the resonance phonon-allowed absorption lines of several liquid species. Resonance absorption with excitation on the symmetry-forbidden but strongly phonon coupled bands in the 230-290 nm spectral band present enhancement corresponding to the vapor phase absorptions rather than those of the liquid phase. This effect is related to the coherence forced by the internal molecular resonance required to absorb light at this energy. Large resonance gains (~1000x) reflect the narrower vapor phase lines. At the low laser fluence used, bubble formation is observed when the excitation energy corresponds to the maximum in Raman signal generation, not at the wavelength of maximum absorption in the liquid sample, which is several nanometers away.

9584-25, Session 6

G-Fresnel cellphone spectrometer

Chenji Zhang, The Pennsylvania State Univ. (United States); Perry S. Edwards, Atoptix, LLC (United States); Zhiwen Liu, The Pennsylvania State Univ. (United States)

The G-Fresnel cellphone spectrometer covering visible wavelength range has been demonstrated previously by our group. The previously demonstrated design however, relies on a two-sided diffractive element design, which poses inconveniences for large scale fabrication. Additionally, the fabrication process imposes limitations on the efficiency of the device. In this work, a holographic fabrication procedure is developed to produce a single-sided G-Fresnel device with improved optical efficiency. The interference lithography setup is described which produces a single-sided device with the desired dual focusing and dispersion functions. Replication of the device by using PDMS soft lithography is also discussed. A spectrophotometer is constructed using the fabricated holographic G-Fresnel and its performance is demonstrated through experimental measurements. The improved sensitivity due to the new device design can enable many applications in biomedical sensing.

9584-26, Session 6

Smartphone spectroscopy for non-invasive point-of-care diagnostics *(Invited Paper)*

Perry S. Edwards, Atoptix, LLC (United States); Zhiwen Liu, The Pennsylvania State Univ. (United States)

An ultra-compact, visible/near-infrared optical spectrometer is demonstrated as an add-on attachment to a smartphone for non-invasive point-of care applications. Spectra captured by the smartphone spectrometer are transferred to a cloud based server and processed using spectral analysis algorithms, which provide near real-time results of vital health information back to the user. The noninvasive, mobile measurement capability shows great promise for improving monitoring and treatment for several health concerns. Our current development of the smartphone spectrometer system for point-of-care applications as well as future development directions will be discussed.

9584-27, Session 7

Axial slice light sheet microscopy with micro mirror array

Yizhu Chen, Mingda Zhou, Yiqiu Xia, Ding Ma, Siyang Zheng, Zhiwen Liu, The Pennsylvania State Univ. (United States)

A novel axial slice light sheet microscopy technique will be presented, which can simultaneously image an axial cross section slice of a specimen by using an array of long-aspect-ratio micro mirrors. The imaging principle, the design and fabrication of micro mirrors will be discussed. Preliminary experimental demonstration will also be presented.

9584-28, Session 7

Compressive sensing in CARS holography

Alexander Cocking, Nikhil Mehta, Zhiwen Liu, The Pennsylvania State Univ. (United States)

Coherent anti-Stokes Raman scattering (CARS) holography has been demonstrated successfully as a single shot, label-free, chemically selective 3D imaging technique. It is well known that hologram samples only very small subset in the k-space describing the 3D image and hence has poor axial resolution. Due to this, images reconstructed using digital holography based on Fresnel kernel suffer from diffraction noise, i.e. out-of-focus background. To help improve the quality of reconstructed 3D images by reducing this noise, we present compressive CARS holography, a numerical technique based on the novel concept of compressive sensing. Compressive sensing is a powerful technique for estimation of sparse signals using relatively few measurements. By applying compressive sensing to our single shot CARS hologram, we demonstrate nearly noise-free retrieval of multiple microspheres within an imaging volume which is nearly 15 um along ‘z’ at every 1 um axial depth. In particular, we use the two step iterative shrinkage threshold (TwIST) algorithm along with l 1 normalization to iteratively minimize the system objective function and retrieve an image in each depth slice. Thus the use of compressive CARS holography enhances the powerful CARS holography technique by reducing noise and thereby effectively emulating higher axial resolution using only single shot hologram.

9584-29, Session 7

Fast acquisition for wide field of view high-resolution phase microscopy *(Invited Paper)*

Laura Waller, Lei Tian, Ziji Liu, Univ. of California, Berkeley (United States); Chenguang Ma, Tsinghua Univ. (China); Simon Li, Kannan Ramchandran, Univ. of California, Berkeley (United States)

This talk will describe new methods for rapid acquisition of 3D and high-resolution phase images across large volumes, in a commercial microscope with partially coherent illumination. We show connections between Fourier Ptychography and light field imaging for 3D complex-field recovery and discuss optimization of coding strategies for fast capture of large-scale large volume image datasets. Such computational approaches to optical microscopy add significant new capabilities to commercial microscopes without much cost or hardware modification.

9584-30, Session 7

Watching photons on the fly by compressed ultrafast photography *(Invited Paper)*

Liang S. Gao, Washington Univ. in St. Louis (United States)

Video recording of ultrafast phenomena using a detector array based on the CCD or CMOS technologies is fundamentally limited by the sensor's on-chip storage and data transfer speed. To get around this problem, the most practical approach is to utilize a streak camera. However, the resultant image is normally one dimensional—only a line of the scene can be seen at a time. Acquiring a two-dimensional image thus requires mechanical scanning across the entire field of view. This requirement poses severe restrictions on the applicable scenes because the event itself must be repetitive.

To overcome these limitations, we have developed a new computational ultrafast imaging method, referred to as compressed ultrafast photography (CUP), which can capture two-dimensional dynamic scenes at up to 100 billion frames per second. Based on the concept of compressed sensing, CUP works by encoding the input scene with a random binary pattern in the spatial domain, followed by shearing the resultant image in a streak camera with a fully-opened entrance slit. The image reconstruction is the solution of the inverse problem of above processes. Given sparsity in the spatiotemporal domain, the original event datacube can be reasonably estimated by employing a two-step iterative shrinkage/thresholding algorithm.

To demonstrate CUP, we imaged light reflection, refraction, and racing in two different media (air and resin). Our technique, for the first time, enables video recording of photon propagation at a temporal resolution down to tens of picoseconds. Moreover, to further expand CUP's functionality, we added a color separation unit to the system, thereby allowing simultaneous acquisition of a four-dimensional datacube (x,y,t,?), where ? is wavelength, within a single camera snapshot.

9584-31, Session 7

Advances in the optical delivery architecture for femtosecond micromachining systems that employ simultaneous spatial and temporal focusing *(Invited Paper)*

Jeffrey A. Squier, Colorado School of Mines (United States)

Simultaneous spatial and temporal focusing (SSTF) has been demonstrated to have many attractive features as applied to micromachining with femtosecond lasers. These include 1) the ability to use low numerical aperture beams that are not compromised by nonlinear effects, 2) an improved depth-of-field as compared to a standard focus with the same lateral spot size, and 3), the ability to create a pulse-front-tilt that can be exploited in terms of material modification in novel ways. To fully exploit this range of features optical delivery systems that are integrated within a chirped pulse amplification architecture are highly desirable. We will present a series of these systems. The first is a novel single grating compressor that can be used in a quartic- or quintic phase limited chirped pulse amplification system in lieu of a standard double-pass grating compressor. The new compressor allows smooth variation of the beam aspect ratio of the SSTF beam. This enables control over the achievable depth of focus and the pulse front tilt. Indeed, with this system the compressor can be varied between a standard focus and an SSTF focus. Next, we demonstrate an optical delivery system that employs in-line refractive optics that facilitates micromachining especially in industrial and medical environments. This type of delivery system is difficult to achieve with a standard focus, and is one of the advantages of SSTF: energetic, femtosecond pulses can travel through extensive path lengths of material without significant degradation in the focus as a result of the accumulation of nonlinear phase shifts.

Three-color two-photon three-axis digital scanned light-sheet microscopy (3c2p3a-DSLM) *(Invited Paper)*

Liangyi Chen, Weijian Zong, Aimin Wang, Peking Univ. (China)

We demonstrate a new two-photon light-sheet microscopy with three-color excitation, diffraction-limited thickness and tailorable illumination area, capable of multi-color multi-scale live imaging in one setup.

9584-33, Session 7

Nonlinear tomographic spatial frequency modulated imaging *(Invited Paper)*

Randy A. Bartels, Colorado State Univ. (United States)

In this talk, we will discuss nonlinear spatial frequency modulated imaging. This approach opens new imaging capabilities, with benefits of high speed and large volume imaging. Super-resolution and tomographic imaging modes will be presented.

9584-34, Session 8

Photonic-crystal-fiber platform for high-power multi-wavelength ultrashort-pulse sources and its applications *(Invited Paper)*

Minglie Hu, Tianjin Univ. (China)

It has been shown by intensive research activities in the laser and photonics fields that many novel properties unimaginable with conventional optical fibers can result from the photonic crystal fibers (PCFs). PCF is a new class of optical fiber based on the properties of photonic crystal, which features micro/nano air hole array or higher-index rode array in the fiber cladding. With its huge degree of design freedom, the propagation properties of PCF can be tailored for any needs. Recently, based on some of these properties, photonic crystal fiber has been successfully applied in femtosecond laser technology and greatly improve the performance of femtosecond laser. A brief review of recent work on high power femtosecond laser based on PCF is demonstrated. Furthermore, garmonic generation, optical parametric process based on the high power femtosecond fiber laser can generate new wavelengths of femtosecond pulses from the ultraviolet to mid-infrared. And the wavelength tunable femtosecond laser have a tremendous impact on physics in subwavelength structure, Chemics and Bioglogy.

9584-35, Session 8

Ultrafast nonlinear THz emission and electrodynamics in low dimensions *(Invited Paper)*

Jigang Wang, Iowa State Univ. (United States) and Ames Lab. (United States)

Nonlinear and non-equilibrium properties of low-dimensional quantum matter are fundamental in nanoscale science yet transformative in nonlinear imaging/photonic technology today. These have been poorly addressed in many nanomaterials despite of their well-established equilibrium optical and transport properties. The development of ultrafast THz sources and nonlinear spectroscopy tools facilitates understanding these issues and reveals a wide range of novel nonlinear quantum phenomena that are not expected in bulk solids or atoms. In this talk, I will discuss our recent discoveries in two model photonic and electronic nanostructures to solve some puzzling questions: (1) how to create nonlinear broadband terahertz

emitters using deeply subwavelength nanoscale meta-atom resonators? (2) How to access one-dimensional dark excitons and their non-equilibrium correlated states in single-walled carbon nanotubes? Finally, I will also discuss their significance for quantum phase discoveries and other nonlinear imaging/spectroscopy applications.

9584-36, Session 8

Ultrafast THz and mid-IR studies of nanoscale charge dynamics and electronic correlations *(Invited Paper)*

Giacomo Coslovich, Ryan P. Smith, Jan H. Buss, Sascha Behl, Bernhard Huber, Lawrence Berkeley National Lab. (United States); Takao Sasagawa, Tokyo Institute of Technology (Japan); Hans A. Bechtel, Michael C. Martin, Robert A. Kaindl, Lawrence Berkeley National Lab. (United States)

We will present our recent experiments employing broadband THz and mid-IR pulses to explore ultrafast charge dynamics and interactions in correlated and nanoscale materials. Transition-metal oxides exhibit an intriguing self-organization of charges into 1D stripes and other atomic-scale patterns, whose complex and dynamic driving forces may be central to understanding high Tc superconductivity. By exploring the mid-IR response of stripe-phase nickelates, we resolve femtosecond charge localization and transient electron-phonon coupling, revealing their precursor role in stripe formation. In turn, the Ni-O bending vibration around 11 THz exhibits a splitting arising from long-range stripe order, while a broad background results from the opening of the electronic pseudogap. Employing optical pump multi-THz probe spectroscopy with high energy resolution allows us to resolve the dynamic modulation of the order-induced phonon splitting and the localization dynamics, thus capturing both the short- and the long-range order dynamics within the single spectrum of a THz pulse. Finally, we will discuss experiments that track the optical conductivity in graphene and transition-metal dichalcogenides via ultra-broadband THz spectroscopy, exposing the high-frequency transport of non-equilbrium Dirac fermions and photo-excited electron-hole pairs.

Optical parametric oscillation in synchronously pumped MgO-doped periodically poled lithium niobate

Ieva Pipinyte, Agne Marcinkeviciute, Rimantas Grigonis, Valdas Sirutkaitis, Vilnius Univ. (Lithuania)

Femtosecond laser pulses tunable in wide spectral range are valuable instruments for investigation of various ultrafast processes or nonlinear imaging. Synchronously pumping optical parametric oscillator (SPOPO) allows generation of tunable radiation at low pump energies and high pulse repetition rate. We present experimental data obtained during investigation of synchronously pumped optical parametric oscillator (SPOPO) pumped by fundamental (1030 nm) radiation of mode-locked Yb:KGW laser, providing 105 fs pulses at 76 MHz repetition rate with an average power of 4 W. We used a 1.5 mm long MgO:PPLN crystal as nonlinear material, which was placed in a four- mirror linear resonator. Spectral tuning and power characteristics of this SPOPO was investigated, while keeping the temperature of MgO:PPLN crystal fixed. Generation of signal pulses tunable in 1.38 – 1.82 ?m spectral range was obtained by changing grating period of the crystal and a cavity length. Temporal characteristics of SPOPO were investigated by using the constructed multi-shot intensity correlator. Furthermore, the group delay dispersion of flat mirrors of resonator was measured by the white light interferometer due to it can have an important influence for temporal properties of SPOPO radiation.

9584-38, Session PMon

Wavelet analysis of polarization maps of the myocardium tissue microscopic images in the diagnosis of the causes of death

Alexander Ushenko, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

By tradition, the processes of transforming optical radiation of phase-inhomogeneous objects and media are considered, as a rule, in a statistical approach (theory of radiation transfer, Monte-Carlo modeling). Among the most spread traditional methods for studying the scattered light fields, one can separate the following independent directions: “scalar” (photometry and spectrophotometry) and “vector” (polarization nephelometry, Mueller-matrix optics). Using these approaches, determined are interrelations between the sets of statistical moments of the 1-st to 4-th orders, correlation functions, fractal dimensionalities that characterize phase-inhomogeneous or rough surfaces and coordinate distributions for phases, azimuths and ellipticity of polarization in their laser images.

In parallel with traditional statistical investigations, formed in recent 10 to 15 years is the new optical approach to describe a structure of polarizationally inhomogeneous fields in the case of scattered coherent radiation. The main feature of this approach is the analysis of definite polarization states to determine the whole structure of coordinate distributions for azimuths and ellipticities of polarization.

This work is aimed at ascertaining the possibilities to diagnose and classify phase-inhomogeneous layers (PhIL) of myocardium of the patients who died of coronary artery disease (CAD) and acute coronary insufficiency (ACI) by determination values and ranges for changing the statistical (moments of the 1-st to 4-th orders), correlation (autocorrelation functions) and fractal (logarithmic dependences for power spectra) parameters that characterize coordinate distributions for polarization-singular states in PhIL laser images.

1. Analyzed in this work are the main physical mechanisms providing formation of polarization singularities in laser images of PhIL with surface, subsurface and bulk light scattering.

2. Offered are statistical, wavelet, correlation and fractal parameters for polarization-singular estimating the optical properties inherent to PhIL of all types.

3. Determined are the ranges for changing the set of criteria that characterize distributions of the amount of polarization-singular states in laser images, which enabled us to realize both “intergroup” classification and differentiation of optical properties related to PhIL of various types.

4. We have demonstrated diagnostic efficiency of the wavelet analysis applied to coordinate distributions for polarization maps in laser images of patients with CAD and ACI.

System of polarization correlometry of polycrystalline layers of urine in the differentiation stage of diabetes

Olexander V. Dubolazov, Yuriy Ushenko, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

Among diverse optical-physical methods of diagnosing the structure and properties of the optical-anisotropic component of various biological objects a specific trend has separated – multidimensional laser polarimetry

Our research is aimed at designing the experimental method of Fourier’s laser polarimetry of human urine polycrystalline layers for the sake of diagnosing and differentiating cholelithiasis with underlying chronic cholecystitis and diabetes mellitus of degree II by means of the statistical analysis of the polarization filtered out scattered coherent radiation in a distant (Fourier) zone of diffraction with due regard for linear and circular birefringence of biological crystals.

A model of generalized optical anisotropy of human urine polycrystalline

layers is suggested and a method of polarimetric of the module and phase Fourier of the image of the field of laser radiation is analytically substantiated, that is generated by the mechanisms of linear (a phase shift between the orthogonal components of the amplitude of a laser wave) and circular (the angle of rotation of the polarization plane) birefringence of polycrystalline networks with a wavelet - diagnosis and differentiation of stage of diabetes.

A set of diagnostic criteria and diagnosis and differentiation of stage of diabetes is identified and substantiated:

- statistical moments of the 3rd and 4th orders, which characterize the distributions of wavelet coefficients of Fourier phase of the image of a polarization inhomogeneous laser image of polycrystalline network of urine.

Confocal fluorescence microscopy for diagnostic of the bone grafts

Pavel E. Timchenko, Elena V. Timchenko, Larisa A. Zherdeva (Taskina), Samara State Aerospace Univ. (Russian Federation); Larisa T. Volova, Samara State Medical Univ. (Russian Federation); Nikolay V. Belousov, Samara State Aerospace Univ. (Russian Federation)

Microscopic analysis of cell osseointegration in the lyophilized bio-implants, made of human connective tissues by «Lioplast»® technology, was conducted. The analysis was carried out using a system of laser confocal fluorescence microscopy, assembled on the basis of Olympus IX71 microscope and ANDOR laser harvester. This system provides the high-speed scanning of up to 25 layers per second and the resolution of up to 400 nm. Processing of the received images was performed using the ANDOR software.

The dynamics of the different cells in the model environment was investigated. Shown, that the cells have a significantly greater length, surface area and form a monolayer in the model environment, unlike the cells in the natural environment. As a result, the image has a low contrast in the confocal mode (no more than 0.2 - 0.3), that is not able to identify the internal structure of cells. Using propidium iodide fluorophore (Ex. wavelength of 488 nm) allows to raise the image contrast up to 0.9 and to register the dynamics of cell growth. The cell integration in bone grafts with different time of demineralization was investigated. Analysis of the micrographs suggests that the cells penetrate into the graft and settle in the inner surface. The average sectional area of the cell in control model environment is 26 μm2, the average diameter – 6 μm.

As a consequence, the method of confocal fluorescence microscopy identifies the viable cells in the composition of cellular-tissue graft, and therefore allows to conduct the quality control of produced grafts.

Optical methods for the demineralization control of bone tissues

Elena V. Timchenko, Larisa A. Zherdeva (Taskina), Pavel E. Timchenko, Samara State Aerospace Univ. (Russian Federation); Larisa T. Volova, Samara State Medical Univ. (Russian Federation); Julia V. Ponomareva, Samara Medicine Univ. (Russian Federation)

The important step in obtaining of the bone biomaterial for defect substitution is a bone demineralization process - processing in an acidic solution, which leads to loss of most of the mineral components, while maintaining the proportion of collagen and proteins necessary for regeneration. Correctly selected of demineralization degree provides the perfect combination of osteoinductive and osteoconductive properties for successful bone regeneration.

Samples of cortical and cancellous bone tissue of «Lioplast» ® technology with different degrees of demineralization were used as objects of study. Raman spectroscopy (RS) was used to control of the demineralization degree of research objects. Change of mineral composition in experimental samples also was monitored by scanning electron microscopy.

The change of Raman band intensity at 1284 cm-1 (amide III region) and 2840 cm-1 (CH3 stretching vibration region) in the process of demineralization experimentally established. Using the spectrum deconvolution, the changes in the region 1200-1500 cm-1 (amide III), 1600-1700 cm-1 (amide I) and 900-1100 cm-1 (RO43- and SO32-) also were detected.

As a result, the demineralization process can be controlled using the ratio of ??43- and amide I, as well as the ratio of ??32- substitution B- and A-type. Raman spectroscopy results of change in the content of the mineral component with demineralization degree were compared with the results of scanning electron microscopy.

9584-42, Session PMon

Spectrally tunable femto-second Erbium fiber laser based on an all-normal-dispersion cavity

Zhiqiang Lv, Zibo Gong, Xing Lu, Peking Univ. (China); Kebin Shi, Peking Univ. (China) and Collaborative Innovation Ctr. of Quantum Matter (China)

Compared with solid state ultrafast lasers, femto-second fiber lasers possess unique properties such as compact, reliable, efficient and low-cost. However, the lacking of spectral tunability greatly limits its using in many applications. Recently fiber laser oscillators with all-normal-dispersion cavity have brought increasing interests due to their capability of avoiding wave-breaking under large nonlinear phase accumulation and consequently supporting higher pulse energy than those in dispersion-managed-soliton configurations. Pulse formations essentially undergo dissipative processes in all-normal-dispersion cavity where chirped pulse spectral filtering mechanism is necessarily adapted for stabilizing the mode-locking. All-normal-dispersion ytterbium fiber lasers operating at ~1?m spectral range were previously studied by utilizing different spectral filtering schemes such as birefringent filters and gratings. The works of erbium fiber oscillator is later published, but there is few work to use the gratings as a filter as well as the benefits of them are not fully developed in the works above. In this work, we report on a spectrally tunable erbium fiber oscillator by using grating based spectral filter consist of a grating and a fiber collimator. The center wavelength and the spectral bandwidth of the laser can be continuously tuned by translating collimator along the perpendicular direction of the grating output and varying the free space distance between the grating and collimator respectively.

9584-43, Session PMon

Ultrafast lattice dynamics in L10 phase FePt nanoparticles measured by MeV electron diffraction

Xiaozhe Shen, SLAC National Accelerator Lab. (United States)

We studied the ultrafast lattice dynamics of a next generation magnetic data storage material FePt using MeV electron diffraction. The sample studied was a free-standing 10nm thick film of aligned FePt grains in the L10 phase separated by Carbon segregants. Each grain is approximately 10nm in diameter, with the c axis orientated perpendicular to the film plane. Lattice dynamics was excited by a 50 fs laser of 800 nm wavelength, and probed by MeV electron pulses with 100 fs bunch length and 100 fC beam charge. The individual Bragg reflections of the electron beam from the FePt grains were resolved as a result of the high degree of alignment between grains. The transient response of (020), (111), (131), and (202) Bragg reflections was measured. It is determined that the thermal expansion along the c axis is an order of magnitude smaller than that along the a and b axes. The transient response can be separated into two characteristic motions

of the grain: a large anisotropic volume expansion, which occurs primarily in the film plane, followed by a volume conserving bulk oscillation. The resolved three dimensional ultrafast lattice dynamics in FePt nanoparticles provides important insight in electronic and lattice heat transport in this technologically important material. In addition, this experiment demonstrates the technique of MeV electron diffraction for high resolution time-resolved measurement of ultrafast lattice dynamics.

Determination of radionucluides concentrations in concrete raw materials via analytical technique

Mohamed M. ElFaham, Banha Univ. (Egypt); Osama M. Khalil, MIT Univ. (Egypt); Asmaa Elhassan, Tenth of Ramadan Institute (Egypt)

The presence of natural radionuclides in raw materials used in cement manufacturing was determined by using analytical methods to analyze the principle components of cement in order to achieve precise chemical proportions. The Raw materials used are limestone, clay, slag, and gypsum, which can be used with different concentration in cement production. The obtained data from our study is important for the development of standards materials and will be guidelines for use and the processing of these materials in cement production to assure high indoor air quality and to show that there is no significant radiological hazards arising from using the cement in house constructions.

9584-45, Session PMon

Coherent interference of a number of filaments as a step to superfilamentation

Daniil Shipilo, Vera Andreeva, Nicolay Panov, Olga G. Kosareva, Lomonosov Moscow State Univ. (Russian Federation); See Leang Chin, Laval Univ. (Canada)

Femtosecond filament is a unique nonlinear medium due to highly localized extended channel of radiation with the peak intensity of about 5·10^13 W/cm^2. However, it is quite complicated to overcome the clamped intensity in the filament. The possibility has been shown recently both theoretically and in the experiment. Theoretically, a fusion of two filaments has been predicted and intensity increase by 20% has been attained as compared with a single filament case [Laser Physics 19, 1776 (2009)]. In the experiment [Physical Review Letters 112, 223902 (2014)], 3 cm loosely focused beam with the peak power of about 200 critical powers for self-focusing has formed tens of filaments, which, after the merging, increased the electron density by a factor of 10 as compared with a single filament case. In the present work, the collision of four and more coherent filaments is considered. Such task is an intermediate step between relatively simple case of two filaments collision and complicated case of multi-terawatt beam. This task, on the one hand, allows us to reproduce the experiment qualitatively and, on the other hand, is relatively simple to analyze. Using Forward Maxwell Equation, we show that the collision of a several coherent filaments leads to intensity increase by 40% and the plasma density increase by 400%. Moreover, we demonstrate a significant (about 10 nm) blue shift of the frequency spectrum maximum from its original position at 800 nm.

Conference 9585: Terahertz Emitters, Receivers, and Applications VI

SPIE. OPTICS+ PHOTONICS OPTICAL ENGINEERING+ APPLICATIONS

Merging THz with optical waveguides for stabilization and modulation of quantum cascade lasers *(Invited Paper)*

Maria Amanti, Margaux Renaudat St-Jean, Univ. Paris 7-Denis Diderot (France); Alfredo Bismuto, Mattias Beck, Jérôme Faist, ETH Zürich (Switzerland); Carlo Sirtori, Univ. Paris 7-Denis Diderot (France)

In this work we present stabilization of the inter-mode separation of a quantum cascade laser (QCL) emitting at 9 ?m, via integration of the laser cavity with a double metal THz waveguide. Quantum cascade lasers are today very attractive powerful semiconductor light sources in a wide frequency range, spanning from the THz region up to 3?m wavelength in the mid-infrared. High frequency modulation and microwave injection at the round trip frequency of these sources are extremely interesting for application as free space communications and high resolution spectroscopy. In this work we present the design of QC laser dielectric guide embedded in a double metal line. In this structure the modulation field oscillating at GHz experiences reduced losses and it has an improved overlap with the optical mode respect to standard lasers. We present experimental results on direct modulation of these devices demonstrating a flat frequency response up to 14 GHz. We present the locking of the laser inter-mode spacing to an external stable source and its tuning in the MHz range. Properties of self stabilization of these cavities are also studied: narrow beating signal at the round trip frequency are presented with typical width of less than 100 kHz, more than one order of magnitude lower than in standard guide. This phenomenon will be presented in the frame of a nonlinear formalism based on the cascading of two second order susceptibilities. This process is demonstrated to be enhanced respect to other cavities by the specific double metal design presented in this work.

9585-3, Session 1

Recent progress of THz-quantum cascade lasers using nitride-based materials *(Invited Paper)*

Hideki Hirayama, Wataru Terashima, RIKEN (Japan)

We demonstrate the first lasing action of III-nitride-based quantum cascade lasers (QCLs). Nitride-based semiconductor is a material having a potential for realizing wide frequency range of QCL, i.e., 3-20 THz and 40-300 THz (1-8 μm) including the unexplored frequency range from 5 to 12 THz, as well as for realizing room temperature operation of THz-QCL, owing to high longitudinal optical phonon energies (ELO ?90 meV) and large band offset (1.8 eV). We fabricated GaN/AlGaN THz-QCLs with active layers consisting of 100-periods of 2 quantum well (QW) by molecular beam epitaxy (MBE) on a sapphire/AlN templates. Low threading-dislocation density (TDD) AlN templates were grown by metal-organic chemical-vapor deposition (MOCVD), which have been developed for use as deep-UV LEDs. A novel pure-3-level scheme design was introduced as an active layer, in order to obtain lasing from targeted levels. A single metal waveguide structure using Cu metal was fabricated. The cavity length and width were approximately 1.5 mm and 100 μm, respectively. A 5.5 THz lasing was obtained from the QCL measured under pulsed current injection at operating temperature of 5.6 K. The threshold current density (Jth) and the applying voltage (Vth) were 1.7 KA/cm2 and 16 V, respectively. We also fabricated GaN/AlGaN QCL by using MOCVD, and obtained 6.97 THz lasing measured at 5.2 K. The Jth of the QCL fabricated by MOCVD were 0.75 KA/cm2.

9585-4, Session 2

Electrically pumped semiconductor lasers with monolithic control of circular polarization *(Invited Paper)*

Federico Capasso, Harvard School of Engineering and Applied Sciences (United States)

As powerful semiconductor sources of mid-infrared and terahertz radiation open up new possibilities for the realization of compact and versatile spectroscopy and detection systems, monolithic control of the laser output characteristics becomes essential. While engineering of spectral characteristics and beam shape has reached a high level of maturity, manipulation of the polarization state remains a challenge. We present a method for monolithic control of the degree of circular polarization by aperture antennas forming a surface emitting grating on a semiconductor laser cavity, and demonstrate its realization for a terahertz quantum cascade laser [1] Our approach is not limited to the terahertz regime, and paves the way to an increased functionality and customizability of monolithic semiconductor laser sources for a variety of applications (e.g. vibrational circular dichroism spectroscopy).

Broadband and enhanced-output-power terahertz-wave emitter based on slot-antenna-integrated uni-traveling-carrier photodiode

Hiroshi Ito, Kitasato Univ. (Japan); Toshihide Yoshimatsu, Nippon Telegraph and Telephone Corp. (Japan); Hiroshi Yamamoto, Kitasato Univ. (Japan); Tadao Ishibashi, NTT Electronics Corp. (Japan)

Photomixing is a promising technique for generating continuous terahertz (THz) waves due to its superior features, such as extremely-wide frequency tunability, very narrow line-width, good frequency stability, and the capability of low-loss signal transmissions through flexible optical fibers. To further increase output powers of the photonic THz-wave emitter, implementation of a resonant antenna is effective. However, the resonant design usually deteriorates the bandwidth of the antenna, so the broadband feature of the photomixer is not effectively utilized. In this work, we integrated two types of slot antennas having relatively weak resonant characteristics with uni-traveling-carrier photodiodes (UTC-PDs) for increasing the THz-wave output powers while maintaining relatively large bandwidths. The fabricated devices were assembled in compact quasi-optical packages, and their output powers were compared with those for a broadband (non-resonant) bowtie-antenna-integrated device. The output powers of the slot-antenna-integrated devices were confirmed to be about two to three times larger at their peak frequencies than those of the broadband device. The output powers were enhanced at frequencies from 350 to 850 GHz for a wider-slot device and from 900 GHz to 1.6 THz for a narrower-slot device. These results agreed well with numerical analysis based on the HFSS. The typical output powers were 28 uW at 700 GHz and 3.5 uW at 1.25 THz both for a photocurrent of 10 mA with a bias voltage of only -0.4 V.

9585-6, Session 2

TeraFermi: The THz beamline at the FERMI Free Electron Laser

Cristian Svetina, Nicola Mahne, Lorenzo Raimondi, Andrea Perucchi, P. Di Pietro, Elettra-Sincrotrone Trieste S.C.p.A. (Italy); Marco Zangrando, Elettra-Sincrotrone Trieste S.C.p.A. (Italy) and IOM-CNR Lab. TASC (Italy)

TeraFERMI is the THz beamline for pump-probe studies on the femtosecond time-scale, under construction at the FERMI Free Electron Laser (FEL) facility in Trieste (Italy). The beamline will take advantage use of the coherent radiation emitted by the electrons already spent from the FEL undulators, before being dumped. This will result in short, coherent, high power THz pulses to be used as a "pump" beam, in order to modulate structural properties of matter, thereby inducing phase transitions. The intense THz pulses are also associated with a remarkably large transient magnetic field, to be used for controlling and manipulating magnetic states of matter. The modifications produced to the ionic and magnetic structures and the corresponding changes induced in the electronic properties will be probed by means of infrared spectroscopy from THz to visible. The domains of application of TeraFERMI will cover a wide range of fields from solid-state physics to biochemistry. We discuss here the source, the optical layout as well as the expected performances of the novel TeraFERMI beamline.

9585-7, Session 3

Negative differential resistance devices for generation of terahertz radiation *(Invited Paper)*

Heribert Eisele, Univ. of Leeds (United Kingdom)

In 1970, Esaki and Tsu proposed a unipolar device structure where Bragg reflection of miniband electrons in a semiconductor superlattice (SL) creates regions of negative differential velocity [1]. Superlattice electronic devices (SLEDs) utilize this effect. They have received much attention since the 1990s [2] because the underlying Bloch effect is associated with much shorter time constants than those of the transferred-electron effect in, for example, GaAs Gunn devices [3].

GaAs/AlAs SLEDs on integral heat sinks were evaluated from wafers grown at Cambridge and at Leeds [5]. The structures grown at Leeds were designed for estimated miniband widths [4] of more than 100 meV and had lengths suitable to achieve operation in D-band (110–170 GHz). SLED fabrication and packaging followed the same procedures as described in [5] except for some changes to facilitate much higher operating frequencies. The same type of top-hat WR-6 waveguide cavity was employed as was previously with fundamental-mode InP Gunn devices [6]. Examples of measured record output powers are 5.0 mW at 123.3 GHz, 2.2 mW at 134.9 GHz, 0.62 mW at 151.5 GHz, and 1.1 mW at 155.1 GHz, all in the fundamental mode, and 0.52 mW at 252.8 GHz in a second-harmonic mode.

Fundamental-mode operation at D-band frequencies was fully confirmed with second-harmonic power extraction and by testing tuneability. The above oscillation frequencies are the highest reported to date and approximately twice as high as those observed with GaAs Gunn devices [7]. Futhermore, these oscillation frequencies exceed those of InGaAs/InAlAs SLEDs [8] and the output powers around 150 GHz are also higher than those in [8]. This superior performance confirms the strong potential of SLEDs for achieving power generation up to at least 1 THz [5]. Substantial increases in output power are expected from optimized thermal management.

Tunnel injection transit-time diodes and Gunn devices have also been investigated for extraction of harmonics, in particular, third and higher harmonics [9]. One example is an oscillator at 480 GHz with an InP Gunn device [9], [10]. More recent measurements show that such third-harmonic power extraction from InP Gunn devices is feasible above 500 GHz [10].

The study of gas species on THz generation from laser-induced air plasma

Ji Zhao, Yuejin Zhao, Beijing Institute of Technology (China); Xiaomei Yu, Peking University (China)

Intense Terahertz waves generated from air-induced plasma and serving as broadband THz source provide a promising broadband source for innovative technology. Terahertz generation in selected gases has attracted more and more researchers' interests in recent years. In this research, the THz emission from different atoms is described, such as nitrogen, argon and helium in Michelson. The THz radiation is detected by a Golay Cell equipped with a 6-mm-diameter diamond-inputting window. It can be seen in the first time that when the pump power lies at a stable level, the THz generation created by the femtosecond laser focusing on the nitrogen is higher than which focusing on the helium, and lower than that produced in the argon gas environment. We believe that the THz intensity is Ar > N > Ne because of its atomic mass, which is Ar > N > Ne as well. It is clear that the Gas molecular decides the release of free electrons ionized from ultra short femtosecond laser through the electronic dynamic analysis. The higher the gas mass is, the stronger the terahertz emission will be. We further explore the THz emission at the different laser power levels, and the experimental results can be commendably quadratic fitted. It can be inferred that THz emission under different gas medium environment still complies with the law of four-wave mixing (FWM) process and has nothing to do with the gas environment: the radiation energy is proportional to the quadratic of incident laser power.

9585-9, Session 3

TE and TM THz intervalence band polaritons and antipolaritons

Mauro F. Pereira, Inuwa A. Faragai, Sheffield Hallam Univ. (United Kingdom)

The interaction of THz cavity modes with intervalence transitions can improve the quantum efficiency of THz-polaritonics devices. These devices have strong potential for applications in spectroscopy, imaging and improved data transmission in communications and ultra-strong coupling of THz radiation with intersubband transitions which can further improve the applicability of polaritonics. Conduction band-based polariton coupling is restricted to the TM mode. However, the fact that valence subband transitions can be coupled with both TE and TM modes polarized cavity modes, stimulated us to extend our studies of TE valence band polaritons [M.F. Pereira and I. A. Faragay, Optics Express 22, 3439 (2014).] by comparing results obtained for THz polaritons and antipolaritons for the two possible modes. Both cases are investigated for different cavities and excitation conditions and the possibility of switching between one mode to the other with a large change in resonant frequency and polariton splittings are discussed. The strong nonparabolicity and k-dependence of the

transition dipole moment has a very strong role in the shifting of effective resonance frequencies between TE and TM modes for the same transition. The numerical results presented can stimulate further experimental investigations for a deeper understanding of the valence band coupling scenario and have potential for applications in which a simple design with two possible outputs with different polarizations and resonant frequencies could be of relevance.

9585-10, Session 3

Research on Output Characteristics of optically pumped THz gas laser

Xiaoyang Guo, Renshuai Huang, Qinglong Meng, Bin Zhang, Sichuan Univ. (China)

The model of the output of optically pumped THz gas laser has been established on the basis of the rate equations theory. And the influence of the Two-Photon light shift (TPLS) on the THz frequency has been analyzed theoretically. The effect of various factors on the output power and frequency of the optically pumped THz gas laser has been discussed numerically and theoretically. Results indicate that, the output THz power increases first and then decreases gradually with the increasing pressure of the gas, while it continues to grow due to the increasing pumping power within certain range. However, increasing the pump laser power may degrade the THz frequency stability to some extent. With given pump laser power, the THz frequency shift caused by TPLS increases first and then decreases with the increasing pump laser frequency offset drifting from the vibrational transition line-center. In addition, the THz frequency shift may be reduced gradually by increasing the pressure of the gas and the operating temperature. Results provide significant guidance for improving energy conversion efficiency and frequency stability in optically pumped THz gas laser.

9585-11, Session 3

Terahertz generation via asymmetric Cherenkov radiation in LiNbO3

Elena V. Svinkina, N.I. Lobachevsky State Univ. of Nizhni Novgorod (Russian Federation)

One of the most efficient optical-to-terahertz converters is the structure consisting of a layer (30-50 μm thick) of LiNbO_3 (LN) attached to a Si-prism outcoupler. A femtosecond laser pulse propagates in the LN layer as a guided mode and produces nonlinear polarization, which emits terahertz Cherenkov radiation to the Si prism. An inherent disadvantage of the converter is a dip in the generated terahertz spectrum originating from the destructive interference of the terahertz waves emitted to the Si prism from the LN layer directly and after reflections from the layer boundaries.

We propose to remove the spectral dip by using the spatial asymmetry of the Cherenkov radiation from a moving nonlinear polarization, which is tilted with respect to the direction of motion.

The crystallographic axes in LN can be arranged in such a way that the line-like nonlinear polarization, produced by a focused-to-a-line pump laser pulse, will be almost orthogonal to the electric field E (tilted with respect to the displacement D) on a half of the Cherenkov wedge. As a result, this half-wedge will be practically not generated.

We propose to apply this phenomenon to suppressing the interference effects in one of the most efficient optical-to-terahertz converters. A null in the emission spectrum of the converter, which limits its application possibilities, can be eliminated.

9585-12, Session 4

Microscopic view on carrier dynamics in Landau-quantized graphene *(Invited Paper)*

Ermin Malic, Chalmers Univ. of Technology (Sweden); Florian Wendler, Andreas Knorr, Technische Univ. Berlin (Germany); Martin Mittendorff, Stephan F. Winnerl, Manfred Helm, Helmholtz-Zentrum Dresden-Rossendorf e. V. (Germany)

We present a microscopic view on the time-resolved carrier dynamics in Landau-quantized graphene. In the presence of a strong magnetic field, graphene exhibits non-equidistant Landau levels. Due to specific optical selection rules, single Landau-level transitions can be selectively excited and probed with circularly polarized light

Based on the density matrix formalism, we derive graphene Bloch equations allowing us to resolve the efficiency of Coulomb- and phonon-induced relaxation channels determining the inter-Landau-level dynamics [1-4]. Surprisingly, our calculations reveal that Auger scattering plays the crucial role despite the non-equidistant spacing between the Landau levels [1]. In most cases, scattering with optical phonons is strongly suppressed due to the mismatch of the phonon energy and the Landau-level separation [2]. In contrast, Auger scattering is highly efficient and can lead to a significant carrier multiplication [3]. Furthermore, we show that Auger-induced depopulation of Landau levels can even be faster than the optical pumping resulting in unexpected features in polarization-resolved pump-probe spectra [1]. Finally, we demonstrate that Auger scattering can be even exploited to generate a population inversion in Landau-quantized graphene suggesting the design of novel Landau level lasers that can be tuned over a wide spectral range [4].

Microscopic theory for the optical properties of dilute semiconductors

Mauro F. Pereira, Chijioke I. Oriaku, Sheffield Hallam Univ. (United Kingdom)

Dilute semiconductors have a strong potential for THz generation, with an extra degree of freedom with controllable fundamental gaps and effective masses at both valence and conduction band methods. However, before intersubband designs that can reach THz frequencies can be delivered, the properties of bulk materials must be fully understood. This paper explains hitherto not clearly understood features in the luminescence spectra of dilute nitrides, bismides and antimonides structures through a combination of many body and inhomogeneous broadening effects, as well as the unexpected influence of strain in samples expected to be relaxed. A seemingly anomalous temperature dependence of the luminescence peak emission is explained and that can have a strong impact in the design of future sources and detectors for the far infrared including interband Mid Infrared and intersubband THz sources. The simple and accurate analytical approximations delivered can be easily programmed and include the main many body effects required to describe bulk semiconductors. The luminescence is connected to the nonlinear absorption and gain and the expressions delivered reduce exactly to Elliott's formula in the low density limit. This leads to a very powerful tool to investigate new materials, starting e.g. from ab initio calculations and has potential for a major impact in the development of new bulk materials for efficient solar cells and for mid infrared radiation generation and detection. The level of agreement between the theory and experimental data clearly demonstrates the power and accuracy of the approach.

(United States); Ki Won Yoon, Stanford Univ. (United States)

Since its discovery, the cosmic microwave background (CMB) has played a pivotal role in cosmology and particle physics. As such, CMB science is led by detector innovation. The frontier of CMB detector development is focused on improving bolometric detectors based on Transition Edge Sensors (TES). Currently, the most competitive CMB detector technologies utilize superconducting microstrip lines to couple radiation on to TES bolometers. Developing low loss microstrip technology makes possible to use in-line filters to define optical detector pass bands, allowing for the fabrication of multi-chroic pixels. In this sense, this work presents the development and characterization of low loss superconducting Nb microstrips to support the fabrication of mm-wave multi-chroic pixels for the upcoming SPT-3G experiment.

To characterize the microstrip loss, a series of half-wavelength microstrip resonators capacitively coupled to a Coplanar Waveguide feedline (CPW) have been fabricated. These resonators consist of 300 nm thick Nb ground plane, 500 nm thick silicon dioxide dielectric spacer, and a 300 nm thick Nb transmission layer. The Nb ground layer and Nb microstrip are deposited by DC magnetron sputtering, whereas SiO2 films deposited both by reactive sputtering and by plasma enhanced chemical vapor deposition (PECVD) are evaluated. The microstrip loss at a few GHz frequencies is determined by measuring the shift in a resonator's resonance frequency as a function of temperature. The measured loss tangent for Nb microstrips deposited on sputtered silicon dioxide is 1.3 x 10-3. Microstrips deposited on PECVD SiO2 films showed a loss tangent as low as 2.1 x 10-3.

9585-15, Session 4

Relativistic Doppler frequency up-conversion of terahertz pulses via reflection from photo-induced plasma fronts in solid-state media *(Invited Paper)*

Mark D. Thomson, Fanqi Meng, Hartmut G. Roskos, Johann Wolfgang Goethe-Univ. Frankfurt am Main (Germany)

We present experimental and theoretical results concerning the use of the relativistic Doppler effect to induce a frequency up-shift for terahertz pulses, reflecting from a charge-carrier plasma front in solid-state media. The plasma front is excited with femtosecond amplifier-laser pulses, and we focus on conventional semiconductors, such as undoped Si and GaAs. Besides offering a possible scheme for extending the bandwidth of existing high-field THz sources, the Doppler geometry constitutes a novel approach to probe the initial charge-carrier dynamics, as any up-shifted radiation arises chiefly due to interaction with the plasma front. This is demonstrated in our Doppler experiments on Si, where the data can be reconciled by assuming an effective Drude scattering time well below 10 fs, i.e. much shorter than that found for the thermalized plasma (~20 fs), which we determined vs. excitation density in additional pump-probe experiments with ultra-broadband THz-mid-infrared probe pulses.

The impact of these charge-carrier dynamics, as well as optical excitation parameters, on the Doppler interaction is investigated with a series of finite-difference time-domain (FDTD) simulations which allow a detailed description of the spatio-temporal interaction between the counter-propagating pump and probe pulses. We also discuss other material systems which might allow one to enhance the performance of the Doppler up-shift, or where the Doppler geometry could offer a unique probe of the photoexcitations.

9585-16, Session 5

TERA-MIR radiation: Materials, generation, detection, and applications *(Invited Paper)*

Mauro F. Pereira, Sheffield Hallam Univ. (United Kingdom)

This paper summarizes the joint progress in different projects in the THz field achieved by the teams in COST ACTION MP1204: TERA-MIR radiation: materials, generation, detection and applications. The results achieved benefit from the unique networking and capacity-building capabilities provided by the COST framework to unify these two spectral domains from their common aspects of sources, detectors, materials and applications. We are building a platform to investigate interdisciplinary topics in Physics, Electrical Engineering and Technology, Applied Chemistry, Materials Sciences and Biology and Radio Astronomy. In this sense THz and MIR are considered jointly, the driving force for both regimes being applications. The main emphasis of the research presented here is on new fundamental material properties, concepts and device designs that are likely to open the way to new products or to the exploitation of new technologies in the fields of sensing, healthcare, biology, and industrial applications. End users are: research centres, academic, well-established and start-up companies and hospitals. The strong coupling of THz radiation and material excitations has potential to improve the quantum efficiency of THz devices.

9585-17, Session 5

High effective algorithm of the detection and identification of substance using the noisy reflected THz pulse

Vyacheslav A. Trofimov, Svetlana A. Varentsova, Vladislav V. Trofimov, Lomonosov Moscow State Univ. (Russian Federation)

We demonstrate principal limitations of standard approach of TDS based on broadband THz pulse for the detection and identification of substance To avoid of these limitations we propose new high effective algorithm for this purpose. We demonstrate its applicability in real situation forvarious substances under consideration.

9585-18, Session 5

Development of ultra-broadband terahertz time domain ellipsometry *(Invited Paper)*

Masatsugu Yamashita, Chiko Otani, RIKEN (Japan)

We present a reflection-type ultra-broadband terahertz (THz) time-domain spectroscopic ellipsometry (THz-TDSE) system covering the frequency range of 0.5–30 THz. GaP (110) and z-cut GaSe crystals are used as emitters to generate the THz and mid-infrared pulses, respectively, and a photoconductive antenna switch using a low-temperature grown GaAs epitaxial layer transferred on Si substrate was used as a detector. By changing the emitter between the GaP and GaSe crystals, the measurable frequency range can be easily switched from the 0.5–7.8 THz range to the 7.8–30 THz range without additional optical alignment. We demonstrated the measurement of the dielectric function in a p-type InAs wafer and the optical conductivity of an indium tin oxide (ITO) thin film. The obtained carrier density and the mobility of the ITO thin film show good agreement with that obtained by the Hall measurement.

9585-19, Session 5

Numerical analysis of a terahertz transmission line resonator for heterodyne photomixing

Lars Juul, Inverto Digital Labs (Luxembourg); Martin Mikuli?, Forschungszentrum Jülich GmbH (Germany); Michel Marso, Univ. du Luxembourg (Luxembourg); Mauro F. Pereira, Sheffield Hallam Univ. (United Kingdom)

Substantial progress has been achieved in the area of CW terahertz sources over the last decade, including highly effective Quantum Cascade Lasers, negative differential resistance devices and terahertz multipliers, but heterodyne photomixing remains far from obsolete. THz photomixers have become commercially available for CW spectroscopy applications and are still among the simplest methods for THz-generation in terms of device complexity and fabrication. In addition, stacked InGaAs and InAlAs quantum well structures have been shown to have a low carrier lifetime and a band gap of 1.55um enabling the use of less costly optical sources.

Using the numerical method presented in [Juul et al, Optical and Quantum Electronics, DOI 10.1007/s11082-014-0048-3], we present a novel and tantalisingly simple terahertz photomixer structure based on a conventional photoconductor driving a coplanar stripline (CPS) terminated with a multilayer capacitance and RF-chokes doubling as bond pads for the photoconductor bias circuit. The transmission line is a better and more compact inductive reactance element than a comparable uniplanar meander structure and contributes to a higher radiation resistance of the resonant circuit.

The design leads to a predicted a radiated power of close to 15 uW at 0.85 THz, which is a five fold improvement over [Duffy et al, IEEE Transactions on Microwave Theory and Techniques 49(6):1032–1038, 2001]. The current distribution on the transmission line indicates a linear polarisation of the radiated power.

The layout features of the design are intentionally conservative and can be produced with conventional, inexpensive photolithographic methods.

9585-20, Session 5

High transmittance silicon terahertz polarizer using wafer bonding technology

Ting-Yang Yu, Hsin-Cheng Tsai, National Chiao Tung Univ. (Taiwan); Shiang-Yu Wang, Academia Sinica (Taiwan); Chih-Wei Luo, Kuan-Neng Chen, National Chiao Tung Univ. (Taiwan)

Increasing the efficiency of THz system with reduced cost is still the most essential task, because of the difficulties in fabricating robust THz optical components with low Fresnel reflection loss. In this report, a new low cost THz polarizer with robust structure is proposed and demonstrated. This new THz wire grid polarizer was based on single anti-reflection layers fabricated with low temperature metal bonding and deep reactive-ion etching (DRIE). After patterning Cu wire gratings and the corresponding In/Sn solder ring on the individual silicon wafers, the inner gratings were sealed by the Cu to In/Sn wafer bonding guard ring providing the protection of humidity oxidation and corrosion. With the low eutectic melting point of In/Sn solder, wafers could be bonded face to face below 150˚C. Two anti-reflection layers on both outward surfaces were fabricated by DRIE. With the mixing of empty holes and silicon, the effective refractive index was designed to be the square root of the silicon refractive index. The central frequency of the anti-reflection layers was designed between 0.5THz to 2THz with bandwidth about 0.5THz. The samples were measured with a commercial free-standing wire grid polarizer by a THz time domain spectroscopy from 0.3THz to 2THz. The power transmittance of the sample is close to 100% at central frequency. Extinction ratio of the polarizer is between 20dB to 40dB depending on the frequency and the Cu wire pitch. The advantages of this new polarizer include high transmittance, robust structure, low cost and no precision alignment required.

9585-21, Session 6

Terahertz detector arrays based on nanometer field effect transistors *(Invited Paper)*

Wojciech Knap, Univ. Montpellier 2 (France); J. Marczewski, Institute of Electron Technology (Poland); Dmytro B. But, Univ. Montpellier 2 (France); Nina V. Dyakonova-Cywinski, Institute of High Pressure Physics (Poland); Maciej Sypek, Warsaw Univ. of Technology (Poland)

We propose an overview of some recent results concerning THz detection related to plasma nonlinearities in nanometer field effect transistors[1,2]. The subjects were selected in a way to show physics related limitations and advantages rather than purely technological/engineering improvements of nanometer Field Effect transistors (FETs) working as Terahertz detectors. We address the basic physics related problems like temperature dependence, of the response [3], helicity sensitive detection [4] and nonlinear/saturation response at high incident power [5]. We present also the first results on new THz detectors based on Si junction-less FETs [6]. The results will be discussed in view of the physical and technical limitations of THz detector arrays based on Field Effect Transistors [7].

The observed high incident power photoresponse nonlinearity is explained by nonlinearity/saturation of the transistor channel current. The theoretical model of terahertz field effect transistor photoresponse at high intensity was developed.

The results show that dynamic range of field effect transistors is very high and can extend over more than six orders of magnitudes of power densities

(from ~0.5 mW/cm2 to ~5 kW/cm2). Nonlinear and saturation regions of detections are seen for intensities above 1kW/cm2.

Silicon based FETs are the most promising for THz focal plane arrays. Standard technology Si –MOSFETS have an important responsivity limitation related to the p-n junction capacitance short-circuiting the incoming THz signals. The new junction-less Si technology transistors based THz detectors will be presented. They show amazingly high signal to noise ratio and unusual – still unexplained-THz responsivity versus gate voltage dependence [6]. We will present also recent results on arrays of GaN and GaAs FET based THZ detectors in view of their applications to on-line nondestructive testing and imaging [7].

On-chip integration solutions of compact optics and detectors in room-temperature terahertz imaging systems

Gintaras Valu?is, Linas Minkevi?ius, Vincas Tamo?i?nas, Irmantas Ka?alynas, Rimvydas Venckevi?ius, Karolis Madeikis, Bogdan Voisiat, Dalius Seliuta, Gediminas Ra?iukaitis, Ctr. for Physical Sciences and Technology (Lithuania)

Reduction of dimensions in room-temperature terahertz (THz) imaging systems remains one of the most challenging tasks in employment them for direct practical applications.

In this communication, we discuss solutions in miniaturization of the THz image recording setup employing compact optics based on zone plates [1] and their on-chip integration with InGaAs-based bow-tie THz detectors [2].

Conventional, inverted and combined zone plates with integrated band-pass filters [1] were designed numerically using the 3D finite-difference time-domain method and produced using laser direct writing technique. Performance of the plates was studied experimentally comparing results with simulated ones. Spatial profiles of the concentrated radiation in the focal plane at the resonant frequency of 0.6 THz are demonstrated and focal depth influence is considered. To investigate the effect of Fabry-Perot resonances phase zone plate made on the silicon substrate was studied in the same experiments.

We demonstrate one order of magnitude detection enhancement of bow-tie-shaped InGaAs-based terahertz detectors at 0.76 THz by on-chip incorporation of the secondary diffractive optics [3].

Good correlation of the experimental and theoretical results shows that the observed enhancement is resulting from the focusing performance of the zone plate rather than by the sensitivity of the single detector.

Plasmonic enhancement of sensitivity in terahertz (THz) photo-conductive detectors

Oleg Mitrofanov, Univ. College London (United Kingdom) and Sandia National Labs. (United States); Ting Shan Luk, Igal Brener, John Reno, Sandia National Labs. (United States)

We demonstrate enhancement of sensitivity in terahertz photoconductive detectors achieved by incorporation of plasmonic structures into the photo-conductive region of the detector. Auston switches based on low-temperature grown GaAs (LT GaAs) have been reliably used for detection of THz pulses over two decades. This material exhibits high electron mobility with sub-picosecond carrier lifetimes and high dark resistivity. This combination is difficult to achieve in other materials. Application of LT GaAs in THz devices is nevertheless limited due to absorption characteristics of this material. Plasmonic structures can be employed to modify the distribution of the optical field in the photoconductive region and hence modify the response of the THz photoconductive detectors.

We will discuss design of plasmonic structures to enhance the response of THz detectors based on LT GaAs and demonstrate incorporation of such structures into THz detectors. We also apply the developed design in integrated photo-conductive probes for THz near-field microscopy, where the enhancement of the material absorption translates into an increase of the detector sensitivity and an improvement in spatial resolution. Performance on these near-field probes that provide a spatial resolution of 3-5 micrometers (~1/100 of the wavelength) will be discussed and demonstrated.

9585-24, Session 6

Theoretical and experimental study on the response of Golay detector to the pulsed light

Weitao Wang, Zhenhua Cong, Xiaohan Chen, Xingyu Zhang, Zengguang Qin, Guanqi Tang, Ning Li, Qiang Fu, Shiqi Jiang, Shandong Univ. (China)

Golay Cells are generally applied to measure the average powers and the pulse energies of the light sources from the ultraviolet to the THz and millimeter waves due to their widely response wavelength range and high efficiency. The manufacturers provide their power responsivities to the continuous wave light signals, while the calibration of their energy responsivities for short pulses is rarely investigated and pendent. In this paper we present a theoretical and experimental study on the response of a Golay Cell (GC-1D, TYDEX) to the pulsed light.

The theoretical expression for the Frequency Transfer Function (FTF) of the Golay Cell together with the oscilloscope with AC-coupling (Tek, TDS 5052B) is first derived. It can be expressed as the function of a wavelength-dependent parameter K and two time parameters T1 and T2. By using the experimental results of an incident 1064 nm step signal, three parameters are determined to be K = 0.101 MV/W, T1 = 0.029 s and T2 = 0.485 s. The response of the Golay Cell to the light pulse is then calculated based on the verified FTF. It is found that, for pulses whose duration is much smaller than T1 and T2, if the response voltage u is defined as the voltage difference between the beginning of the pulse and the maximum value in the waveform, the energy responsivity Rp (the ratio of u to the pulse energy

E) will be (1/T1-1/T2)K. It is independent of the pulse duration and repetition frequency. The experimental results agree well with the calculated results. For THz waves, K is different while T1 and T2 keep the same.

Coherent detection for continuous terahertz wave

Hui Yuan, Tielin Lu, Yuejin Zhao, Beijing Institute of Technology (China); LiangLiang Zhang, Cunlin Zhang, Capital Normal Univ. (China)

We demonstrate a coherent raster-scan imaging system that can acquire phase information based on continuous terahertz imaging. It mixes the terahertz with a femtosecond laser at a electro-optic zinc telluride(ZnTe) crystal to make a hybrid modulation on the ZnTe crystal to achieve continuous terahertz detection. It can not only propagate for a long distance but also achieve phase detection for continuous terahertz imaging. The surface images of objects that are under test can be obtain with a BWO(backward-wave oscillator) output power of 10mW at 205.994GHz and a MaiTai laser output power of 1W and 100fs pulse light at 800nm with repetition frequency of 80MHz. The images can achieve diffraction-limited resolution approximately. And the results show that the system can obtain phase imaging of test objects based on continuous terahertz source. And it has significant meaning for coherent detection of continuous terahertz source. And it makes significance for development of coherent detection for continuous terahertz wave.

9585-25, Session 7

Multifrequency high precise subTHz-THz_IR spectroscopy for exhaled breath research *(Invited Paper)*

Vladimir L. Vaks, Institute for Physics of Microstructures (Russian Federation) and N.I. Lobachevsky State Univ. of Nizhni Novgorod (Russian Federation)

Nowadays the development of analytical spectroscopy with high performance, sensitivity and spectral resolution for exhaled breath research is attended. The method of two-frequency high precise THz spectroscopy and the method of high precise subTHz-THz-IR spectroscopy are presented. Development of a subTHz-THz-IR gas analyzer increases the number of gases that can be identified and the reliability of the detection by confirming the signature in both THz and MIR ranges. The testing measurements have testified this new direction of analytical spectroscopy to open widespread trends of its using for various problems of medicine and biology. First of all, there are laboratory investigations of the processes in exhaled breath and studying of their dynamics. Besides, the methods presented can be applied for detecting intermediate and short time living products of reactions in exhaled breath. The spectrometers have been employed for investigations of acetone, methanol and ethanol in the breath samples of healthy volunteers and diabetes patients. The results have demonstrated an increased concentration of acetone in breath of diabetes patients. The dynamic of changing the acetone concentration before and after taking the medicines is discovered. The potential markers of pre-cancer states and oncological diseases of gastrointestinal tract organs have been detected. The changes in the NO concentration in exhaled breath of cancer patients during radiotherapy as well as increase of the NH3 concentration at gastrointestinal diseases have been revealed. The preliminary investigations of biomarkers in three frequency ranges have demonstrated the advantages of the multifrequency high precise spectroscopy for noninvasive medical diagnostics.

9585-26, Session 7

Toward THz imaging of human eye: Direct mapping of corneal tissue water content with THz imaging

Shijun Sung, Somporn Chantra, Neha Bajwa, Ryan McCurdy, Gintare Kerezyte, James Garritano, Jean-Pierre Hubschman, Univ. of California, Los Angeles (United States); Sohpie X. Deng, Univ. California, Los Angeles (United States); Warren Grundfest, Zachary Taylor, Univ. of California, Los Angeles (United States)

THz imaging applied in ocular tissue water content sensing can address shortfalls in current clinical challenges of accurately measuring corneal hydration. Hydration sensing ability in THz band can also be a powerful tool in ophthalmologic science, as many pathologies such as Fuchs' endothelial Dystrophy, and pseudophakic bullous keratopathy result in increased corneal tissue water content (CTWC).

This paper presents a pilot study of edema an in vivo rabbit model and demonstrates a significant difference between THz reflectivity in the control group and treatment group in which the water content of the cornea was perturbed through surgical means.

The endothelium of the cornea was surgically excised and the resulting increase in corneal tissue water content was monitored by a non-contact THz imaging system and compared with current clinical standard of corneal pachymetry (central corneal thickness measurement). We demonstrate direct measurement of CTWC in in-vivo is possible with ~ 2mm spatial resolution. The technique is robust, sensitive, and does not rely on assumptions of healthy cornea central thicknesses. This allows the technology to be robust to physiologic variation and feasible to be translated into clinical application. Imaging system design and optical engineering challenges associated with ophthalmologic applications are also presented.

9585-27, Session 7

New way for both quality enhancement of THz images and detection of concealed objects

Vyacheslav A. Trofimov, Vladislav V. Trofimov, Lomonosov Moscow State Univ. (Russian Federation)

We developed new real-time algorithm, based on the correlation function, for the detection of concealed objects by using computer processing of the passive THz images without their viewing. This algorithm allows us to make a conclusion about presence of forbidden objects on the human body. To see this object with high quality we propose one more algorithm which allows to increase the image quality. Current approach for computer processing of the THz images differs from approaches developed by us early.

We apply new algorithms with success to the images captured by passive THz camera TS4 manufactured by ThruVision Inc. The distance between the camera and person is changed from 4 to 10 metres.

9585-28, Session 7

Ultrafast field-resolved multi-THz spectroscopy on the sub-nanoparticle scale *(Invited Paper)*

Tyler L. Cocker, Max Eisele, Markus A. Huber, Markus Plankl, Univ. Regensburg (Germany); Leonardo Viti, Daniele Ercolani, Lucia Sorba, Miriam S. Vitiello, Scuola Normale Superiore (Italy); Rupert Huber, Univ. Regensburg (Germany)

Over the past 20 years, terahertz and multi-terahertz spectroscopy have provided valuable insights into ultrafast carrier dynamics in nanomaterials. Nevertheless, researchers have had to contend with various effective medium theories to extract nanoscale information, and have been limited to studying ensembles of nano-objects. Conversely, scattering-type near-field scanning optical microscopy (s-NSOM) in the mid-infrared can measure the dielectric properties of surface features as small as 10 nm. Until very recently, though, ultrafast near-field studies in the infrared had not been reported. Here, we demonstrate a combination of ultrafast multi-terahertz spectroscopy with s-NSOM that achieves simultaneous sub-cycle temporal resolution and 10 nm spatial resolution: Phase-stable multi-terahertz pulses are coupled to the tip of the s-NSOM and the scattered electric near-field is detected by electro-optic sampling. The broad phase-matching bandwidth of the GaSe detection crystal ensures that the oscillating electric near field is recorded with a time resolution defined by the duration of the electro-optic gate pulse (10 fs). Meanwhile, the 10 nm spatial resolution of our nano-spectroscopy is given by the radius of curvature of the s-NSOM tip apex, which was confirmed by electro-optic line scans. We have applied our novel microscope to the study of photoinduced carrier dynamics in isolated InAs nanowires. Ultrafast imaging provides a map of the photoinduced carrier density, while nano-spectroscopy reveals the local evolution of the plasma frequency. Finally, by using the tapping amplitude of the s-NSOM tip to control the nano-spectroscopy probing volume, we observe the build-up of a carrier depletion layer on the nanowire surface.

9585-29, Session 7

Exploration of burn wound induction parameters on wound edema

Neha Bajwa, Ctr. for Advanced Surgical and Interventional Technology (United States); Shijun Sung, James Garritano, Ctr. for Advanced Surgical & Interventional Technology (United States); Michael Fishbein, Univ. of California, Los Angeles (United States); Warren Grundfest, Zachary Taylor, Ctr. for Advanced Surgical & Interventional Technology (United States)

The high contrast resolution afforded by terahertz (1 THz = 1012 Hz) imaging of physiologic tissue continues to drive explorations into the utility of THz technology for burn wound detection. Although we have previously reported the use of a novel, reflective THz imaging technology to sense spatiotemporal differences in reflectivity between partial and full thickness burn wounds, no evidence exists of a one-to-one correlation between structural damage observed in histological assessments of burn severity and THz signal. For example, varying burn induction methods may all result in a particular burn classification, however, burn features observed in parallel THz imagery may not be identical. Successful clinical translation of THz technology as a comprehensive burn guidance tool, therefore, necessitates an understanding of THz signal and its relation to wound pathophysiology. This work aims to perform THz imaging of in vivo rat burn wounds (n=4) induced using multiple brands (~ 20 mm x 4 mm rectangular brass heads with varying topology on the inferior side) to investigate the effects of contact brand geometry on THz reflectivity signal. Steps toward exploring the sensitivity of THz imaging to varying burn tissue boundaries (rigid vs curved) will help define the ultimate potential of the technology as well as lead to better design of instrumentation and analytical techniques to delineate tissue regions for effective and accurate prognosis.

9585-30, Session 7

Investigation of pharmaceutical drugs and caffeine-containing foods using Fourier and terahertz time-domain spectroscopy

Gintaras Valu?is, Mindaugas Karali?nas, Rimvydas Venckevi?ius, Irmantas Ka?alynas, Ctr. for Physical Sciences and Technology (Lithuania); Uro? Puc, Andreja Abina, Anton Jegli?, Aleksander Zidan?ek, Jo?ef Stefan Institute (Slovenia)

Feature of terahertz (THz) radiation to penetrate through paper- or plastic-based packaging can be not only used in development of security systems to observe hidden objects via THz imaging, but also be served as a powerful tool for identification of various materials employing spectroscopic approaches.

In this work, several pharmaceutical drugs like ascorbic acid, melatonin, etc. as well as caffeine-containing foods were tested using terahertz time-domain spectroscopy (TDS) and Fourier spectroscopy (FS).

The dry powder of pharmaceutical drugs was mixed with polyethylene and pressed into the pellets using hydraulic press. The coffee grounds were also pressed into the pellets after ball-milling and mixing with polyethylene powders. The caffeine-containing liquid foods were dried out on the paper strips of various stacking.

TDS experiments were carried out employing T-Spec (Teravil Ltd) commercial spectrometer in combination with a femtosecond laser (Toptica, Femto Fiber Pro) having 800 nm emission wavelength, less than 90 fs pulse duration and 80 MHz repetition rate for THz generation and detection. Additionally, TDS system based on organic electrooptic crystals was used [1]. Samples transmission spectra at frequency range of 0.3-10 THz with the resolution of 1 cm-1 were measured by the Fourier spectrometer with vacuum option.

Experiments allowed one to determine characteristic spectral signatures within THz range of the objects under test. Spectroscopic THz imaging approach [2] was considered as possible option to identify packaged pharmaceutical drugs.

9585-31, Session 8

Quantum spin dynamics at terahertz frequencies in 2D hole gases and improper ferroelectrics *(Invited Paper)*

James Lloyd-Hughes, The Univ. of Warwick (United Kingdom)

Terahertz time-domain spectroscopy permits the excitations of novel materials to be examined with exquisite precision. Improper ferroelectric materials such as cupric oxide (CuO) exhibit complex magnetic ground states. CuO is antiferromagnetic below 213K, but has an incommensurate cycloidal magnetic phase between 213K and 230K. Remarkably, the cycloidal magnetic phase drives ferroelectricity, where the material becomes polar. Such improper multiferroics are of great contemporary interest, as a better understanding of the science of magnetoelectric materials may lead to their application in actuators, sensors and solid state memories. Improper multiferroics also have novel quasiparticle excitations: electromagnons form when spin-waves become electric-dipole active. By examining the dynamic response of spins as they interact with THz radiation we gain insights into the underlying physics of multiferroics.

In contrast to improper ferroelectrics, where magnetism drives structural inversion asymmetry (SIA), two-dimensional electronic systems can exhibit non-degenerate spin states as a consequence of SIA created by strain and/or electric fields. We identify and explore the influence of the Rashba spin-orbit interaction upon cyclotron resonance at terahertz frequencies in high-mobility 2D hole gases in germanium quantum wells. An enhanced Rashba spin-orbit interaction can be linked to the strain of the quantum well, while a time-frequency decomposition method permitted the dynamical formation and decay of spin-split cyclotron resonances to be tracked on picosecond timescales. Long spin-decoherence times concurrent with high hole mobilities highlight the potential of Ge quantum wells in spintronics.

9585-32, Session 8

THz polarization difference imaging of aqueous targets

Shijun Sung, Neha Bajwa, Ryan McCurdy, Gintare Kerezyte, James Garritano, Warren Grundfest, Zachary Taylor, Univ. of California, Los Angeles (United States)

This paper describes the basic design, implementation, and testing of a polarization difference imaging system for use on aqueous targets. The ultimate performance limitation of THz imaging in many active areas of research is clutter from surface geometry. While the signal to nose ratio (SNR) of standard THz imaging systems are quite large, the signal to clutter ratio (SCR) often faced in an imaging application is orders of magnitude lower and, in many cases, lower than the contrast to noise (CNR) resulting in imagery where the contrast mechanism of interest does not significantly contribute to the overall observed contrast.

To overcome these limitations we developed a system that uses a circularly polarized source, polarization demultiplexer, and linearly polarized detectors to resolve the transverse electric (TE) and transverse magnetic (TM) reflectivities of a target simultaneously. The targets were illuminated at an oblique incidence angle thus creating a difference in reflectivites of the two polarizations and enabling a differential measurement.

Tissue mimicking phantoms were fabricated using hydrogels with spatially varying water content and modified with a range of surface topologies and surface roughness. The results indicated that the imaging field clutter affected both polarization channels nearly equally allowing the system to resolve differences in phantom water content. This design holds significant promise for clinical translation where patient imaging is dominated by clutter.

9585-33, Session 8

Nonlinear dynamics in THz metamaterials: From impact ionization to field emission *(Invited Paper)*

Richard D. Averitt, Univ. of California, San Diego (United States)

Recent advances in the generation of picosecond high-field terahertz pulses enables novel studies of nonlinear dynamics in materials ranging from semiconductors to correlated electron materials. Suitably designed metamaterials localize and enhance the electric and magnetic fields of incident terahertz pulse pulses.This talk will describe our recent results in this area which includes creating superconducting perfect absorbers and terahertz induced field emission in metamaterials. In particular, we have created YBCO superconducting split ring resonators and configured them into a perfect absorber geometry. We observe a nonlinear response as a function of the incident THz field strength in these metamaterial structures. In separate experiments, we have measured the THz induced field emission current across the capacitive gap of field enhanced metamaterials structures.

Silicon based active terahertz metamaterial devices

Hyun-Woong Kim, Jeong Min Woo, Sung-Min Hong, Jae-Hyung Jang, Gwangju Institute of Science and Technology (Korea, Republic of)

Terahertz (THz) modulators based on active metamaterials have conventionally been realized on compound semiconductors. Spectral responses of metamaterials realized on semiconductors were controlled by optical pumping, electrical power, or thermal power to demonstrate the intensity modulation of the transmitted THz wave.

In this study, silicon (Si) based THz modulator which can be controlled by the electrical power input is reported. All the fabrication processes are compatible with the conventional Si integrated circuit technologies. Metamaterials composed of metallic slot array was formed on top of silicon on insulator (SOI) substrates. The metamaterial structure is used as an anode electrode and the other cathode electrode has been placed beside the anode electrode by forming ohmic contact to the doped Si layer. When electrical bias is applied to the devices, the current flowing through the diode structure elevates the lattice temperature of the silicon layer. At the elevated temperature, the mobility of carriers in the Si layer is dramatically decreased meanwhile the carrier density in the Si layer is preserved. The decreased mobility of the carriers in Si layer leads to the increased resistance in the slot structures, and the quality factor of the slot is increasing. By controlling the quality factor of the metamaterial structures, the transmission of THz waves was successfully controlled. The resulting modulation depth calculated by the change of transmittance over the maximum transmittance was 42% with the highest bias voltage of 12 V. This work is supported by National Research Foundation of Korea through a grant (No. 20110017603).

9585-36, Session PMon

Development of magnetic system with high-anisotropy localized magnetic field for terahertz time-domain spectroscopy

Solveyga E. Azbite, Mikhail K. Khodzitsky, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

At the present time researches of biological objects spectra in terahertz frequency range attract the widespread interest, because in this frequency range there are vibrational and rotational transition frequencies for many molecules. The THz setups need for magnetic systems to improve THz radiation generation. At this moment there are three types of magnetic systems for THz time-domain spectrometers, namely the superconductor ones operating at low temperatures, the electromagnet systems including an optional power source and permanent magnetic ones. The 1st and 2nd ones produce strong magnetic field, and the last one has a small field.

In this paper magnetic system with a localized high-intensity magnetic field due to giant magnetic anisotropy magnets was proposed for THz time-domain spectroscopy. The design consists of two pairs of conical magnets, which form two semi-spheres[1]. Each pair of cones (apart from the central one) was divided into some equal sectors. The stray strong magnetic field is localized at the center of semi-sphere. Such two semi-spheres design will be used for an improvement of THz generation, it turns direction of dipole radiation pattern. One semi-sphere will be used for investigation of spectral and optical properties of an object at strong magnetic field.

The proposed magnetic system was numerically calculated in COMSOL MultiPhysics using AC/DC Module. Stray magnetic field for various geometrical parameters of system and different magnetic materials was analytically evaluated. These results may be used for development of real magnetic THz time-domain spectroscopy system.

Conference 9586: Photonic Fiber and Crystal Devices: Advances in Materials and Innovations in Device Applications IX

SPIE. OPTICS+ PHOTONICS OPTICAL ENGINEERING+ APPLICATIONS

Sunday - Monday 9 –10 August 2015

Part of Proceedings of SPIE Vol. 9586 Photonic Fiber and Crystal Devices: Advances in Materials and Innovations in Device Applications IX

9586-1, Session 1

Polymer-inorganic nanocomposite thin film emitters, optoelectronic chemical sensors, and energy harvesters produced by multiple-beam pulsed laser deposition

Abdalla M. Darwish, Dillard Univ. (United States); Sergey Sarkisov, SSS Optical Technologies, LLC (United States); Darayas Patel, Oakwood Univ. (United States); Allan Burkett, Simeon Wilson, Ashley Blackwell, Dillard Univ. (United States); Brent Koplitz, Tulane Univ. (United States)

Huge variety of new photonic devices, including light emitters, chemical sensors, and energy harvesters, can be made of the polymer-inorganic nanocomposite thin films produced by the new multiple-beam pulsed laser deposition process (MB-PLD). We describe the PLD system and the film deposition process itself, particularly the multiple-beam matrix assisted pulsed laser evaporation (MB-MAPLE) version. We also report on the results of the investigation of optical, electrical, morphological, and performance characteristics of the three types of the fabricated nanocomposite thin film photonic devices: upconversion light emitters, chemical (ammonia) sensors, and thermo-electric energy harvesters. The emitters were made of poly(methyl methacrylate) (PMMA) film impregnated with nanoparticles of rare-earth (RE) fluorides such as NaYF4: Yb3+, Er3+, NaYF4: Yb3+, Ho3+, and NaYF4: Yb3+, Tm3+. They demonstrated the quantum yield of upconversion visible emission approaching one percent when being pimped with 980-nm infra-red laser. The same films, but doped with an indicator dye, were tested as ammonia sensors. They demonstrated the drop of upconversion emission (registered by a photodetector) due to the rise of the optical absorption of the indicator dye affected by ammonia. The capability of detecting fractions of one percent (by volume) of ammonia was established. The thermo-eclectic energy harvesting films (useful for concentrated solar power) were made of aluminum-zinc-oxide with nanodefects produced my polymer dopants. The role of nanodefects was to disrupt the phonon-related thermoconductivity while maintain electroconductivity high in order to enhance the Seebeck effect figure-of-merit (make it greater than one).

9586-2, Session 1

Negative differential resistance behaviors in SnO2 thin film

Chih-Yi Hsieh, Cheng-Yi Liu, National Central Univ. (Taiwan)

Negative differential resistance (NDR) characteristics is usually observed in tunneling diode. In this work, we found NDR characteristics in a single undoped SnO2 thin film. The highest peak-to-valley current ratio (PVCR) is estimated to be 4.54. In addition, the overall transmittance of undoped SnO2 thin films is higher than 90% in the visible region. The undoped SnO2 thin films were deposited on the glass substrates by the magnetron sputtering system. The NDR characteristics of the undoped SnO2 thin films only observed under oxygen-rich ambient during the sputtering process. Also, NDR behavior depends on the size of the probe (or the size of the contact pad). The NDR characteristics are used on the applications on tunnel diode, and resonant tunnel diode. Therefore, the mechanism of the NDR characteristic of the undoped SnO2 thin films is very interested to be understood. In this talk, we will discuss the mechanism of the NDR characteristic of the undoped SnO2 thin films. X-ray diffraction, X-ray photoelectron spectroscopy and uv-visible spectroscopy analysis on the undoped SnO2 thin films also would be reported.

9586-3, Session 1

Orientation dependence of dispersion and band gap of PIMNT single crystal

Chongjun He, Nanjing Univ. of Aeronautics and Astronautics (China); Hongbing Chen, Ningbo Univ. (China); Jiming Wang, Xiaorong Gu, Tong Wu, Youwen Liu, Nanjing Univ. of Aeronautics and Astronautics (China)

Refractive indices and optical transmission of PIMNT single crystal with three orientations have been measured. Their Sellmeier dispersion equations of the refractive indices were obtained through least square fitting. After poled, optical transmission of [011] oriented crystal is much higher than that of [001] and [111] oriented crystals. The optical band gap was determined from absorption coefficient spectra. These results provide an important basis for further theoretical study and practical device fabrications based on PIMNT single crystal.

9586-4, Session 1

Significant near-IR light transmission asymmetry demonstrated in an all-dielectric (1+2)-dimensional photonic crystals

Lukasz Zinkiewicz, Univ. of Warsaw (Poland); Jakub Haberko, AGH Univ. of Science and Technology (Poland); Piotr Wasylczyk, Univ. of Warsaw (Poland)

We demonstrate the design, optimization, fabrication and characterization of an all-dielectric photonic structure with a significant, broadband asymmetry in transmission of the near-infrared radiation for opposite propagation directions. Our approach is based on a two-layer crystal made of a quarter wavelength stack (Bragg mirror) topped with a transmission phase diffraction grating consisting of a series of parallel lines. The structure performance can qualitatively be understood as follows. If a light beam of properly chosen frequency impinges at normal incidence from the dielectric stack side, it will be transmitted with high efficiency and afterwards will be diffracted on the grating, while the sum of all diffraction orders contributes to the total transmitted intensity. However, if the same wave arrives at the structure from the other side, first illuminating the grating of an optimized lines geometry, a significant fraction of energy may be transformed into higher orders, now propagating in the stack at different angles, so that it is highly reflective and thus total light transmission is significantly smaller. The asymmetry, defined as the difference between the intensity transmission coefficients, reaches 0.72±0.06 for a single wavelength and exceeds 0.2 over a spectral range spanning from 700-850 nm for one incident polarization and 750-800 nm for both polarizations. The experimental results are consistent with the numerical model of light propagation in the structure. This concept can be directly adopted at shorter wavelengths, covering the visible and near UV regions.

9586-5, Session 1

Polarization holograms in gold nanoparticle-doped PQ/PMMA photopolymer

Liangcai Cao, Chengmingyue Li, Zheng Wang, Guofan Jin, Tsinghua Univ. (China)

Thick phenanthrenequinonedoped poly (methyl methacrylate) (PQ/PMMA) photopolymer was reported as an attractive candidate for volume polarization holographic recording [1]. When doping the gold nanoparticles, a strong absorption grating could be introduced as a result of localized surface plasmon resonance effect of gold nanoparticles and the multicomponent diffusion process. The linear photoinduced birefringence of the gold nanoparticle-doped PQ/PMMA photopolymer is observed experimentally to be increased, compared with the pure PQ/PMMA photopolymer [2]. The volume polarization gratings could be recorded and even multiplexed with the orthogonal circular polarized beams. The principles of the polarization gratings are investigated to achieve a better dynamic range and material sensitivity for the volume holographic material. Based on above analyses and volume holographic performance of the gold nanoparticle-doped PQ/PMMA photopolymer, a polarization multiplexing holographic memory for higher density and lower crosstalk is designed and experimentally demonstrated

9586-6, Session 1

Terahertz electrical and optical properties of LiNbO3 single crystal thin films

Moumita Dutta, Xomalin G. Peralta, Carol Ellis, Amar S. Bhalla, Ruyan Guo, The Univ. of Texas at San Antonio (United States)

Lithium niobate crystals are known to have important applications as acousto-optic, pyro-electric, electro-optic, SAW, signal processing and many more. In this work we report the electrical and optical properties ranging from terahertz to optical frequencies. The techniques used include terahertz time domain spectroscopy, Raman spectroscopy, optical spectrometer, ellipsometry and vibrometry. While bulk crystals have been extensively studied, LiNbO3 thin films, especially the single crystal thin films (<700nm in thickness), have been seldom reported. This work focuses on the single crystal LiNbO3 thin films to present a comparative study with that of bulk crystals. Both the orientation of the films and the configuration of the film-interlayer-substrate systems are studied to explore suitable configuration for high speed and efficient modulator applications in wide range of frequencies including terahertz.

9586-7, Session 1

Magneto-acoustic-electroporation (MAEP): In-vitro visualization and numerical characterization

Soutik Betal, Binita Shrestha, The Univ. of Texas at San Antonio (United States); Luiz F. Cotica, Univ. Estadual de Maringá (Brazil); Liang Tang, Kelly L. Nash, Amar S. Bhalla, Ruyan Guo, The Univ. of Texas at San Antonio (United States)

Magneto-Acoustic-Electroporation (MAEP) is a magnetically controlled acoustic-electroporation observed while core-shell Magneto-electric nanoparticles interact with Biological Cells. The surface polarity change of the piezoelectric coating (BaTiO3) due to absorption of pressure created due magneto-striction of core (CoFe2O4) in AC magnetic field results in electric field (Uext) change at the external vicinity of the cell membrane when nanoparticles are nearby. This results in transmembrane Voltage (Um) change which is basically the difference in Cell's internal potential (Uint) and external potential. The nonlinear permeability change of cell membrane due to change in Um opens the nano-pores on the membrane. The magnetic moment of the nanoparticles further helps in penetration of the Magneto-electric nanoparticles inside the cell through these magneto-electrically controlled newly opened nano-pores on cell's membrane. MAEP is analyzed through in-vitro analysis and Mathematical equations are formulated for numerically expressing its fundamental effect. TEM imaging, XRD analysis, Zeta-potentiometer measurement and AFM imaging are confirming the coating of the piezoelectric layer on Magneto-stricitve nanoparticles, Acoustic measurements confirms the photo-acoustic and magneto-acoustic property of CoFe2O4 nanoparticles and Fluorescence microscopy as well as Confocal microscopy are confirming the penetration of particle inside the Human Epithelial cells (HEP2). These particles can be used as nano-probes for electroporation experiments and Cell membrane permeability study & exploring this mechanism can introduce a new level of remotely controlled efficient treatment of various diseases by accurate & efficient targeted delivery of drug into the infected cells.

9586-8, Session 1

Design and development of a high sensitive low cost fiber optic refractometer

Vayunandana Kishore Pabbisetti, National Institute of Technology, Warangal (India)

A simple and low-cost fiber optic refractometer is designed and demonstrated. The sensor is configured by etching a short region of a standard single-mode circularly bent fiber. Circularly bent three fiber loops are etched in equal lengths and arranged parallel to each other. The working principle of the sensor is evanescent field modulation with respect to the change in ambient refractive index at the sensing region. In the present study sugar solution with various concentrations, possessing different refractive indices is chosen as the ambient.

There have been many efforts to show that bent and etched optical fiber sensors have increased sensing capabilities but they are very much prone to fracture and breakage. The proposed sensor is stable showing very less tendency towards any breakage or fracture. Light from a broad band light source is coupled to the sensor and the output is detected by using a photo detector. The sensitivity of the sensor is tested for various sugar concentrations. It is evident from the experimental results that with the increase of sugar concentration the output intensity of the sensor is decreased linearly. The effect of number of fiber loops, diameter of the fiber loop and length of the etched region on the sensitivity of the sensor will be investigated. The proposed sensor may find applications in detecting various chemical species, biochemical testing and many other fields.

9586-9, Session 1

Study of P-type TiO2 thin film and transparent p-n junction device

Chia-Hua Lin, National Central Univ. (Taiwan)

This study reports a transparent p-type TiO2 thin film by DC reactive magnetron sputtering method under oxygen rich ambient. The p-type TiO2 thin film has a low resistivity (about 0.8 ?·cm) and a high hole concentration (about 4.6?1019 cm-3). The p-type conduction was also confirmed by Seebeck effect. In addition, the overall transmittance of the p-type TiO2 thin film is higher than 80% in the visible region. P-type conduction of TiO2 thin film is believed to be achieved by the so-called "self-substitution reaction", which means that the Ti ions with a low valence number in the TiO2 thin film substitute the Ti ions with higher valence number. For example, Ti3+-Ti4+ and Ti2+-Ti4+ substitution reactions are the two possible self-substitution reaction in the TiO2 thin film. These two substitution reactions have been verified by XPS analysis. Using the produced p-type TiO2 thin film, transparent p-TiO2/n-ITO p-n junctions were fabricated. The I-V characteristics of the p-TiO2/n-ITO junction exhibit distinct diode

characteristics. The transparent p-TiO2/n-ITO diode can be further applied in invisible electronics.

9586-10, Session 2

Formation of ultrashort parabolic pulses via passive nonlinear reshaping in normal dispersive optical fibers at 1550 nm

Igor A. Sukhoivanov, Univ. de Guanajuato (Mexico); Sergii O. Iakushev, Kharkiv National Univ. of Radio Electronics (Ukraine); Oleksiy V. Shulika, Erick R. Baca Montero, Alejandro Barrientos García, Luis A. Herrera Piad, Igor V. Guryev, José A. Andrade Lucio, Univ. de Guanajuato (Mexico)

We have investigated ultrashort parabolic pulse formation via passive nonlinear reshaping in normal dispersive optical fibers at 1550 nm in the transient-state regime and in the steady-state regime. Numerical simulations have been made based on generalized nonlinear Schrödinger equation taking into account high-order dispersion terms (third-order dispersion) and high order nonlinear terms such as self-steepening and the intrapulse Raman scattering. The impact of initial pulse parameters such as initial pulse shape, pulse energy and chirp on the pulse reshaping were investigated. It was found the areas of parameters providing the formation of parabolic pulses in available commercial fibers with normal dispersion at 1550 nm. It was found that small amount of positive second-order dispersion and quite sufficient third-order dispersion can restrict strongly the formation of parabolic pulses at 1550 nm. The most suitable fiber for pulse reshaping has been found. We have shown that femtosecond parabolic pulses can be formed as short as 200-300 fs in the transient-state regime and 700-800 fs in the steady-state regime. In the first case shorter parabolic pulses can be obtained but they are not stable during further propagation in the fiber. Whereas in the steady-state regime the duration of parabolic pulses is larger, but they remain the parabolic shape during subsequent propagation in the fiber. Such parabolic pulses can be used for pulse amplification and compression as well as in many optical communications applications such as optical regeneration, pulse re-timing, and mitigation of the linear waveform distortions.

9586-11, Session 2

A novel As2S5-tellurite hybrid photonic crystal fiber for long mid-IR supercontinuum fiber lasers

Mbaye Diouf, Univ. Cheikh Anta Diop (Senegal); Amine Ben Salem, Rim Cherif, National Engineering School of Communication of Tunis (Tunisia); Ahmadou Wague, Univ. Cheikh Anta Diop (Senegal); Mourad Zghal, National Engineering School of Communication of Tunis (Tunisia)

Recently, non-silica glasses like Tellurite and chalcogenide have been extensively studied owing to their wide transparency in the mid-IR region as well as their intrinsic and strong nonlinearities. By combining these characteristics with ultra-small waveguide structures like photonic crystal fibers, the waveguiding properties are enhanced through the large contrast difference between the core and the cladding refractive index. Thus, major and important effects on the nonlinear response of the waveguide are expected.

In this work, we numerically demonstrate the supercontinuum (SC) generation in a novel chalcogenide As2S5 nanowire embedded-core into Tellurite photonic crystal fiber (PCF). This hybrid As2S5-tellurite small core PCF has a pitch of 0.7 μm and air hole diameter of 0.2 μm. It exhibits a zero dispersion wavelength (ZDW) of 3.25 μm with an overall highly engineered group velocity dispersion (GVD) shifted to the mid-IR wavelengths region. By injecting 100 fs hyperbolic-secant input pulses delivered by available tunable optical parametric oscillator (OPO) system at the pump wavelength of 3.389 μm, we obtain a broadband coherent mid-IR SC generated in only 1 mm-long PCF with a peak power of 9 kW. An ultra-large mid-IR bandwidth extending from 1000 to 7300 nm is generated with more than 60% of the total power which is available beyond 3 μm. The proposed hybrid PCF structure shows to be very promising for designing new compact, stable and powerful SC fiber laser sources in the long mid-IR wavelength region.

9586-12, Session 2

The impacts of ageing effects due to radiation burden on optical fiber couplers

Frantisek Perecar, V?B-Technical Univ. of Ostrava (Czech Republic); Ondrej Marcinka, Research Ctr. Rez (Czech Republic); Lukas Bednarek, V?B-Technical Univ. of Ostrava (Czech Republic); Michal Lucki, Czech Technical Univ. in Prague (Czech Republic); Andrej Liner, Lukas Hajek, Martin Papes, Jakub Jaros, Vladimir Vasinek, V?B-Technical Univ. of Ostrava (Czech Republic)

This article focuses on applied research and experimental development of resources for safety operation of optical networks since monitoring of ageing substantially contributes to its security. It addresses issues of accelerated ageing of optical fiber elements in their burdened with gamma radiation. How does radiation energy of gamma radiation influence optical network elements? This effect is explored just very little bit and is yet another unanswered question. In addition to the destruction of coating materials, gamma radiation has its effect on the internal structure of the optical fiber. It is necessary to specify the changes in the optical coupler and find out why these changes occur. This article contains experimental measurement of the impact of gamma radiation Cobalt-60 on the optical couplers of various split performance ratio. Optical passive components, couplers, were exposed to gradually increasing doses of 60Co. Measurements are focused on the overall distribution of the energy of LP01 mode in the core and cladding various branches of SM optical fiber couplers. Graphical and mathematical detect changes in the dissemination of energy coupler after single doses of gamma radiation are useful to understand the phenomenon of accelerated ageing elements of optical networks in environments with an increased incidence of radiation energy.

9586-13, Session 2

Improve the light power of InP based 100nm tunable AMQW lasers using forced electrical confinement method

Hesham M. Enshasy, King Faisal Univ. (Saudi Arabia)

100 nm Broadly tunable InGaAsP/InP asymmetric multiple quantum well (AMQW) ridge waveguide laser diodes has limited applications because of its low output power problem. The current injection efficiency of such lasers in average is 18 %. A FlexPDE simulation model showed that the main reason for this poor current injection efficiency is the ridge structure. Since the ridge structure is an essential part of these type of laser diodes, we proposed a forced electrical confinement method to improve current injection efficiency of these lasers. The simulation data for the proposed method showed that it is possible to increase the current injection efficiency up to 90 %. The simulation data also, showed a reduction of nearly 10°C in the maximum temperature of these devices compared with original AMQW devices. This temperature improvement is significant and can lead to a significant improvement of the laser output power. Experimental data however, give less optimistic results. The experimental data did show improvement in the current injection efficiency but also showed creation of recombination centers that reduce the temperature and power improvement. The proposed method can be efficient but a passivation technique needs to be developed for these devices.

9586-14, Session 2

Design and analysis of rectangular photonic crystal fiber for supercontinuum generation

Than Singh Saini, Ajeet Kumar, Rim Cherif, Ravindra K. Sinha, Mourad Zghal, Delhi Technological Univ. (India)

Now-a-days the mid-infrared supercontinuum generation (SCG) is one of the most exciting research topics due to its major impact on spectroscopy and molecular sensing. SCG is a process in which ultra-short pulses of laser light evolves into the light with a broadband spectrum. It happens when optical pulses pass through a highly nonlinear optical medium. The spectral brightness of supercontinuum is million times brighter than the conventional light sources. The mid-infrared spectral domain is particularly important because of not only it contains two important window in which the earth's atmosphere is relatively transparent but also the strong characteristic vibrational transitions of most of the molecules in this domain. Mid-infrared molecular 'fingerprint region' is applicable in various important applications in different diverse fields such as medical, industry and security. In this work, we present numerical modeling of mid-infrared supercontinuum generation using a new design of rectangular-core photonic crystal fiber pumped with 50 fs optical pulses of 500 W peak power at 2800 nm. Proposed design of photonic crystal fiber offers nonlinear coefficient as high as 20956 W-1km-1 with effective mode area of 2.57 ?m^2 at pump wavelength. Supercontinuum spectra spanning 1480 – 9990 nm [which covers the atmospheric transparent windows (3 – 5 μm) in mid-infrared domain] have been generated using only 4 mm long proposed photonic crystal fiber. Proposed design of rectangular-core photonic crystal fiber has potential applications in gas sensing, food quality control and early cancer diagnostics.

9586-15, Session 2

Design of single mode single polarization large mode area photonic crystal fiber

Kishor D. Naik, Than Singh Saini, Ajeet Kumar, Ravindra K. Sinha, Delhi Technological Univ. (India)

Recently, Photonic crystal fibers have attracted significant attention for their applications in optical communication systems. In polarization sensitive applications photonic crystal fibers with single mode and single polarization are highly desirable. In this paper a rectangular core large mode area photonic crystal fiber has been designed for single mode and single polarization. Large mode area with effective single mode operation is achieved based on higher order mode filtering. Single polarization is obtained by introducing a very large confinement loss for one polarization and very low confinement loss for other polarization of fundamental mode. All the simulations have been performed by using a full vectorial finite element method with anisotropic perfectly matched layer. The variations of confinement loss and effective mode area of x and y-polarization of fundamental mode have been observed by varying the structural parameters of proposed photonic crystal fiber design. At optimized parameters the confinement loss and effective mode area is obtained as 0.9 dB/m and 927 μm2 respectively for x-polarization of fundamental mode. While, the confinement loss is as large as 12.53 dB/m for y-polarized fundamental mode at 1.55 μm. Therefore, only 1.6 m length of fiber will be sufficient to get x-polarized fundamental mode with effective mode area as large as 927 μm2.

9586-16, Session 2

Design and development of high-temperature sensor using FBG

Venkata Reddy Mamidi, Venkatappa Rao Thumu, National Institute of Technology, Warangal (India)

In this article we present design and development of a fiber Bragg grating (FBG)-based novel high-temperature sensor that measures temperature from 20°C to 1500°C. FBGs are the most attractive sensing elements for temperature. For many years, a large quantity of development and research have been reported in the field of FBG low-temperature sensing, but the area of high-temperature sensing is comparatively immature. The standard Type-I FBGs imprinted by weak and strong excimer laser survive up to 450°C and 700°C respectively, beyond the limit the gratings get erased if they are directly subjected to the temperature. However, Fs-IR laser induced Type-II gratings and regenerated gratings are proved to withstand higher-temperature up to 1000°C, they are observed to have short term stability. It is therefore necessary to have an alternative design/technique to stabilize and to enhance the temperature range beyond 1000°C. The designed FBG temperature sensor works based on measurement of the shift in Bragg wavelength that corresponds to the temperature induced strain by making use of a transducer. The transducing element provides temperature dependent strain on FBG by means of differential linear thermal expansion of ceramic alumina and silicon carbide. A Type-I FBG is glued on transducer, and experienced an induced strain of 3.15 x10-6 for increase of each 1°C. In response to this temperature induced strain the Bragg wavelength is found to be shifted at 3.78 pm/°C, over the range of 20-1500 °C. The achieved resolution of the sensor is 1°C.

9586-17, Session 2

Investigation of electrical, optical and structural properties of sputtered indium tin oxide thin film

Md. Tanvir Hasan, Amar S. Bhalla, Ruyan Guo, The Univ. of Texas at San Antonio (United States)

Transparent and conductive Indium Tin Oxide (ITO) films were grown on borosilicate glass substrate by radio frequency (RF) magnetron sputtering process. The effects of changing sputtering parameters e.g. substrate temperature and RF power on electrical, optical and structural properties were delved. The results showed that films crystallinity, conductivity and transparency were greatly influenced by substrate temperature. It has also been noted that surface roughness and grain size of the films were affected by changing substrate temperature. For the case of 200?C substrate temperature the measured thickness and bandgap of the film was 130.18 nm and 3.66eV respectively. In the visible region, optical transmission for this film was found as ~ 80%. At 200?C, it showed the best electrical and optical properties. By changing the RF power and keeping other deposition parameters as constant, it's been found that the conductivity of the films were increased significantly by increasing the RF power. Just by changing the RF power (35W to 80W) and without applying any substrate temperature it's been seen that the films were still amorphous. By varying the RF power the change in film thickness, surface roughness, grain size and optical transmission were also observed.

9586-18, Session 2

Developing of 2D helical waves in semiconductor under the action of femtosecond laser pulse and external electric field

Vyacheslav A. Trofimov, Vladimir A. Egorenkov, Mariya M. Loginova, Lomonosov Moscow State Univ. (Russian Federation)

We analyze laser-induced periodic structure developing in a semiconductor under the condition of both optical bistability existence and action of 2D external electric field. Optical bistability occurs because of nonlinear dependence of semiconductor absorption coefficient on charged particles concentration. The electron mobility, diffusion of electrons, and laser-induced electric field are taken into account for laser pulse propagation analyzing. 2D external electric field together with electric field of free

electrons and ionized donors governs the electron motion. Under certain conditions the additional positive inverse loop between electron motion and electric field caused by redistribution of free charged particles appears. As a result, the helical wave for free charged particle concentration of electron-hole plasma in semiconductor develops under action of the electric field.

For computer simulation of a problem under consideration, a new finite-difference scheme is proposed. The main feature of proposed methods consists in constructed iterative process.

9586-20, Session 3

Massive orbital angular momentum channels for high capacity optical communication using Dammann gratings

Ting Lei, Shenzhen Univ. (China); Meng Zhang, Nankai Univ. (China); Yuru Li, Zhaohui Li, Jinan Univ. (China); Xiaocong Yuan, Shenzhen Univ. (China)

The orbital angular momentum (OAM) in optical vortex (OV) beams has recently been shown to dramatically increase the data transmission rate in both free-space optical (FSO) and fiber optical communication systems. However, practical applications of massive OAM channels in optical communications still represent significant challenges from the receiver end, namely the parallel detection of multiple OAM states.

In this work, we propose and demonstrate a robust and efficient mechanism, by which collinear OV beams carrying multiple individually modulated OAM states can be demultiplexed and detected in a parallel manner with a Dammann optical vortex grating (DOVG). This contrasts with the previously demonstrated OAM-based communication systems using spiral phase planes or spatial light modulators by enabling simultaneous detection of massive OAM states. Additionally, our proposed scheme only requires two sets of gratings rather than bulky optics setup and expensive opto-electronic devices. In the experiment, we have achieved real-time data detections of 80Tbit/s QPSK signals and off-line detections of 160Tbit/s 16-QAM signals from 1,600 independent channels by demultiplexing 10 OAM states along with 80 wavelengths and two polarizations. We also demonstrate OAM based optical interconnect functions, such as reconfigurable switching, broadcasting and filtering of the communication channels using a digital micromirror device. The DOVG as the key component are capable of further increasing numbers of available OAM channels from tens to hundreds by a straightforward extension to a two-dimensional DOVG. The DOVG also enables uniform power distributions across all the OAM channels removing the power non-uniformity constraint of conventional diffraction gratings.

9586-21, Session 3

Global sensitivity analysis for fine-tuning the dispersion properties of photonic crystal fibers

Igor V. Guryev, Igor A. Sukhoivanov, Jose A. Andrade Lucio, Everardo Vargas Rodrigues, Oleksiy V. Shulika, Univ. de Guanajuato (Mexico)

In the work, we have applied the global sensitivity analysis technique to photonic crystal fibers to investigate the sensitivity of the wavelength of dispersion maximum as well as its absolute value as respect to fiber parameters variation. Namely, we have considered two structures. The first one was hexagonal-symmetric fiber with constant radii within a single ring which has given 5 parameters (pitch, 1st ring radii, 2nd ring radii, 3rd ring radii and radii of external rings). The second structure was hexagonal-symmetric fiber with radii varying within a single ring which has given 7 parameters. According to global sensitivity analysis, in each case, the position and the absolute value of fiber dispersion was computed for random set of the parameter. Then the sensitivity characteristics has been analyzed. The sensitivities obtained in this manner have been used for fine-tuning the fiber dispersion.

To make the realization of the technique possible, the dispersion characteristics of the photonic crystal fiber have been computed using plane wave expansion (PWE) method. It is not as accurate as, for instance, finite elements method (FEM). However, in case of strongly localized field as is observed in fibers it gives satisfactory results. Moreover, the computation of a single dispersion characteristic using the PWE method takes several minutes while the FEM gives the same result in about 10 hours which is essential when about 1000 computations are required.

The method has been verified by tuning the dispersion characteristic of the fiber presented in previous works.

9586-22, Session 3

Break-through of the spatial bandwidth product limit of digital holographic image detection by a light pipe

Yeh-Wei Yu, Ting-Wei Lin, Ching-Cherng Sun, National Central Univ. (Taiwan)

For the application of digital holographic imaging detection, the spatial bandwidth product is limited by the total pixels number of the image sensor. The product of the field of view (FOV) and the spatial frequency of the target is thus limited. In this paper, we break the spatial bandwidth product limit of a digital holographic microscope with the aid of a light pipe. The light pipe is put between the target and the image sensor and is used to replace the objective lens. When laser beam passes through target, the diffracted light with small diffracting angle illuminates the image sensor directly, the diffracted light with large diffracting angle is also directed to the image sensor by the light pipe. Thus, all of the signal are superposed on the image sensor. In order to retrieve the target, we develop a mirroring-matrix reconstruction method. In our simulation and experiment, we not only demonstrate the enhancement of FOV with constant resolution but also demonstrate the enhancement of resolution with constant FOV. Accordingly, we demonstrate the break-through of the spatial bandwidth product.

9586-23, Session 3

Numerical investigation of silicon nitride trench waveguide

Qiancheng Zhao, Yuewang Huang, Rasul Torun, Shah Rahman, Tuva C. Atasever, Ozdal Boyraz, Univ. of California, Irvine (United States)

We numerically investigated optical properties, including effective refractive index, dispersion coefficient, mode confinement, mode area, and nonlinear parameter, of the sub wavelength silicon nitride trench waveguides fabricated by using conventional lithography. The waveguides are etched 3.5 ?m deep by potassium hydroxide for triangle and trapezoidal waveguides or by plasma etching for rectangular waveguides, then followed by 3 ?m thermal oxidation and 725 nm silicon nitride deposition. 7 trapezoidal and rectangular waveguide structures with different waveguide widths are studied. Simulation reveals that waveguide modes, which are guided in the valley of the trench, are sensitive to waveguide structure. Narrower waveguides can support both TE and TM modes, whereas wider waveguides can support only TE mode. TM mode has higher refractive index in triangular and trapezoidal waveguides, while TE mode has higher refractive index in rectangular waveguides. All waveguides have small dispersion parameter |D| < 100 ps/(nm?km) in the wavelength range from 1350 nm to 1650 nm. The wider the waveguide width, the smaller the absolute value of dispersion parameter is. On the contrary to triangle and trapezoidal waveguides which have normal dispersion, rectangular waveguides are in anomalous dispersion regime. The triangular trench waveguide has 2.73 ?m2 mode area for TE mode and 2.32 ?m2 for TM mode at 1550 nm. The mode area decreases with increasing waveguide width. Waveguides fabricated by dry etching offer larger confinement factor (> 0.5) than wet etching counterparts. However, larger evanescent modes of the waveguides fabricated by wet etching offer higher efficiency in sensing applications. In addition, the calculated nonlinear parameter ? = 0.21 W-1/m for TE

mode and 0.25 W-1/m in triangular trench waveguide indicates promising applications in nonlinear optics.

9586-24, Session 3

Slow light generated via Brillouin scattering in small core chalcogenide photonic crystal fiber

Amira Baili, Rim Cherif, Amine Ben Salem, Ajeet Kumar, Ravindra Kumar Sinha, Mourad Zghal, SUP'COM (Tunisia)

Stimulated brillouin scattering (SBS) is a third-order nonlinear process arising from the interaction between propagating optical and acoustic waves. Nonlinear coupling between traveling-wave photons and phonons through SBS has been widely exploited in many applications, such as optical frequency conversion, radio frequency signal processing, fiber amplifiers and lasers, distributed fiber sensors and slow light. Slowing down the group velocity of light has been recognized as a key technology in future optical communication and microwave photonics systems for its potential applications such as optical delay, data synchronization, optical buffering, and pattern correlation. This technique, based on SBS in optical fibers, has recently attracted interest of many researchers.

In our contribution, we report on full modal analysis of the SBS in newly designed As2Se3-based chalcogenide photonic crystal fibers. Such fibers have drawn much interest because of their capacity of increasing the SBS gain and thus decrease the required input power. A Brillouin gain coefficient, gB, of 9.055 10-9 m.W-1 is found around the acoustic frequency of 8.087 GHz and 1.67 10-10 m.W-1 around 8.347 GHz in 1.69 μm core diameter. The calculated effective mode area is 1.5μm2 at 1550 nm. The Brillouin threshold Pth is evaluated to be 0.82 mW for a 10 m long fiber. A time delay of 94 ns can be achieved using only 1.15 mW pump power in 10 m As2Se3-based chalcogenide photonic crystal fiber.

9586-25, Session 3

Angular interrogation of evanescent wave absorption spectroscopy based sensors for harsh environment sensing applications

Paul R. Ohodnicki Jr., Michael P. Buric, Zsolt L. Poole, National Energy Technology Lab. (United States)

Evanescent wave absorption based spectroscopy (EWAS) sensors offer a number of unique advantages which include compatibility with remote optical sensing, simplicity of sensor design, low cost of sensing elements, and compatibility with harsh environment sensing applications. This presentation will focus on a detailed comparison between modeling of wave propagation in EWAS based sensors and measured transmitted intensity in selected sensors for harsh environment applications as a function of both launch and collection optics.

In particular, EWAS sensors that employ functional sensing elements of metal oxides and nanocomposite sensing layers targeted for ambient and high temperature H2 sensing will be investigated. Experimentally derived optical transmission spectra as a function of light launch conditions as well as collection optics will be directly compared with theoretically derived results using a single-layer waveguide model that permits finite film thickness relevant for the sensor layers under investigation. Based upon the results obtained, the potential for sensing response optimization using advanced interrogation approaches in this unique class of sensors will be demonstrated and critically discussed.

9586-26, Session 3

Simultaneous multi-parametric sensing in phase-shifted waveguide gratings

Renilkumar Mudachathi, Takuo Tanaka, RIKEN (Japan); Manoj M. Varma, Indian Institute of Science (India)

The emerging customized point of care (POC) and home health care diagnostic applications demand the development of highly integrated, compact, smart and low cost biosensors. The recent advances in the integrated silicon photonics have stimulated research around the globe on the development of such label free chemical and biosensing platform using photonic resonant structures. We present a scheme for multi parametric sensing based on phase-shifted waveguide grating.

The device is a grated waveguide with a defect at the center, in which multiple transmission modes could be excited containing defect mode and band edge transmissions. These transmission modes respond differently for different parameters such as surrounding refractive index change, temperature gradient and strain. That is, the same sensor element produces multiple signals; each carries separate information of the measurands. A semi-analytical model of the device in the general framework of transfer matrix method has shown that the wavelength of defect mode transmission depends only on the defect layer and those of band edge transmission on the bulk grating properties, providing a means for simultaneous multi-parametric sensing. Several devices with and without defect layer have been fabricated on SOI wafer using the micro-fabrication technique. The presence of multiple transmission modes with defect mode wavelength at 1545nm and band edge mode wavelengths at 1510nm and 1565nm providing a wide dynamic range of about 50nm was confirmed. In the presentation, the simultaneous multi-parametric sensing experiment will be demonstrated.

9586-27, Session 3

Digital holographic interferometer with a self-pumped phase conjugating mirror

Prathan Buranasiri, King Mongkut's Institute of Technology Ladkrabang (Thailand)

A digital holographic interferometer having a self-pumped phase conjugating mirror using cerium doped barium titanate crystal is demonstrated. The self-pumped phase conjugate beam is readily generated from stimulated photorefractive scattering and four-wave mixing inside the crystal. First, the fringe patterns obtained from the interferometer have been investigated. Then, the interferometer has been used to exploring a fingerprint pattern on a plain mirror. In both experiments, the images recorded on CMOS camera have been reconstructed by using numerical process. Finally, the experimental image results are compared with the image results that get from the conventional interferometer with regular mirrors.

9586-28, Session 4

Nanosecond speed KTN beam deflector

Shizhuo Yin, Juhung Chao, Wenbin Zhu, Chao Wang, The Pennsylvania State Univ. (United States); Robert Hoffman, U.S. Army Research Lab. (United States)

In this paper, a nanosecond speed KTN beam deflector is presented. The beam deflector is based on the combination of pre-injected space charge field and high speed (nanosecond) switching field. A beam deflection speed <= 1 ns was demonstrated, which was faster than the speed predicted previously (on the order of several hundred MHz). The experimentally results confirmed that the speed limitation of KTN beam deflector was not limited by the EO effect itself but the driving electric source and circuit. With a faster speed driving source and circuit, it is possible to develop GHz frequency beam deflector.

9586-29, Session 4

Fibre optic sensors for load-displacement measurements and its comparisons to piezo sensor based electromechanical admittance signatures

Muneesh Maheshwari, Venu Gopal M. Annamdas, John H. L. Pang, Swee Chuan Tjin, Anand K. Asundi, Nanyang Technological Univ. (Singapore)

Structural health monitoring techniques using smart materials are on rise to meet the ever ending demand due to increased construction and manufacturing activities worldwide. The civil-structural components such as slabs, beams and columns and aero-components such as wings are constantly subjected to some or the other forms of external loading. This article thus focuses on strain measurement due to loading-unloading cycle for a simply supported aluminum beam using multiple smart materials. On the specimen, fibre optic polarimetric sensor (FOPS) and fibre Bragg grating (FBG) sensors were glued. Piezoelectric wafer active sensor (PWAS) was also bonded at the centre of the specimen. FOPS and FBG provided the global and local strain measurements respectively whereas, PWAS predicted boundary condition variations by electromechanical admittance signatures. Thus these multiple smart materials together successfully assessed the condition of structure for loading and unloading tests.

9586-30, Session 4

Supersymmetric mode converters

Matthias Heinrich, Friedrich-Schiller-Univ. Jena (Germany); Mohammad-Ali Miri, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States); Simon Stützer, Stefan Nolte, Alexander Szameit, Friedrich-Schiller-Univ. Jena (Germany); Demetrios N. Christodoulides, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

In recent years, the ever-increasing demand for high-capacity transmission systems has driven remarkable advances in technologies that encode information on an optical signal. Mode-division multiplexing makes use of individual modes supported by an optical waveguide as mutually orthogonal channels. The key requirement in this approach is the capability to selectively populate and extract specific modes. Optical supersymmetry (SUSY) has recently been proposed as a particularly elegant way to resolve this design challenge in a manner that is inherently scalable, and at the same time maintains compatibility with existing multiplexing strategies.

Supersymmetric partners of multimode waveguides are characterized by the fact that they share all of their effective indices with the original waveguide. The crucial exception is the fundamental mode, which is absent from the spectrum of the partner waveguide. Here, we demonstrate experimentally how this global phase-matching property can be exploited for efficient mode conversion. Multimode structures and their superpartners are experimentally realized in coupled networks of femtosecond laser-written waveguides, and the corresponding light dynamics are directly observed by means of fluorescence microscopy. We show that SUSY transformations can readily facilitate the removal of the fundamental mode from multimode optical structures. In turn, hierarchical sequences of such SUSY partners naturally implement the conversion between modes of adjacent order. Our experiments illustrate just one of the many possibilities of how SUSY may serve as a building block for integrated mode-division multiplexing arrangements. Supersymmetric notions may enrich and expand integrated photonics by versatile optical components and desirable, yet previously unattainable, functionalities.

9586-31, Session 4

Design and implementation of super broadband high speed waveguide switches

Shizhuo Yin, Wenbin Zhu, Juhung Chao, Chao Wang, Jimmy Yao, The Pennsylvania State Univ. (United States)

In this paper, based on the theory of dynamic waveguiding effect in nanodisordered KTN crystals, a detailed design and implementation of a super broadband 1x2 high speed waveguide switch is presented. The important waveguide parameters, including the dimension, the refractive index distribution, and the electric field distribution within the waveguide are quantitatively simulated and analyzed. An experimental verification of switching effect based on the design is also conducted, which confirmed the design. The broadband and high speed nature of such kind of switch can play a key role in data center networks and cloud computing, which needs low power consumption and high speed switches.

9586-32, Session 4

Slow light effect in pinch waveguide in photonic crystal

Ravindra K. Sinha, Preeti Rani, Yogita Kalra, Delhi Technological Univ. (India)

Recently, photonic crystal has attracted wide attention due to its feasibility for slow light effect. Till now various designs has been proposed for the slow light effect in photonic crystal based waveguides. In this paper, we have proposed slow light effect in pinch waveguide created in photonic crystal. The proposed design consists of two dimensional (2D) triangular arrangement of air holes in silicon on insulator (SOI) substrate with the radius of air holes, r=0.3a, where 'a' is the lattice constant. The 2D effective refractive index method has been used to estimate the properties of slow light. Initially a row of air holes has been removed from the bulk arrangement and a pinch waveguide has been created by joining a row of air holes with the air slots. The pinch photonic crystal waveguide leads to the enhancement of localized fields than those of the traditional slot or photonic crystal waveguide structures. The size and shape of the pinch waveguide has been optimized to get the slow light effect. For the proposed structure the group index and group velocity dispersion (GVD) has been calculated from the dispersion relation of the pinch waveguide structure. From the calculations it has been found out that for the proposed structure the group index is high and GVD is low, which are the basic requirements for the slow light effect. The confinement of light in the pinch waveguide with slow light can be useful for sensor applications.

9586-33, Session 4

Investigation the effects of dispersion and intensity on supercontinuum spectrum

Abolfazl Safaei, Mohammad Agha Bolorizadeh, Aliasghar Zakerifar, Graduate Univ. of Advanced Technology - Kerman (Iran, Islamic Republic of)

When a light pulse is launched into a highly nonlinear fiber, the frequency broadening is observed due to dispersive and nonlinear effects, known as Supercontinuum Generation. One of the most significant current discussions in this course (SC) is supercontinuum generation in photonic crystal fiber.

This article provides numerically study of the nonlinear effects on a light pulse that is launched into a Photonic crystal fiber. The basic theory on SC generation process is explained briefly and more than that the physics behind the SC mechanisms is introduced. Also the higher order dispersion effects on Supercontinuum (SC) generation in microstructure fibers are analyzed by studying the temporal and frequency dependence of the ejected pulse via numerical study. As each dispersion coefficient cause a deformation in pulse shape, we work out to consider the effect of higher order dispersion on pulse shape.

The equation that governs supercontinuum generation is generalized nonlinear equation. The solution of this equation is Soliton that have different orders (N). However, there are a myriad of numerical methods to solve the equation, in this essay, Split Step Fourier method is applied to reach the aims.

To sum up, we investigate the higher order dispersion effects on supercontinuum (SC) generation in microstructure fibers. We also investigate the Soliton formation and spectrum broadening spectrum. In these processes, we observed dispersive wave generated due to Soliton fission. Here, we solve nonlinear Schrodinger equation by Split Step Fourier method.

9586-19, Session PMon

Integrated Ti:lithium niobate digital optical switch (DOS) for quantum information processing

Richard S. Kim, Eunsung Shin, Attila Szep, Michael Fanto, Paul M. Alsing, Air Force Research Lab. (United States); Antao Chen, Beckman Coulter, Inc. (United States)

Integrated photonic switches have been extensively researched for a long time in photonic communications to develop large-capacity optical cross connections or add/drop multiplexers. Digital optical switch (DOS) has several advantages including its high insensitivity to wavelength, refractive index, polarization, and temperature. Due to its step-like switch response to an applied voltage, DOS can be an effective tool to switch or distribute simultaneously its output power of both TM and TE modes with certain splitting ratios; for example, 100%:0% for TM wave and 66%:33% for TE wave. In this work, a novel design of 1x2 Y-branch DOS based on Ti:LiNbO3 optical waveguide operating at a wavelength of 810nm is simulated based on the BEAMPROP, and fabricated for application of simultaneous switching of both modes in quantum information processing (QIP). Its optical crosstalk, optical loss, tuning ability of splitting ratio, and required driving power are experimentally carried out and its potentials for manipulating modal qubits in photonic quantum circuit are discussed.

Post-shaping optical fiber taper filters

Alejandro Martínez-Rios, Guillermo Salceda-Delgado, Ctr. de Investigaciones en Óptica, A.C. (Mexico); Romeo Selvas-Aguilar, Univ. Autónoma de Nuevo León (Mexico); Gilberto Anzueto-Sanchez, Univ. Autónoma del Estado de Morelos (Mexico); Victor Manuel Duran-Ramirez, Univ. de Guadalajara (Mexico); Daniel Toral-Acosta, Univ. Autónoma de Nuevo León (Mexico)

Geometrical shaping of non-adiabatic single tapers is used to modify the filtering characteristics. The fiber tapers are shaped by successive tapering. The taper shaping produces deeper rejection bands. As an application of the shaped tapers, fluidic temperature sensing cells were fabricated. In a first case, the wavelength shift of a single rejection band was monitored, showing a nonlinear response and low sensitivity to temperature changes. In a second case, a shaped taper fluidic cell containing two rejection bands was used, and the wavelength shift of the half intensity points of the transmission band (between the rejection bands) was taken as a measure of the temperature change. In this case, the fluidic cell showed a linear sensitivity of 481.9 pm/°C in a temperature range of 25°C-60°C.

3 x 3 free-space optical router based on crossbar network and its control algorithm

Peipei Hou, Jianfeng Sun, Zhou Yu, Wei Lu, Lijuan Wang, Liren Liu, Shanghai Institute of Optics and Fine Mechanics (China)

A 3 ? 3 free-space optical router, which comprises optical switches and polarizing beam splitter (PBS) and based on crossbar network, is proposed in this paper. A control algorithm for the 3 ? 3 free-space optical router is also developed to achieve rapid control without rearrangement. In order to test the performance of the network based on 3 ? 3 free-space optical router and that of the algorithm developed for the optical router, experiments are designed. The experiment results show that the interconnection network based on the 3 ? 3 free-space optical router has low cross talk, fast connection speed. Under the control of the algorithm developed, a non-block and real free interconnection network is obtained based on the 3 ? 3 free-space optical router we proposed.

According to difference by poly styrene-block-poly-2-vinyl pyridine of molecular weight and swelling solution change, color difference in particle of photonic crystal

Jin Youb Lim, Hongik Univ. (Korea, Republic of)

Commonly unidimensional construct has restriction of viewing angle. We report a new facile strategy to Particle Photonic Crystal which is ellipsoidal block copolymer nanoparticles. it has a wider viewing angle as well as easy to make. We made particle of photonic crystal based on Poly Styrene-block-Poly-2-Vinyl Pyridine(PS-b-P2VP) in chloroform. After using Poly Vinyl Alcohol(PVA), It was in state of emulsion and self assembly method was followed by. In a first step, we observed particle structure variation according to difference in molecular weight such as 25k-25k, 52k-57k, 75k-66.5k. After wards, we exhibited how particle structure changed by swelling solution of difference which is Alcohol. The molecular structure of particle photonic crystal was investigated by Transmission Electron Microscope and Dynamic Light Scattering. The color was measured by color-difference meter.

According to diblock copolymer photonic film of various molecular weight, difference of wavelength change

Sang Wook Lee, Hongik Univ. (Korea, Republic of)

Optical properties of photonic crystal film were investigated by tuning photonic band gap (PBG). The lamellar-forming photonic films were prepared by nearly symmetric poly(styrene-b-2-vinyl pyridine) (PS-b-P2VP) block copolymers. Molecular weight of PS-P2VP is 25k-25k, 52k-57k, 57k-57k, 75k-66.5k, 190k-190k(g/mol), respectively. The lamellar stacks, which are alternating layers of hydrophilic and hydrophobic moiety of PS-b-P2VP, are obtained by exposing the spin coated film under chloroform vapor. The band gaps of the lamellar films interestingly varied after immersion into the quaternizing solvents containing 5wt% of iodomethane solubilized in n-hexane. Reflection color of photonic film was measured by uv-vis spectrophotometer. The change of pH gradation, metal ions and solvents of films can be changing the photonic band gap by molecular weight of PS-b-P2VP. The methods of control of reflection color show the shift of wavelength which is red shift or blue shift.

The ageing process of optical couplers by gamma irradiation

Lukas Bednarek, V?B-Technical Univ. of Ostrava (Czech Republic); Ondrej Marcinka, Research Ctr. Rez (Czech Republic); Frantisek Perecar, Martin Papes, Lukas Hajek, Jan Nedoma, Vladimir Vasinek, V?B-Technical Univ. of Ostrava (Czech Republic)

Scientists have recently discovered that the ageing process of optical elements is faster than it was originally anticipated. It is mostly due to the multiple increase of the optical power in optical components, the introduction of wavelength division multiplexers and, overall, the increased flow of traffic in optical communications. This article examines the ageing process of optical couplers and it focuses on their performance parameters. It describes the measurement procedure followed by the evaluation of the measurement results. To accelerate the ageing process, gamma irradiation from 60Co was used. The results of the measurements of the optical coupler with one input and eight outputs (1:8) were summarized. The results gained by measuring of the optical coupler with one input and four outputs (1:4) as well as of the optical couplers with one input and two outputs (1:2) with different dividing ratios were also processed. The optical powers were measured on the input and the outputs of each branch of each optical coupler at the wavelengths of 1310 nm and 1550 nm. The parameters of the optical couplers were subsequently calculated according to the appropriate formulas. These parameters were the insertion loss of the individual branches, split ratio, total losses, homogeneity of the losses and directionalities alias cross-talk between the individual output branches. The gathered data were summarized before and after the first irradiation when the configuration of the couplers was 1:8 and 1:4. The data were summarized after the second irradiation when the configuration of the couplers was 1:2.

DLC and AlN thin films influence the thermal conduction of HPLED light

Ming Seng Hsu, Chinese Military Academy (Taiwan); Ching Yao Hsu, Cantwell-Sacred Heart of Mary High School (United States); Jen Wei Huang, Feng Lin Shyu, Chinese Military Academy (Taiwan)

Thermal dissipation had an important influence in the effect and life of light emitting diodes (LED) because it enables transfer the heat away from electric device to the aluminum plate that can be used for heat removal. In the industrial processing, the quality of the thermal dissipation decides by the gumming technique between the PCB and aluminum plate. In this study, we fabricated double layer ceramic thin films of diamond like carbon (DLC) and alumina nitride (AlN) by vacuum sputtering soldered the substrate of high power light emitting diodes (HPLED) light to check the heat conduction. The ceramic dielectric coatings were characterized by several subsequent analyses, especially the measurement of real work temperature. The X-Ray diffraction (XRD) patterns reveal those ceramic phases were successfully grown onto the substrate. The work temperatures show DLC and AlN thin film coating had limited the heat transfer by the lower thermal conductivity, 3.5 Wm-1K-1, of DLC. Obviously, it hadn't transferred heat and limited work temperature of HPLED better than AlN thin film only.

S-band multi-wavelength Brillouin Raman fiber laser utilizing FBG and Raman amplifier in the ring cavity

Nor Azura Malini B. Ahmad Hambali, Nur Elina B. Anwar, Muhammad Halim B. Abdul Wahid, Mukhzeer B. Mohamad Shahimin, Mohd Azarulsani B. Md. Azidin, Amira Zakiah B. Malek, Roshidah B. Yusof, Univ. Malaysia Perlis (Malaysia)

This paper is focusing on simulates and evaluates the performance for S-band multiwavelength Brillouin–Raman fiber laser (MBRFL) utilizing Fiber Bragg Grating (FBG) and Raman Amplifier in ring cavity using Optisystem software. Raman amplifier- average power model is employed for signals amplification.This laser system is operates in S-band wavelength region (1566 nm to 1620 nm) due to vast demanding on transmitting the information. Multiwavelength fiber lasers based on hybrid Brillouin-Raman gain configuration supported by Rayleigh scattering effect have attracted significant research interest due to the large numbers of channel generation from a single light source. When narrow bandwidth Brillouin gain combines with broad bandwidth Raman gains, hundreds of channels would be generated. In MBRFL configuration, single mode fiber (SMF) is utilized as the nonlinear gain media. When a single laser launches into a distributed Raman gain area, it grows very fast through stimulated Raman scattering, and when it acquires threshold condition, it is back-scattered through nonlinear Brillouin and Rayleigh effects, inelastically and elastically inside the gain media respectively. From output results, the output coupling ratio of 90% provides the higher output Stokes power at input power at 20 dBm and Raman pump power is at 14dBm. The average output powers are around 20 dBm to 45dBm. As the input power increases, the number of Stokes signals also increases, because there will be more than enough power to overcome the SBS threshold. Meanwhile, the total number of the number of Stokes signal produces is 7.

Two-center recording in LiNbO3:Fe:Ru and LiNbO3:Ce:Ru crystals

Zhifang Chai, East China Normal Univ. (China)

To realize nonvolatile photorefractive holograms, Buse et al., proposed a two-center holographic recording method in doubly doped LiNbO3:Fe:Mn crystals in 1998. The key point of this technique is that two different dopants are used to provide shallower and deeper centers in LiNbO3 crystals. From 1998, the development of new materials with different dopants has become an important direction for two-center recording, so that the optimized performance can be obtained. Doubly-doped LiNbO3 crystals, such as LiNbO3:Fe:Cu, LiNbO3:Ce:Cu, and LiNbO3:Ce:Mn et al., are reported to perform two-center recording effectively. Low holographic scatter noise and high fixed diffraction efficiency can be obtained in LiNbO3:Ce:Cu crystals.

Ru can be used as the deep center in doubly doped LiNbO3 crystals, and LiNbO3:Fe:Ru and LiNbO3:Ce:Ru crystals can be used to realize two-center recording effectively, too. In this paper, the two-center recording with 633nm recording and 404nm sensitizing is performed in oxidized LiNbO3:Fe:Ru and LiNbO3:Ce:Ru crystals, respectively. Performance measures, such as dynamic range, recording sensitivity and holographic scatter noise, are calculated and compared according to the time evolution curves of diffraction efficiency. The results show that the high recording sensitivity and dynamic range can be obtained in LiNbO3:Fe:Ru crystal. However, the low scattering noise can be observed in LiNbO3:Ce:Ru crystals. At last, the theoretical analysis is carried out based on jointly solving the two-center material equations and the coupled-wave equations.

Photon management assisted by surface modes on a photonic crystal platform

Angelo Angelini, Politecnico di Torino (Italy); Luca Boarino, Istituto Nazionale di Ricerca Metrologica (Italy); Peter Munzert, Fraunhofer-Institut für Angewandte Optik und Feinmechanik (Germany); Natascia De Leo, Istituto Nazionale di Ricerca Metrologica (Italy); Emiliano Descrovi, Politecnico di Torino (Italy)

The ability of modifying the radiation pattern of emitters is gaining attention

in a variety of applications related to nanophotonics, such as few-molecule and quantum emitters detection. In this framework, Surface Plasmon Coupled Emission (SPCE) has demonstrated to be an effective way to address this issue. Generally, plasmonic-based mechanisms exploit a near-field transfer of energy from the emitters to plasmonic modes. However, the main drawback in using plasmons on metal is represented by ohmic losses, producing broad resonances and absorption of useful signal.

An effect similar to SPCE occurs on properly tailored one dimensional photonic crystals (1DPC). 1DPC can indeed sustain resonant surface electromagnetic modes, that we call Bloch Surface Waves (BSWs), at the truncation interface of the dielectric stack.

Due to the low absorption coefficient of the 1DCP materials, BSW-coupled fluorescence can propagate for longer distances as compared to plasmons. In addition, the use of dielectric structures offers interesting advantages such as a wide spectral tunability (from UV to IR), the possibility to have either TE or TM polarized BSW and higher Q-factors.

By properly structuring the surface of 1DPC, light coupled to BSWs can be manipulated in several ways (e.g. diffracted, guided, focused). In particular, spontaneous emission of emitters lying on the surface of 1DPC can be efficiently beamed out in arbitrary directions with low divergence by employing surface relief diffraction gratings.

An implementation of a biosensing platform based on such fluorescence beaming effect is provided, showing an enhancement factor of the detected fluorescence of about 100 if compared with the signal detected on a simple glass coverslip using an equal numerical aperture collection system.

A tunable wavelength erbium doped fiber ring laser based on mechanically induced long-period fiber gratings

Miguel Perez Maciel, Yanelis López Dieguez, Roberto Rojas Laguna, Eduardo H. Huerta Masscote, Daniel Jauregui Vazquez, Juan M. Sierra Hernández, José Alejandro Montenegro Orenday , Julián Móises Estudillo Ayala, Univ. de Guanajuato (Mexico)

In this work, a tunable wavelength erbium doped fiber ring laser is proposed and demonstrated; the ring fiber laser is based on mechanically induced long-period fiber gratings (LPFG). In the scheme a semiconductor laser of 980nm is pumped in the cavity, where 4.30 meters of erbium doped fiber is used like active medium, the signal laser is monitoring by using a coupler 90/10, here the 90% of the signal is feedback into the cavity and only the 10% is analyzed by the optical spectrum analyzer (OSA); by using an insulator the light in the cavity has a single direction. In order to, tuning the laser, a controlled load was applied to the mechanical long period grating as a result the transmission spectrum change. The load was applied by pressing a plate with periodic grooves against a short length and controlled by using a digital torque tester. The grooves used in the plates have a period around 630 μm. However, this set-up, can be easily reconfigurable to tuned other wavelengths by a simple modification on the groves. Moreover, control polarization was set in the cavity to provided stability and by changing the polarization of our system the single line emission can be tuned in the L-band telecommunications, where the laser line presents high stability in the room temperature. Furthermore, the mechanical long-period fiber gratings implemented in this work offers unique advantages, they are tunable, erasable, reconfigurable and exhibit transmission spectra and high thermal stability, similar to photoinduced LPFG's. This laser present a stability of 60 minutes and can be tuned by applying a .05lbf.

A cylindrical structure fiber-optic amplifier with broad-side pump coupling

Steven R. Laxton, Tyler Bravo, Christi K. Madsen, Texas A&M Univ. (United States)

We propose a unique physical structure for coupling a low brightness source to a dual-clad fiber for amplification. A pumped-cylindrical structure is used to greatly enhance the area for pump coupling over standard end-fiber coupling into a dual-clad fiber. In addition, it provides a compact volume for fiber amplification. Pump signal is inserted by photonic broadside coupling into the external surface area of the coil. We will discuss the basic coupling mechanism, simulations and prototype fabrication overview. Our first experimental results will employ a 980nm pump laser and 1550nm for the amplified signal. We will then test using a broadband source and compare to the pump laser results. Excess losses, mainly due to bend loss, are characterized across the wavelength range of interest.

9586-45, Session PMon

Investigation of the laser energy parameters for laser initiation

Natalia Korobova, Veniamin A. Vodopyanov, Evgeny Paderin, Evgeny Sholokhov, Sergey P. Timoshenkov, Valeri Timoshenkov, National Research Univ. of Electronic Technology (Russian Federation)

Insensitivity light detonators to electromagnetic interference and static electricity charges have been used as one of the advantages of laser initiation. High level of light detonator insulation from the false pulse has been done, as in the optical range there were no random sources with sufficient power to undermine the detonator. Pulse energy density was determined using Yb fiber laser with Ho3+ gate which worked in a Q-switched modulation. The calculations of the mode change field, power density and energy density according to the distance from the fiber end at the maximum pump current have been presented. Composite materials with thickness 0.3 to 0.5 mm were used as samples of polymeric matrix and reinforced by nanocarbon particles. During the study of the sample pulse characteristics focusing node input was using and sample was placed in the focus. This scheme actually complicates the design of the input node radiation, but at the same time potentially allows for greater energy per pulse correctly focused beam. For the beam at the output of focusing input node and the maximum pump current we had the following values: mode field diameter at the fiber end 9.88 um, mode field area of 7.66•10-7 cm2, power density (irradiance) in the beam 5.22 •106 W/cm2, energy density at the output of the focusing input node 261 mJ/cm2. It was experimentally established that burning time order of several milliseconds can be achieved by the correct selection of the focus radiation. Recommendations for the design input node of radiation to initiate known types of explosives have been done.

Sputtered germanium/silicon devices for photonics applications

Naga Korivi, Melvin DeBerry, Nabila Nujhat, Jean-Pierre Papouloute, Li Jiang, Tuskegee Univ. (United States)

We report on the ongoing investigation of germanium (Ge)/silicon (Si) photodetector devices for photonics applications. The devices are made by depositing Ge and in some cases, Si layers by radio frequency and direct current magnetron sputtering and patterning them by standard ultra-violet light photolithography. The development of Ge/Si devices has till date involved methods such as molecular beam epitaxy to deposit Ge on Si and SOI wafers. The sputtering-based developments in our present research are expected to provide for a flexible and economically viable manufacturing process for such devices.

In this work, photodetector devices with diode type structures and hetero-junctions integrated with sputtered Si waveguides are being investigated. The devices and waveguide structures are made by sputtering Ge and Si layers on a substrate, followed by a combination of photolithographic patterning and rapid thermal annealing to impart a polycrystalline nature to the sputtered materials. All sputtering processes are done at an elevated temperature (450-500 °C). The annealing is done in nitrogen ambient at

temperatures of more than 600 °C. Initial prototypes of sputtered Ge/Si diodes have been developed, while fabrication of heterojunction field effect transistors is in progress. Stand-alone Si waveguides have been fabricated with a polymeric cladding. The fabricated devices and waveguides have been evaluated for response to 1500 nm wavelength light through an externally mounted optical fiber. A significant difference is observed in current-voltage behavior under the dark and illuminated conditions, indicating a clear response to 1550 nm light.

Memristor memory element based on ZnO thin film structures

Armen R. Poghosyan, Elbak Y. Elbakyan, Institute for Physical Research (Armenia); Ruyan Guo, The Univ. of Texas at San Antonio (United States); Ruben K. Hovsepyan, Institute for Physical Research (Armenia)

The memristor element for random access memory (resistance random access memory - ReRAM) has been developed and studied. The developed structure consists of a Schottky diode (1D) based on ZnO:Ga/ZnO:Li/ZnO heterostructure and memristor (1R) based Pt/ZnO/ZnO:Li/Al heterostructure. Thus the unipolar memristor memory element of 1D1R type has been obtained. The heterostructures were made by the electron-beam vacuum deposition method. The laboratory samples of the memory elements have been prepared and their characteristics have been studied. The proposed device has a high stability and withstands 1000 switching cycles without derating.

9586-48, Session PMon

80 channels HDTV signal transmission using optical carrier suppression scheme and injection-locked FPLDs

Ardhendu S. Patra, Sidho-Kanho-Birsha Univ. (India)

A novel bidirectional ROF configuration has been proposed and developed to transmit 80 channels HDTV signal of datat-rate 1.25 Gbps over 80 km SMF integrating mutually injection locking, optical carrier suppression (OCS) and reflective semiconductor optical amplifier (RSOA) based remodulation techniques. The RSOA is deployed at the user end to reuse and remodulate the downstream HDTV signal to upstream transportation over same 80km fiber-link. Noise due to the Rayleigh backscattering and Fresnel backreflection are the main limitation for the RSOA based configurations. To reduce these effects and the power consumption in the transmission the OCS scheme has been used in the ROF designs. As the power consumption is reduced by the suppressing carrier mode the effects of backscattering is also degraded. Therefore the crosstalk and inter-symbol interference are also mitigated. Dual-arm LiNbO3 Mach-Zehnder modulator which is biased at Vϖ and driven by two complementary RF signals of 30GHz is used at transmitter end to realize the OCS scheme. To make cost-effective, the scheme of mutually injection locking of FPLDs has been used.The uplink and downlink transmission performances are observed and analyzed by excellent eye-diagram and low bit error rate values. The received optical power is recorded as -21dBm and -18dBm at the BER of 10-9 order for downlink and uplink transmission respectively. At the 80 km length of SMF the power penalty is 3dB between the uplink and downlink transmission. This architecture can play an important role in the future broadband access network to transmit HDTV signals over long-haul SMF.

9586-49, Session PMon

Bidirectional and simultaneous FTTX/ Ethernet services using RSOA based remodulation and polarization multiplexing technique

Ardhendu S. Patra, Anindya Sundar Das, Sidho-Kanho-Birsha Univ. (India)

A bidirectional WDM-PON architecture has been investigated for simultaneous transmission of 2.5 Gbps and 10 Gbps over 50 km single mode fiber employing polarization multiplexing (POLMUX) technique at OLT and ONU. POLMUX technique has been introduced to minimize the cost and complication of the multi-service provider systems. This scheme is based on equally splitting an optical field into two components and employs them as optical carrier to transmit simultaneously independent data-rates over same wavelength and increases the spectral efficiency and transmission capacity of the system. The POLMUX technique is embraced by polarization beam splitters and polarization beam combiners in the system. Unlike the previous works RSOA have been used for reusing and remodulation of 2.5 Gbps and 10 Gbps at the same time in upstream transmission over the same 50km SMF. The downlink and uplink transmission performances are observed by eye diagrams and bit error rate (BER) values, obtained at BER analyzer. The clear eye diagrams, low BER values and low power penalties are observed at downlink and uplink and prove that the proposed configuration is suitable to provide the FTTH, Ethernet services simultaneously to the user. Using of single source for different services have reduced the cost of the system and increases the spectral efficiency of configuration. The transmission capacity is also increased as our proposed architecture have successfully transmitted 10 Gbps to 50 km reach in uplink, which is much better than the previous works. Therefore this configuration will be suitable for the next generation high speed networks.

9586-50, Session PMon

Gray-level encoded fringe projection for profile measurements

Wei-Hung Su, Bo-Chin Huang, National Sun Yat-Sen Univ. (Taiwan)

An encoding algorithm to identify the fringe orders for Fourier transform profilometry is described. Phase unwrapping is then performed with reference to the encoding algorithm. Even though the inspected object is colorful or sensitive to the reflectance variation, unwrapping can be performed without ambiguity. The computation cost is very low, and its unwrapped errors can be confined in a local area.

9586-51, Session PMon

Projected fringe profilometry for metal surfaces

Wei-Hung Su, Bo-Chin Huang, National Sun Yat-Sen Univ. (Taiwan)

A non-scanning fringe projection method to describe the 3D profile of a metal surface is proposed. Fringes projected on the inspected surfaces are formed by launching a laser beam into a hologram. The size of the hologram is large enough that fringes on the surface are collected from various diffraction directions. Shinny or specular reflection can be efficiently reduced. This makes it possible to inspect the entire metal surface at a desirable viewpoint.

9586-52, Session PMon

Three-dimensional shape measurements using endoscopes

Wei-Hung Su, Tzu-Chien Hsu, Cho-Yo Kuo, National Sun Yat-Sen Univ. (Taiwan)

We present a structured light illumination system embedded into an endoscope to describe the absolute shape of an inspected object. A fringe pattern generated by launching incoherent light waves into a volume hologram is projected on the inspected surface. The endoscope observes the projected fringes at another point of view. Fringes on the obtained image are deformed both by the topography of the object, and are analyzable to retrieve the 3D shape.

9586-53, Session PMon

A reliable image processing algorithm using the scanning fringe projection for 3D profile measurements

Wei-Hung Su, National Sun Yat-Sen Univ. (Taiwan); Nai-Jen Cheng, National Kaohsiung Univ. of Applied Sciences (Taiwan)

A reliable image processing method is provided to enhance the accuracy of the scanning fringe projection technique. Noises and errors for surfaces on the edge area can be efficiently detected and reduced. To accurately describe the shape of a complicated object is available.

9587-1, Session 1

Multi-terabit/in2 holographic data storage demonstration *(Invited Paper)*

Mark R. Ayres, Ken E. Anderson, Fred Askham, Brad Sissom, Adam C. Urness, Akonia Holographics, LLC (United States)

Holographic data storage (HDS) employs the physics of holography to record digital data in three dimensions in a highly stable photopolymer medium. As such, it enjoys a substantial density advantage over rival technologies which are fundamentally two-dimensional. We have previously reported results using a demonstrator designed to implement dynamic aperture multiplexing, quadrature homodyne detection, and phase quadrature holographic multiplexing in a monocular architecture. In this presentation, we report on further progress and recording density results.

The Akonia AP1 demonstrator previously achieved a raw recording density of 1.5 Tbit/in2, easily exceeding that of commercially available technologies. This result was accomplished using the new DRED high-dynamic range recording medium formulation and the new technique of dynamic aperture holographic multiplexing. However, the coherent channel techniques were not yet incorporated. The first coherent channel technique, quadrature homodyne detection, enables the use of phase shift keying (PSK) for signal encoding, which dramatically improves recording intensity homogeneity and increases SNR. The second, phase quadrature holographic multiplexing, further doubles density by recording pairs of holograms in quadrature (QPSK encoding).

We report on the incorporation of these coherent channel techniques into the AP1 demonstrator, and on the results of recording experiments.

9587-2, Session 1

Numerical evaluation of multilayer holographic data storage with a varifocal lens generated with a spatial light modulator

Teruyoshi Nobukawa, Takanori Nomura, Wakayama Univ. (Japan)

The feasibility of multilayer recording in holographic data storage have been studied. Multilayer recording allows to use the dynamic range of a recording medium effectively and improve a recording density. Conventional multilayer recording, however, requires a movable stage for shifting a recording medium along an optical axis. This makes an optical setup complicated and large. In order to solve the problem, we propose the multilayer recording with a varifocal lens generated with a phase-only spatial light modulator. In the proposed method, a focal plane is shifted by adding a spherical phase to a phase modulation pattern which consists of a random phase mask and a computer-generated reference pattern. We investigate the shift selectivity along an optical axis in the proposed method and perform multiplexed recording with a numerical simulation. In the numerical simulation, calculation for a propagation is based on a scalar diffraction theory, and an optical setup is assumed to be a coaxial holographic data storage. The numerical results show that the proposed method enables us to implement multilayer recording without moving both a stage and a recording medium. We believe that the proposed method contributes the realization of compact and high-density multilayer recording holographic storage.

9587-3, Session 1

Design of binary data page with a phase mask for high-density holographic recording

Daisuke Barada, Shigeo Kawata, Toyohiko Yatagai, Utsunomiya Univ. (Japan)

Holographic memory is expected for a storage with large data capacity and high data transfer rate because two dimensional coding pattern called data page can be recorded onto the volume of a recording medium. The data page is given to a signal beam by a spatial light modulator (SLM). To realize high data transfer rate, ferroelectric liquid crystal spatial light modulator (FLC-SLM) is used. The FLC-SLM modulates a light to two states so that binary pattern is used as the data page. The data page pattern is focused by a lens and the Fourier pattern is illuminated onto a recording medium. In order to limit the recording area of the medium, a rectangular aperture is used. Then, the resolution of the SLM is limited because the rectangular aperture plays the role of a spatial frequency filter. In this study, a binary data page coding method was proposed with a phase mask. When the rectangular aperture size is not enough corresponding to the resolution of the SLM, the pattern from a pixel becomes broaden and interpixel cross-talk noise is increased in reconstruction. In our proposed method, the cross-talk effect is aggressively utilized. The complex value of a pixel with a designed phase mask can be switched to two constant vectors on the complex plane. By superposing some constant vectors, arbitrary vector can be expressed. The interpixel superposition is realized by limiting the size of the aperture. In reconstruction, the complex value is measured by phase-shifting algorithm and the data is extracted from the complex value. It was numerically confirmed that the noise level can be suppressed by using our proposed method in the case of decreasing the aperture size.

9587-4, Session 1

Optimization of holographic data storage system based on Seidel aberrations reduction

Ren-Chung Liu, National Chiao Tung Univ. (Taiwan)

Volume holographic data storage is regarded as a potential technology for next generation optical storage in the era of cloud computing. It has attracted intense research effort from both academia and industries. Storage capacity (SC) and bit-error-rate (BER) are two parameters that are often used to evaluate the performance of holographic data storage systems. Bit errors can be induced by many factors such as material scattering, device imperfections, system misalignment, intra-page cross-talk between pixels of the same page, inter-page cross-talk between different pages, and optical aberrations, etc. When bit error occurs, it will require more error correction codes and thus the storage capacity will be degraded. In this talk, we consider the influence of optical aberrations on BER and SC of holographic data storage systems. A system model for holographic data storage system (HDSS) with multiple lenses is proposed, and the point spread function (PSF) for the system is derived. The PSF is used to investigate the influence of aberrations on the probability density function (PDF) of the retrieved data from the HDSS, and thus the SC and BER are developed. Then, parametric studies on numerical apertures and Seidel aberration on SC and BER of HDSS are performed. Tolerances of Seidel aberrations with different NA are obtained. Performance improvement and optimization of HDSS for achieving lower BER and higher SC will be presented. We also consider further improvement of HDSS by using circular spatial light modulator for displaying the data pages.

Quantitative roadmap of holographic media performance *(Invited Paper)*

Benjamin A. Kowalski, Robert R. McLeod, Univ. of Colorado at Boulder (United States)

We calculate the theoretically achievable refractive index modulation for a broad range of commercially and academically interesting holographic media. In each case, a comparison of this theoretical upper limit to the reported performance reveals that a significant fraction of the writing chemistry is wasted due to unwanted reactions. Design strategies to reduce this wasted fraction are evaluated, leading to a quantitative roadmap of the performance improvements that can be expected in state-of-the-art media. Finally, we derive additional theoretical bounds on media performance from fundamental scaling relationships between recording-induced scatter (typically the dominant noise term) and index modulation and sensitivity.

9587-7, Session 2

High dynamic range holographic data storage media

Mark R. Ayres, Fred Askham, Adam C. Urness, Akonia Holographics, LLC (United States)

Photopolymer based photonic materials find relevance in a wide range of applications including holographic data storage, display holography, holographic and graded refractive index (GRIN) optical elements, waveguides, etc. Their importance stems from an ability to respond to a patterned light intensity by forming a corresponding permanent refractive index structure within the material. The effectiveness of a particular material derives largely from the maximum contrast which can be achieved as the initially homogeneous material is induced to separate into volumes of high and low refractive index.

Previous strategies for producing materials with greater dynamic range have included widening the difference in refractive index between monomer and matrix by judicious choice of their compositional elements, or simply increasing the initial concentration of the writing monomer. While these methods have achieved some success, practical constraints due to recording induced physical shrinkage, solubility and expense limit the degree to which they can be employed.

In contrast, Akonia's DRED technology provides a new method which increases the efficiency with which the monomer is used, thereby leading to large increases in the dynamic range performance of these materials. This technology employs a class of compounds (termed "Dynamic Range Enhancing Dopants") having defined reactivity features that dramatically increase the medium's dynamic range when added in small amounts to existing formulations. In some embodiments, a quintupling of the material's M/# performance has been achieved without an increase in recording induced shrinkage.

We report details on these materials and their holographic recording performance characteristics.

9587-8, Session 2

Proposal for one-beam microholographic recording using radially polarized light beam

Ryuichi Katayama, Fukuoka Institute of Technology (Japan)

Microholographic recording is promising for realizing next-generation optical data storage systems because of its affinity with conventional optical disk systems. However, there is a problem in the microholographic recording that two beams facing each other in between the recording medium are necessary for recording, which makes the optical configuration complicated. This paper proposes a novel microholographic recording using only one beam for recording.

In the recording process, a radially polarized light beam is used. When the radially polarized light beam is focused, lights from two parts located symmetrically with respect to the optical axis interfere with each other. As a result, a microhologram whose grating vector is perpendicular to the optical axis is formed in the recording medium, in contrast to the conventional microholographic recording in which the grating vector of the microhologram is parallel to the optical axis.

In the readout process, a circularly polarized Laguerre Gaussian light beam is used. A radially polarized light beam can be generated by synthesizing two circularly polarized Laguerre Gaussian light beams whose handednesses are opposite to each other. Therefore, if a right-handed circularly polarized Laguerre Gaussian light beam is focused on the microhologram, a left-handed circularly polarized Laguerre Gaussian light beam is generated as a diffracted light beam. Here, the diffracted light beam is generated in the transmission direction, in contrast to the conventional microholographic recording in which it is generated in the reflection direction. The diffracted light beam is detected and discriminated from a non-diffracted light beam using their different handednesses.

Metasurface: Where meta, microfluidic, and tunable meet? *(Invited Paper)*

Wei Zhang, Nanyang Technological Univ. (Singapore); D. T. Tsai, National Taiwan Univ. (Taiwan); Zhen Chuan Yang, Xing Zhu, Peking Univ. (China); Federico Capasso, Harvard School of Engineering and Applied Sciences (United States); Ai Qun Liu, Nanyang Technological Univ. (Singapore)

A perfect absorber, which fully absorbs the incoming electromagnetic (EM) wave and transfers it into other forms of energy, is intensively studied for its wide applications in energy harvesting, military defense, EM wave modulation and communications, etc. The metamaterial, an artificial material consisting of subwavelength meta-atoms, has been designed for perfect absorption by utilizing the impedance matched meta-atoms. Although successfully demonstrated, they are usually limited in a narrow working bandwidth. The rigid structure of the design also hampers its real life applications that require all-directional absorption. In this talk, a soft metamaterial is proposed to realize the perfect absorption in microwave regime, which can be easily deformed to face to different directions. The polymer polydimethylsiloxane (PDMS) is used as the soft substrate, which is filled with the most common material in nature, i.e. water. Due to the extremely high dielectric constant and high absorption by its polar molecules in microwave regime, water is a perfect candidate for perfect absorption. By properly patterning the PDMS channels, which are filled with water, the microwave across a wide band is well confined and fully absorbed. The perfect absorption is further manipulated in two aspects: first, the absorption band is shifted by deforming the water pattern under different inlet water pressures applied in the PDMS channel. Second, the absorption coefficient of the soft metamaterial can be effectively controlled by mixing water with other organic solvent, such as ethanol in this work. By controlling the volume ratio of the water and ethanol, the tunability

from zero absorption to full absorption is realized. With the wideband and tunable capability, the proposed perfect metamaterial absorber gives a promising applications in energy harvesting, stealth system and microwave communications.

9587-10, Session 3

Potential of multi-photon reading and writing for optical data storage systems *(Invited Paper)*

Thomas D. Milster, Phat Lu, Khanh Kieu, College of Optical Sciences, The Univ. of Arizona (United States)

Several examples of multi-photon (MP) media for optical data storage (ODS) include the Call/Recall fluorescent disc, vitreous silica, MP excitable resins, photorefractive polymers, bulk glass, molecular glasses, highly linked polymers, sapphire, and others. These media all utilize MP interaction to form data bits. In addition, some readout systems use MP interactions to limit inter-layer crosstalk. Typically, a 2-photon interaction is the basis for writing data. That is, the polarization of the illuminated material responds to the square of the electric field amplitude, which has the effect of localizing the interaction to a very small volume near the tightly focused laser beam. Higher-order interactions, if possible, could limit the interaction volume to much smaller dimensions. For example, in the laboratory, tenth-order voids in glass have been demonstrated. The lasers used to generate the femto-second pulses and kW peak powers necessary for writing MP data have dramatically reduced in size and cost in just the last few years. It is now possible to purchase a hand-held femto-second laser operating at 1560nm that produces over 1nJ per pulse. Near-term advances in this laser technology promise to provide smaller footprints, higher powers and a wide selection of wavelengths. Lastly, we will discuss a new mechanism of MP field enhancement that may be useful to increase the contrast of ODS readout signals. We have demonstrated a third-harmonic generation signal enhancement factor of 8 when scanning a laser beam over a structured surface.

9587-11, Session 3

Roll-to-roll fabrication of multilayer polymer films for high capacity optical data storage *(Invited Paper)*

Kenneth D. Singer, Cory W. Christenson, Anuj Saini, Case Western Reserve Univ. (United States); Christopher J. Ryan, Heather Mirletz, Irina Shiyanovskaya, Folio Photonics LLC (United States); Kezhen Yin, Eric Baer, Case Western Reserve Univ. (United States)

Multilayer optical data storage is a promising approach for realizing archival optical discs with terabyte capacity for applications in enterprise data storage. We report on the fabrication of optical discs containing dozens of layers from a high-scalable multilayer polymer film co-extrusion process.

Polymer co-extrusion is a well-established roll-to-roll manufacturing process with applications as diverse as food packaging and high performance optical filters. We have adapted this to produce films with up to dozens of layers of photo-patternable material. The film is easily fabricated into optical discs with the potential capacity of several terabytes.

Data is stored in voxels defined by photobleaching a fluorescent dye contained in writable layers of 200-300nm thickness separated by inert layers of 2-3 microns. We have shown that at short pulse durations of a pulse-modulated commercial BDXL laser, the nonlinear writing process within the absorption band of the dye exhibits a distinct threshold, thus promising low crosstalk and sub-diffraction limit bit patterns. The writing process exhibits a crossover from a linear to nonlinear regime at pulse durations of a few hundred microseconds. We describe the physics of the writing process in terms of a thermal diffusion.

We have recently demonstrated that data can be written and read using a modestly adapted commercial BDXL pick-up. The confocal optical configuration for reading suggests that the drive developed for our discs could be backward compatible with earlier commercial optical discs. Studies of photostability and defect density suggest the suitability of this technology for long-term, high-performance enterprise archival data storage.

9587-12, Session 3

Air gap control and residual aberration compensation in a Hyper Blu-Ray Disc (NA=1.4) objective

Victor E. Densmore, Young-Sik Kim, Thomas D. Milster, College of Optical Sciences, The Univ. of Arizona (United States); Matthew C. Watson, Dolaphine Kwok, The Univ. of Arizona (United States)

Nano-scale resolution in miniature optical systems has been realized in the optical data storage industry. Numerical apertures greater than unity have been achieved in by utilizing the high index material of a hemispherical Solid Immersion Lens (SIL), which increases the resolution of the backing objective by a factor that is related to the refractive index of the SIL. In this research, a custom Hyper-Blu-Disc (HBD) NA=1.4 SIL objective is utilized for high-fidelity readout of data pits beneath a 100?m thick cover layer on an optical Blu-Ray Disc. If realized commercially, the increase in data density could be 3X today's Blu-Ray technology. A distinct difference between this work and other work with SILs in optical data storage is the data storage capacity improvement is made using the current Blu-Ray Disc structure that uses a 100?m thick cover layer. In this report, a phase plate is designed to compensate for residual aberrations resulting from non-ideal cover layer thicknesses and a method for controlling the air gap height of the SIL-cover layer region is proposed.

9587-13, Session 3

Optimized six-dimensional optical storage: A practicable way to large capacity and fast throughputs

Shangqing Liu, Willow Optics Corp. (Canada)

An optimized six-dimensional optical storage system has been designed and investigated theoretically. This system uses multiple beams with different wavelengths, coded polarizations and graded intensities to create multiple and overlapped micro gratings as each storage cell. Because the storage cell capacity depends exponentially on the write beam wavelength number, and the data are written and read by the multiple beams simultaneously, this system can have large storage capacity and fast data throughputs.

By two-photon absorption writing, up to 180 data layers can be created in a DVD sized disk. Also by optical coherence tomography reading, the stored data can be retrieved with high signal-to-noise ratio of over 66 dB. Furthermore, the superresolving pupil filters are used to optimize the system. By reducing the beam focus diameters, the storage cell density can be increased obviously, resulting in larger storage capacity (over 1 Pbyte per DVD sized disk and ~60 Pbytes per disk is potential) and faster data throughputs (reading speed is over 117 Gbits/s).

In addition, the storage cell sizes (~ 1?m ? 6?m) of this system are much larger than those (less than several tens of nm) required for the large capacity three-dimensional storage system, which can greatly reduce the huge difficulties for creating and addressing the tiny data spots.

This system structure is very like a standard drive, and so has good compatibility with the CD and DVD disks.

These comprehensive advantages will make this technology become an actually practicable one for extra-large capacity and extra-fast throughputs optical storage.

9587-14, Session 4

Modeling and measures against the effect of mechanical instabilities on holographic data storage system *(Invited Paper)*

Kenichi Shimada, Toshiki Ishii, Taku Hoshizawa, Hitachi, Ltd. (Japan); Yuzuru Takashima, The Univ. of Arizona (United States)

The volume of worldwide digital data is expanding exponentially and will reach 44ZB (1ZB = 10^9 TB) in 2020. Under the circumstances, the significance of Optical Data Storage (ODS) as archival data storage is affirmed because of their lower bit cost and longer archival life. Holographic Data Storage System (HDSS) has been considered as one of promising candidates for future ODS due to its abilities of high density recording and fast transfer rate. However, in a HDSS, tolerance of vibrations caused by mechanical instabilities is subject to become severe in return for their high density recording. Thus, it is crucial to understand effects of vibrations on HDSS in order to make recording density of the system enlarged maximally. We analytically formulated the effects on the HDSS by incorporating the concept of a Time-Averaged Holography. Mechanical parameters such as amplitude and frequency of mechanical oscillation are related to optical parameters such as amplitude and phase of reference and signal beams in the formalization. Based on the formalization, we analyzed how the effects are related to system performances and developed write mode control technique to prevent data transfer rate decrease in writing holograms. Then, the analytical formulation led to a new technique of optical and post compensation for mechanical instability during recording hologram. These techniques enable a robust implementation of HDSS against mechanical instabilities.

9587-15, Session 4

Enhancement of data rates by single and double cavity holographic recording

Bo E. Miller, Yuzuru Takashima, College of Optical Sciences, The Univ. of Arizona (United States)

To satisfy the growing need for faster archival data storage and retrieval, we proposed an improvement to the read and write data transfer rates of Holographic Data Storage Systems (HDSS). Conventionally, reading and writing of data utilize only a fraction of the available light. Our techniques apply a resonator cavity to the readout and recording of holograms so that more of the available light is used. Functionally, more power is used than what is provided without violating energy conservation. Thus, data rates and/or capacities can be increased due to enhanced power. These improvements are also inversely related to the diffraction efficiency of a hologram, which makes these cavity enhanced techniques well suited to HDSS where large numbers of multiplexed holograms require low diffraction efficiencies.

Previously, we presented the theory of Cavity Enhanced HDSS and the results of enhanced readout upon diffraction efficiency and Bragg selectivity. We have now formalized the enhancement in writing power and experimentally evaluated the improvement in writing speed over conventional means for writing a single plane wave hologram in Fe:LiNbO3 with a 532 nm wavelength, CW, single mode, DPSS, Nd:YAG, laser with a cavity on one of the writing arms. The diffraction efficiency was read during the recording by using a 632.8 nm wavelength HeNe Laser. We found that the enhancement of recording power for this configuration asymptotically approaches a factor of two, while the use of cavities in both writing arms provides a power enhancement which is limited only by the losses in the cavities.

9587-16, Session 4

Optimized aperture for collinear holographic data storage system

Jinqiu Liu, Yan Zhao, Liangcai Cao, Hao Zhang, Guofan Jin, Tsinghua Univ. (China)

The quality of the reconstructed data pages is an important factor representing the performance of the collinear holographic data storage system [1]. It is primarily determined by the quality of the source, the input data page. In our collinear holographic data storage system, the input data page is uploaded by a spatial light modulator, which has a micron-size pixel structure. Both the object beam and reference beam are converged into the objective lens through a set of relay lens [2-3]. The quality of the input data page is highly influenced by the aperture in the Fourier plane of the relay lens. Limited size of the aperture causes the interpixel cross talk, which reduces the signal-to-noise ratio (SNR). In this work, an spectrum model for the imaging of the pages from the spatial light modulator are proposed in the collinear holographic data storage system. It can be used to analyze the impact of the aperture on the input image quality on the recording media. Experiments are conducted to evaluate the effects of different diffracted orders in the Fourier plane. Simulated and experimental results show that higher SNR can be achieved by optimized apertures for different kinds of image patterns. This work provides a simple and practical method for improving the SNR of the reconstructed data page. The understanding of the spatial spectrum of the input data page offers one of the guidelines for the design of the collinear holographic system.

Volume holography with Bessel-like reference beams

Raphael A. Guerrero, Jonathan P. Manigo, Ateneo de Manila Univ. (Philippines)

We report volume holographic recording and reconstruction of plane waves using reference beams with Bessel-like propagation properties. A photorefractive lithium niobate crystal (0.05% Fe:LiNbO3) is employed as the holographic medium in a two-wave mixing set-up. Our light source is a 4 mW HeNe laser operating at a wavelength of 543.5 nm. The laser output is collimated and split into an unmodified plane wave object beam and a Bessel-like reference beam. A Bessel-like beam is generated by an annular slit, with diameter = 0.75 mm and slit width = 0.15mm, placed at the back focal plane of a lens with focal length = 50 cm. Recording time is set at 5 minutes. Reconstructed images are captured with a CCD camera positioned at increasing distances from the crystal starting at 10 cm. The reconstructed plane wave has the same appearance as a Bessel beam, displaying a central maximum and concentric rings. Over a propagation range of 10 to 50 cm, the central intensity is observed to oscillate between maximum and zero intensity. Taking into account the well-established self-healing nature of Bessel beams, we also examine the effects of using a partially blocked reference beam. A small obstruction with width = 0.5 mm is placed 2.5 cm after the lens used to produce the Bessel-like beam. The reconstructed wave initially appears altered but recovers its original intensity profile after propagating 40 cm. The propagation properties of the beam reconstructed via our method have potential utility in holographic storage and optical trapping.

Conference 9588: Advances in X-Ray/EUV Optics and Components X

Tuesday - Wednesday 11–12 August 2015

Part of Proceedings of SPIE Vol. 9588 Advances in X-Ray/EUV Optics and Components X

9588-1, Session 1

Multilayer coatings for free-electron laser sources

Alain J. Corso, Paola Zuppella, Davide Bacco, Enrico Tessarolo, Marco Nardello, Francesca Gerlin, Univ. degli Studi di Padova (Italy); Emiliano Principi, Erika Giangrisostomi, Filippo Bencivenga, Alessandro Gessini, Claudio Masciovecchio, Angelo Giglia, Stefano Nannarone, Elettra-Sincrotrone Trieste S.C.p.A. (Italy); Maria G. Pelizzo, Univ. degli Studi di Padova (Italy)

Extreme ultraviolet (EUV) multilayer (ML) technology has been intensively applied in many scientific and technological fields such as solar physics and photolithography. More recently, the advent of free electron lasers (FEL) emitting bright sub-ps pulses with very high quality in term of intensity stability, coherence and temporal shape has encouraged the usage of multilayer coatings also in the transport and manipulation of FEL radiation. In fact, conventional single layers coated mirrors provide negligible reflectance in the EUV spectral range whereas ML mirrors can reach high efficiency at normal incidence without affecting the pulses characteristics. Such optical elements have been also exploited at FERMI@ELETTRA FEL where novel multilayer coatings specifically conceived for pump and probe experiment and ultrafast absorption spectroscopy have been designed. The main results are reported.

9588-2, Session 1

Graded multilayers for figured Kirkpatrick-Baez mirrors on the new ESRF end station ID16A

Christian Morawe, Raymond Barrett, Peter Cloetens, Benjamin Lantelme, Jean-Christophe Peffen, Amparo Vivo, ESRF - The European Synchrotron (France)

The upgraded ESRF end station ID16A was equipped with a new Kirkpatrick-Baez (KB) nano-focusing setup. The figured KB mirrors were coated with steeply graded W/B4C multilayers to account for the variable angle of reflection along the beam footprint. The multilayers were deposited at the ESRF Multilayer Facilities by DC magnetron sputtering in dynamic mode, where the substrates move in front of the sputter cathodes. The present work deals with the design, the fabrication, and the characterization of the coatings. First results obtained during commissioning experiments on ID16A complement the report.

9588-3, Session 1

In-situ GISAXS monitoring of ultrashort period W/B4C multilayer x-ray mirror growth

Martin Hodas, Peter ?iffalovi?, Yuriy Halahovets, Marco Pelletta, Karol Vegso, Matej Jergel, Eva Majkova, Institute of Physics SAS (Slovakia)

Ultrashort period multilayer X-ray mirrors with the layer thickness down to 1 nm or less represent a technological challenge. Here, the layer thickness becomes comparable to the interface roughness and discontinuous layers producing strong diffuse scattering may appear. The grazing-incidence small-angle X-ray scattering (GISAXS) is a unique nondestructive technique to probe the mirror quality in terms of the statistical interface roughness and its correlation properties. We present the first in situ laboratory GISAXS experiments of monitoring the multilayer mirror growth in order to better understand and optimize the deposition process. A microfocus X-ray source IuS with focusing Montel optics (Incoatec) and 2D X-ray detector Pilatus 200K (Dectris) were mounted on a custom-designed dual-ion beam sputtering apparatus (Bestec). Two W/B4C mirrors with 15 periods of 1.8 nm and 2.1 nm were prepared as determined from the post-deposition specular X-ray reflectivity measurements. The in situ GISAXS tracking was done by a fast repeated collection of the GISAXS frames with the integration time of 8 s at the incidence angle of 0.25 degree. Two distinct features along qz at qy=0, namely Yoneda and Bragg-like (BL) multilayer peaks evolved in the GISAXS pattern. Oscillatory behavior of the latter in terms of intensity and FWHM was observed after the initial stage. Lateral cuts of the diffuse scattering concentration stripes surrounding BL peaks in particular GISAXS frames provided temporal evolution of the correlation and fractal interface parameters. Their potential for tailoring the multilayer properties is discussed.

9588-4, Session 1

Multilayer optics for monochromatic high-resolution x-ray imaging

Philippe P. Troussel, Berenice Loupias, Vincent dervieux, Ludovic Lecherbourg, Dominique Gontier, Commissariat à l'Énergie Atomique (France); Alexandre DO, Sophie D. Baton, Frédéric Perez, Ecole Polytechnique (France) and Ctr. National de la Recherche Scientifique (France); David Dennetiere, Synchrotron SOLEIL (France)

Within the framework of its researche on Inertial Confinement Fusion (ICF), the "Commissariat à l'Énergie Atomique et aux Énergies Alternatives" (CEA) studies and designs advanced X-ray diagnostics in order to probe dense plasmas produced by Laser facilities.

We have chosen to present two types of advanced High Resolution X-ray Imaging (HRXI) microscopes who have high spatial resolution capability (3-6 μm) and high efficiency for monochromatic focusing x-ray radiation.

The first microscope consists of two toroïdals mirrors mounted into a Wolter type geometry and working at grazing incidence. Non-periodic multilayer (depth graded) mirrors were developed with special coatings designed to provide broadband X-ray reflectance and to be use in the 1-22 keV energy range. Mainly, a high resolution, high X-ray photon energy involving state-of-the-art toroïdal mirror and W/Si multilayer mirrors coating are detailed. Associated to this Wolter microscope a potential monochromatic third mirror coated with a multilayer stack can be used for monochromatic application in that range.

The second microscope is composed of a transmission gold Fresnel Phase Zone plate (FPZP) and of a very narrow bandwidth multilayer mirror. We present an experimental study with X-ray plasma-source. We show the interest in the case of broadband source imaging (plasma source) associated with the FPZP a multilayer mirror.

Potentialities (a few μm spatial resolution monochromatic images) and complementarity of these two monochromatic HRXI are discussed.

The multilayer mirrors and sub-nanoscale layers characterization were detailed.

9588-21, Session 1

High-reflectance La/B-based multilayer mirror for 6.x-nm wavelength

Dmitry S. Kuznetsov, Marko Sturm, Robbert W. E. van de Kruijs, Andrey E. Yakshin, Eric Louis, Fred Bijkerk, MESA+ Institute for Nanotechnology (Netherlands)

For future photolithography processes, the wavelength of 6 nm can be considered. The perspective of this chip fabrication technique however, will depend essentially on the performance of multilayer reflective mirrors, which will need to be based on La/B. One of the issues is formation of LaxBy compounds at the interfaces, which decreases the optical contrast and therefore dramatically reduces the reflectivity. To prevent such chemical interaction, passivation of La by nitrogen has been investigated. We successfully synthesized LaN layers that resulted in a new world record reflectivity of 64% at 6.6 nm at near normal incidence. This reduces the gap to the target of 70% desired for a possible next generation lithography.

9588-5, Session 2

Development of an adaptive K-B mirror for hard x-ray nanofocusing using piezoelectric deformable mirrors

Takumi Goto, Satoshi Matsuyama, Osaka Univ (Japan); Hiroki Nakamori, JTEC Corp. (Japan); Takashi Kimura, Hokkaido Univ. (Japan); Yasuhisa Sano, Osaka Univ (Japan); Yoshiki Kohmura, Makina Yabashi, Tetsuya Ishikawa, RIKEN/SPring-8 (Japan); Kazuto Yamauchi, Osaka Univ (Japan)

We have been developing an adaptive x-ray focusing optical system that consists of two-stage Kirkpatrick-Baez deformable mirrors. The optical system can provide focused x-ray beam with controlled beam size in diffraction-limited condition at the fixed focal point. To realize the optical system, we developed an ultraprecise deformable mirror with a piezoelectric bimorph structure. It consists of a quartz glass substrate, four piezoelectric actuators and 18 electrodes on each actuators. The substrate has dimensions of 50?100?t5 mm3. The four actuators, which have dimensions of 17.5?100?t1 mm3, were attached to face and back sides of the substrate. To investigate the performance of the optical system, we performed a two-dimensional focusing test by using an adaptive K-B mirrors at the EH3 of BL29XUL of SPring-8 using 10keV X-rays. To deform the mirrors to the required elliptical shape, first, the mirror is deformed by applying initial voltages that has been predetermined by performing a deformation test with an optical interferometer. Then, to correct deformation errors, we adjusted supply voltages according to the measured mirror shape by pencil-beam scanning. As a result, the deformation accuracy of 2 nm (peak-to-valley) was achieved. In addition, a focused beam with full width at half maximum of 110 ? 65 nm2 (V ? H) was obtained.

9588-6, Session 2

MZP design and fabrication for efficient hard x-ray nano-focusing and imaging

Christian Eberl, Florian Döring, Hans-Ulrich Krebs, Markus Osterhoff, Georg-August-Univ. Göttingen (Germany)

Efficient focusing optics are a key ingredient for high-resolution (few nano metre) hard x-ray imaging. In recent years, a combined optical scheme uses prefocusing to match the coherent fraction of the synchrotron beam to a high-resolution multilayer zone plate (MZP) has been presented. This scheme allows for sub-5?nm focusing of hard x-rays in two dimensions.

We present latest optimisations achieved in both design and fabrication of high-resolution MZPs. First lenses produced by Pulsed Laser Deposition from alternating W and Si layers suffered from droplet formation during an unfavourable growth process. The material combination has been changed to Ta2O5 and ZrO2, allowing for much faster and more accurate layer growth. The initial roughness of the central core has been minimised by using a pulled glass fibre, bringing the focusing efficiency close to seven per cent (+1st order).

9588-7, Session 2

Adaptive optics at the angstrom scale: from discrete to continuous surface manipulation

Benjamin J. Wylie-van Eerd, Univ. Twente (Netherlands); Bram Krijnen, DEMCON (Netherlands); Fred Bijkerk, Guus J. H. M. Rijnders, Eric Louis, Univ. Twente (Netherlands)

Adaptive optics are of great utility in increasing the performance of optical systems. However, they are not currently widely used in EUV, X-ray and higher energy ranges due to the difficulties of surface manipulation with angstrom scale precision.

In this presentation we will show progress in creating an piezoelectric based adaptive optic system suitable for correcting wave fronts at EUV and X-ray wavelengths. In particular, novel technology allowing wave front correction by continuous rather than discrete manipulation of surface elements will be demonstrated. The theoretical concept behind this technology and experimental proof will both be shown.

The continuous surface manipulation technique is capable of creating surfaces much better suited to wave front correction than individual discrete elements while still benefiting from the speed and precision of piezoelectric materials. The current state of the technology, advantages of its use and the outstanding challenges will be discussed.

Such a technology can be used for example in EUV lithography systems, to increase tolerances for imperfections elsewhere in the multiple mirror system. This allows leeway for a challenging problem in the optical system, and accelerates the technology towards market readiness.

9588-8, Session 2

Evaluation of surface figure error profile of ultra-precise ellipsoidal mirror for soft x-ray focusing

Yoko Takeo, Takahiro Saito, Hidekazu Mimura, The Univ. of Tokyo (Japan)

Soft X-ray nanofocusing with high efficiency and no chromatic aberration is possible by using the ultra-precise ellipsoidal mirror. Surface figure metrology is key for improving surface figure accuracy. In this research, we use ptychographic phase retrieval using a visible light laser for measuring surface figure error profiles of ellipsoidal mirrors. Recently, the measurement accuracy has been further increased by employing advanced calculation methods and improving the experiment system. In this presentation, we will explain the method in detail and show the measurement performance of the developed system.

9588-9, Session 3

Profile-coating of x-ray optics using the new magnetron sputtering deposition system

Bing Shi, Jun Qian, Raymond Conley, Argonne National Lab. (United States)

X-ray mirrors and multilayer optics for synchrotron beamlines have been fabricated using the newly developed magnetron sputtering system at the Optics Group at Advanced Photon Source (APS). This new linear deposition system has two cathodes with DC power supplies. It has been equipped recently and used in the fabrication of multilayers and profile-coating mirrors. The commissioning of this machine, the fabrication of x-ray mirrors using profile-coating technique, the results of the mirrors fabricated, the coating materials testing for thin film optics stress reduction, the existing issues, and the future plan will be presented.

9588-10, Session 3

Recent advances in multilayer Laue lens fabrication techniques

Raymond Conley Jr., Argonne National Lab. (United States) and Brookhaven National Lab. (United States); Nathalie Bouet, Juan Zhou, Hanfei Yan, Xiaojing Huang, Kenneth Lauer, Evgeny Nazaretski, Matthew Vescovi, Brookhaven National Lab. (United States); Adam Kubec, Fraunhofer IWS Dresden (Germany); Albert T. Macrander, Jörg Maser, Bing Shi, Argonne National Lab. (United States); Yong S. Chu, Brookhaven National Lab. (United States)

Multilayer Laue lens (MLL) fabrication techniques have gradually matured from providing only limited production of small “proof of concept” devices to true nanofocusing optics ready for beamline deployment. New multilayer material systems and deposition techniques that offer both larger aperture growths and higher optical performance are introduced. Wedged MLL, where the individual layers within the stack are both depth-graded and laterally graded in thickness, have been produced with apertures greater than 30?m. Initial synchrotron results at beamlines 1-BM and 34-ID at the Advanced Photon Source on tilted and wedged large aperture MLLs indicate clear performance increases and point the way towards the next fabrication challenges to overcome.

Work at Argonne National Laboratory was supported by the Department of Energy, Office of Basic Energy Sciences under contract DE-AC-02-06CH11357. Work at Brookhaven National Laboratory was supported by the Department of Energy, Office of Basic Energy Sciences under contract DE-AC-02-98CH10886.

Development of polycapillary x-ray optics for synchrotron spectroscopy

Daniel Bennis, Incom Inc. (United States)

A new spectrometer design that will result in a highly efficient, easy to handle, low-cost, high-resolution spectroscopy system with excellent background suppression is being developed for the NSLS-II Inner-Shell Spectroscopy beamline. This system utilizes non-diffractive optics comprised of fused and directed glass capillary tubes that will be used to collect and pre-collimate fluorescence photons. There are several advantages enabled by this design; a large energy range is accessible without modifying the system, a large collection angle is achieved per detection unit: 4-5% of the full solid angle, easy integration in complex and harsh environments is enabled due to the use of a pre-collimation system as a secondary source for the spectrometer, and background from a complex sample environment can be easily and efficiently suppressed.

Development of the polycapillary x-ray focusing optics for this application will be presented. This includes simulation of key design parameters of x-ray optics to guide optimization efforts, improvement in manufacturing methods of polycapillary structure for x-ray optics, forming the polycapillary structure to produce x-ray optics to achieve the required solid angle collection and transmission efficiency, and measurement of x-ray focusing properties of the optics using an x-ray tube source.

9588-12, Session 3

RXR: a new experimental station for 2D and 3D micro-XRF based on polycapillary optics

Claudia Polese, Istituto Nazionale di Fisica Nucleare (Italy) and Sapienza Univ. di Roma (Italy); Andrea Liedl, Dariush Hampai, Istituto Nazionale di Fisica Nucleare (Italy); Sultan B. Dabagov, Istituto Nazionale di Fisica Nucleare (Italy) and Russian Academy of Sciences (Russian Federation) and National Research Nuclear Univ. MEPhI (Russian Federation); Francesco Taccetti, Istituto Nazionale di Fisica Nucleare (Italy)

XRF imaging spectrometry is a powerful tool for materials characterization, for example in the cultural heritage field. A high spatial resolution is often required, in order to appreciate very tiny details of the studied object. With respect to simple pinholes, polycapillary optics allows much more intense fluxes to be achieved. This is fundamental to detect elements in trace and to strongly reduce the global acquisition time that is actually among the main reasons, in addition to radioprotection issues, affecting the competitiveness of XRF imaging with respect to other faster imaging techniques such as multispectral imaging. Unlike other well-known X-ray optics, principally employed for high brilliant radiation source such as synchrotron facilities, polyCO can be efficiently coupled also with conventional X-ray tubes. All these aspects make them the most suitable choice to realize portable, safe and high performing μXRF spectrometers.

In this work the first results achieved with a novel 2D and 3D XRF facility, Rainbow X-Ray (RXR), are reported, with particular attention to the spatial and energy resolution achieved. RXR is based on the confocal arrangement of three polycapillary lenses, one focusing the primary beam and the other two capturing the fluorescence signal. The detection system is split in two couples of lens-detector in order to cover a wider energy range. The entire device is a laboratory user-friendly facility and, though it allows measurements on medium size objects, its dimensions do not preclude it to be transported for in situ analysis on request, thanks also to a proper shielded cabinet.

9588-13, Session 3

Large-area kapton x-ray windows

Mikhail A. Antimonov, Univ. of Illinois at Chicago (United States); Ali M. Khounsary, X-ray Optics, Inc. (United States) and Illinois Institute of Technology (United States); Steven J. Weigand, Jack Rix, Denis T. Keane, Jim Grudzinski, W. Jansma, Argonne National Lab. (United States); Zhenwen Zhou, Univ. of Illinois at Chicago (United States); A. Johnson, Bowling Green State Univ. (United States)

Some X-ray instruments require the utilization of large-area windows to provide vacuum barriers. The necessary attributes of the window material include transparency to X-rays, low scattering, and possession of suitable mechanical properties for reliable long-term performance. Kapton is one such material except that it is a polymer and a large window made from Kapton undergoes substantial deformation at room temperature under a pressure difference of the order of the atmospheric pressure.

In this paper, we report on the mechanical testing of sample Kapton foils including creep, comparison with published data, and use this data and analytical/numerical models to predict the changing profile of Kapton windows over time, showing good correlation with experimental measurements.

Acknowledgements

Portions of this work were performed at the DuPont-Northwestern-Dow Collaborative Access Team (DND-CAT) located at Sector 5 of the Advanced Photon Source (APS). DND-CAT is supported by Northwestern University, E.I. DuPont de Nemours & Co., and The Dow Chemical Company.

This research used, in part, the resources of the Department of Civil and Materials Engineering (CME) at the University of Illinois, Chicago (UIC) and of Argonne National Laboratory (ANL) and the Advanced Photon Source (APS), a U.S. Department of Energy (DOE) Office of Science User Facility operated for the DOE Office of Science by ANL under Contract No. DE-AC02-06CH11357. Fruitful discussions with Dr. A. Chudnovsky at UIC/CME, the technical staff at DuPont, and Ben Stillwell at APS are graciously acknowledged.

9588-14, Session 4

Effect of beamline optics vibration on the source size and divergence for synchrotron radiation

Shunji Goto, Japan Synchrotron Radiation Research Institute (Japan)

Suppression of the beamline optics vibration is crucial particularly for a low-emittance storage ring. Reflection optics such as mirror and crystal monochromator affect light source size and divergence virtually due to the optics vibration. Minute vibrations result in degradation of synchrotron radiation beam quality: photon flux density, focusing property, averaged coherence.

Variations of the beam size and divergence were formulated using a simple geometrical model. The vibration effect was involved in the phase space. An angular vibration effect was examined for source size, source divergence, beam size at the sample position, and also distance between light source beam waist and optics. A typical arrangement of the SPring-8 beamline was assumed with the primary reflection optics at 40 m from the source. The vertical source size increase is significant compared with the other values for vertical-deflection optics. Suppression of the angular vibration less than 0.1 micro-radians (rms), for example, is required to maintain the 5-micron beam with less than 10% increase.

9588-15, Session 4

Development of split-delay optics with wide range of photon energy for XFEL pump/XFEL probe experiments

Takashi Hirano, Taito Osaka, Osaka Univ. (Japan); Yuichi Inubushi, Japan Synchrotron Radiation Research Institute (Japan); Yasuhisa Sano, Satoshi Matsuyama, Osaka Univ. (Japan); Kensuke Tono, Tetsuo Katayama, Japan Synchrotron Radiation Research Institute (Japan); Tetsuya Ishikawa, RIKEN/SPring-8 (Japan); Kazuto Yamauchi, Osaka Univ. (Japan); Makina Yabashi, RIKEN/SPring-8 (Japan)

Ultra-intense transversely-coherent, and ultrafast hard x-ray pulses provided from x-ray free-electron laser (XFEL) sources, such as SPring-8 Angstrom Compact free-electron LAser (SACLA) in Japan are powerful tools to explore ultrafast science with hard x-rays. Development of a split-delay optics (SDO), which provides two replica XFEL pulses with time delay precisely controlled, is essential for XFEL pump/XFEL probe experiments. An SDO based on Bragg diffraction of Si(220) single crystals consists of sub 10-um-thick beam splitter/mixer crystals, two beam reflectors (thick crystals), and a pair of channel-cut crystals, thus it yields high throughput and is applicable in wide ranges of delay time and photon energies. The SDO is contemplated in combination with a focusing system to realize high power density field, hence the replica XFEL pulses need to be overlapped each other onto the focal plane where samples are set in experiments. In order to achieve not only spatial overlap of the replica pulses but also high throughput, precise parallelization of the two beams is required. A tolerated error in crystal angle of ±0.2 urad was calculated by ray trace calculations. We devised a simple and precise alignment procedure and have demonstrated it at SPring-8. We obtained well-overlapped two-dimensionally focal profiles and the world's highest throughput of ~25%, its collinearity was evaluated to be 0.03 urad (H) ? 0.24 urad (V). In the presentation we report about the test at SPring-8 and commissioning at SACLA performed on May in this year.

9588-16, Session 4

0.1-meV-resolution broadband imaging spectrographs for inelastic x-ray scattering

Yuri V. Shvyd'ko, Argonne National Lab. (United States)

A spectrograph is an optical instrument that disperses photons of different energies into distinct directions and space locations, and images photon spectra on a position-sensitive detector. Spectrographs consist of collimating, angular dispersive, and focusing optical elements. Feasibility of hard x-ray spectrographs with an ultra-high spectral resolution (0.1-meV resolution) has been experimentally demonstrated recently [1]. Bragg reflecting crystals arranged in an asymmetric scattering geometry are used as the dispersing elements. The spectral window of imaging in the demonstrated device, however, was narrow, only 0.45 meV. Here we show that the ultra-high-resolution spectrographs with a significantly increased spectral window of imaging of up to a few tens of meVs are feasible and can be efficiently applied for inelastic x-ray scattering (IXS) spectroscopy [2]. Such spectrographs, equivalent to an IXS spectrometer with more than hundred 0.1-meV resolution analyzers, will enable IXS spectroscopy with the ultra-high resolution and very high efficiency, applicable both at synchrotron and x-ray free-electron laser facilities.

Virtual x-ray differential phase contrast imaging system simulator

Young-Sik Kim, Chris Summitt, Sunglin Wang, The Univ. of Arizona (United States); Yin Yuen, Charles Qi, Lambertus Hesselink, Stanford Univ. (United States); Yuzuru Takashima, The Univ. of Arizona (United States)

X-ray differential phase contrast (DPC) imaging system consisting of source amplitude grating (G0), phase grating (G1), and analyzer amplitude grating (G2) is widely adopted because of its compatibility with low brilliance and incoherent X-ray sources, high detection sensitivity of index of refraction (< 1E-6) while having reasonably short system size (~1m), and is expected to be used for security screening applications as luggage inspections. For such applications, object of interest is surrounded by various kinds of and randomly oriented clutter which alters amplitude, spectra and phase of X-ray detected by detector. Such effects ideally have to be taken into account during the design phase of the X-ray DPC imaging modalities. Thus, we developed an integrated and end-to-end simulation environment to systematically optimize and predict imaging performances of X-ray DPC imaging systems. The simulation environment consists of two off-the-shelf modules, such as 3D CAD and Optical Ray-trace Code, as well as a custom physical optics module to simulate polychromatic fringe formation. Each module are interfaced to pipeline data so that the 3D CAD data of the object under inspection and clutter is exported to Ray-trace Code. The Ray-trace Code calculates shift of monochromatic fringes by non-sequential ray-tracing though objects and clutter. Finally the ray-trace data is interfaced to the physical optics module to obtain signal from scanned G2 grating. The virtual X-ray DPC simulator enables optimizing the system parameters, design energy, X-ray tube voltage and beam hardening while taking into account practical objects and clutter. We also present comparison of simulation results with experimental results for objects surrounded by clutter.

9588-18, Session 5

Waveguiding, mode filtering, and polarization control at extreme-ultraviolet frequencies

Sergey Zayko, Georg-August-Univ. Göttingen (Germany)

Lensless imaging techniques have a unique potential for direct investigation of the field distributions, governed by the nanoscale structures, in the spectral ranges where applicability of the conventional optical elements is limited. Here, we present a study of the extreme ultraviolet wave propagation in the nanoscale designed masks by means of coherent diffractive imaging (CDI) utilizing high-harmonic generation source. Exit surface waves, scattered from the objects, are reconstructed from their far field diffraction patterns using iterative phase retrieval algorithm. Reconstructions are susceptible to multiple scattering within the depth of the object and demonstrate pronounced waveguiding entailing strong high order modes suppression and substantial transmission contrast for varying light polarization. The observed phenomena are reproduced in semi-analytical and numerical simulations indicating the potential of designing new optical elements such as mode filters, wave plates and polarizers for extreme-ultraviolet spectral range.

9588-19, Session 5

Development of ellipsoidal focusing mirror for soft x-ray and EUV

Hidekazu Mimura, Yoshinori Takei, Takahiro Saito, Takehiro Kume, Hiroto Motoyama, Satoru Egawa, Yoko Takeo, Takahiro Higashi, The Univ. of Tokyo (Japan)

Ellipsoidal mirror is one of promising focusing optics for soft X-ray and EUV. We have been developing the manufacturing system of ultra-precise ellipsoidal mirrors for 4 years. This system consists of mandrel fabrication, electroforming, wavefront measurement and additional deposition. We successfully fabricated an ellipsoidal mirror with 50 nm-level figure accuracy and evaluated its focusing performance using EUV light produced by a high order harmonic generation. In this presentation, we will introduce fabrication process and show the focusing performance of the ellipsoidal mirror.

9588-20, Session PWed

X-ray crystal optic fabrication process of the OPT Group of the X-ray Science Division at the Advanced Photon Source of Argonne National Laboratory

Michael Wieczorek, Xianrong Huang, Elina Kasman, Lahsen Assoufid, Argonne National Lab. (United States)

One of the missions of the OPT group of the X-ray Science Division at Argonne National Laboratory is to fabricate crystal-based X-ray optics from materials such as Silicon, Germanium, Quartz, and Sapphire, which is a unique capability in the USA for the synchrotron light source community. Some of these finished optics include single-bounce monochromators, channel-cut crystals, analyzers, and other devices. These optics are placed in the beamlines of the Advanced Photon Source to provide users with useful X-ray data in conjunction with electro-mechanical systems and measurement electronics. The steps involved in making these optics include slicing, cropping, grinding, crystal plane orienting, ultrasonic milling, wet chemical etching, and polishing. This poster illustrates these steps so the viewer may obtain a better understanding and appreciation of how X-ray optics are fabricated.

Conference 9589: X-Ray Lasers and Coherent X-Ray Sources: Development and Applications XI

SPIE. OPTICS+ PHOTONICS OPTICAL ENGINEERING+ APPLICATIONS

Wednesday - Thursday 12–13 August 2015

Part of Proceedings of SPIE Vol. 9589 X-Ray Lasers and Coherent X-Ray Sources: Development and Applications XI

9589-1, Session 1

Observation of dynamics and modification of solid surface using a picosecond soft x-ray laser *(Invited Paper)*

Masaharu Nishikino, Tetsuya Kawachi, Noboru Hasegawa, Masahiko Ishino, Japan Atomic Energy Agency (Japan); Takuro Tomita, Univ. of Tokushima (Japan); Naofumi Ohnishi, Tohoku Univ. (Japan); Atsushi M. Ito, National Institute for Fusion Science (Japan); Takashi Eyama, Naoya Kakimoto, Rui Idutsu, Univ. of Tokushima (Japan); Yasuo Minami, Yokohama National Univ. (Japan); Tohru Suemoto, The Univ. of Tokyo (Japan); Anatoly Y. Faenov, Osaka Univ. (Japan); Nail A. Inogamov, Russian Academy of Sciences (Russian Federation); Mitsuru Yamagiwa, Japan Atomic Energy Agency (Japan)

Short pulse x-ray sources are widely used as probing beams for new material development and non-destructive x-ray imaging. The high quality soft x-ray laser (SXRL) source enables us to achieve quite high spatial-resolution as a probe and quite intense x-ray as a pump. As an application using the SXRL, we have observed the spallative ablation process by the interaction with SXRL or femto-second (fs) laser. The dynamical processes of the SXRL and/or the fs laser-induced surface modifications come to attract much attention for the micro processing. However, it is difficult to observe the spallative ablation dynamics, because of non-repetitive, irreversible and rapid phenomena in a small feature size. In the case with SXRL irradiation (13.9 nm, 7 ps, 60 mJ/cm^2), we have observed the damage structures and the optical emission from the ablated materials. When focused SXRL pulses were have been irradiated onto the metal surface, we have confirmed damage structures, however no optical emission signal during SXRL ablation could be observed. The electron temperature is estimated to be around a few eV at the ablated surface. In the case with fs laser irradiation (795 nm, 80 fs, 1.5 J/cm^2), we have observed the surface morphology of fs laser ablation by the SXRL interferometer and SXRL reflectometer. The time resolved image of nano-scaled ablation dynamics of the sample surface was observed. The numerical simulation study is underway by using a molecular dynamics code. These results lead to understanding the full process of the interaction with the SXRL and/or fs laser.

9589-2, Session 1

An overview of the application of extreme ultra-violet lasers in plasma heating and diagnosis

Gregory J. Tallents, Valentin Aslanyan, Andrew K. Rossall, Sarah Wilson, The Univ. of York (United Kingdom)

Laser-plasma studies have been undertaken for over 50 years now using infra-red, visible and ultra-violet lasers. The critical density at infra-red to ultra-violet wavelengths is below the density of free electrons in a solid resulting in infra-red to ultra-violet lasers interacting with a solid target predominantly by collective absorption effects at densities up to a critical electron density which is typically at a material density 2 – 3 orders-of-magnitude below the solid density. With pulse durations > 1 ps, the incoming laser interacts with an expanding plume of plasma formed by early components of the laser pulse and does not penetrate to the solid target surface. Extreme ultra-violet radiation (wavelength < 50 nm) has a critical electron density well-above any electron density formed by ionization at solid material density and so potentially can penetrate to a much greater depth into a solid density plasma. We explore in this talk the importance of this penetration in ablating solid targets, in creating novel warm dense matter and in the diagnosis of plasmas. We show that a new regime of extreme ultra-violet laser-produced plasmas are created and explore some of their properties.

9589-3, Session 1

Low electron temperature in ablating materials formed by picosecond soft x-ray laser pulses

Masahiko Ishino, Noboru Hasegawa, Masaharu Nishikino, Japan Atomic Energy Agency (Japan); Tatiana A. Pikuz, Russian Academy of Sciences (Russian Federation) and Osaka Univ. (Japan); Igor Y. Skobelev, Russian Academy of Sciences (Russian Federation) and National Research Nuclear Univ. MEPhI (Russian Federation); Anatoly Y. Faenov, Russian Academy of Sciences (Russian Federation) and Osaka Univ. (Japan); Nail A. Inogamov, Russian Academy of Sciences (Russian Federation); Tetsuya Kawachi, Mitsuru Yamagiwa, Japan Atomic Energy Agency (Japan)

To study the ablation process induced by the soft x-ray laser pulse, we investigated the electron temperature of the ablating material. Focused soft x-ray laser pulses having a wavelength of 13.9 nm and duration of 7 ps were irradiated onto the LiF, Al, and Cu targets, and we observed the optical emission from the surfaces by use of an optical camera. On target surfaces, we could confirm damage structures, but no emission signal in the visible spectral range during ablation could be observed. Then, we estimated the electron temperature in the ablating matter. To consider the radiation from a heated layer, we supposed a black-body radiator as an object. The calculation result was that the electron temperature was estimated to be lower than 1 eV and the process duration was shorter than 1000 ps. The theoretical model calculation suggests the spallative ablation for the interaction between the soft x-ray laser and materials. The driving force for the spallation is an increasing pressure appearing in the heated layer, and the change of the surface is considered to be due to a splash of a molten layer. The model calculation predicts that the soft x-ray laser with the fluence around the ablation threshold can create an electron temperature around 1 eV in a material. The experimental result is in good accordance with the theoretical prediction. Our investigation implies that the spallative ablation occurs in the low electron temperature region of a non-equilibrium state of warm dense matter.

9589-4, Session 1

Advances in nanoscale 3D molecular imaging by soft x-ray laser ablation mass spectrometry

Ilya Kuznetsov, Jorge Filevich, Mark R. Woolston, Tyler Green, Colorado State Univ. (United States); David Carlton, Weilun Chao, Eric Anderson, Lawrence Berkeley National Lab. (United States); Elliot Bernstein, Dean Crick, Debbie Crans, Colorado State Univ. (United States); Valentin Aslanyan, Andrew Rossall, Greg Tallents, The Univ. of York (United Kingdom); Tomas Burian, Libor Juha, Institute of Physics of the ASCR, v.v.i. (Czech Republic); Jorge Rocca,

Carmen Menoni, Colorado State Univ. (United States)

Laser ablation and ionization combined with mass spectrometry (MS) forms the basis of one of the most widely exploited analytical tools of the solid state. This paper describes advances in three dimensional (3D) molecular composition imaging with nanoscale spatial resolution by soft x-ray (SXR) laser ablation time of flight (TOF) MS. The use of the SXR laser light of 46.9 nm wavelength from a compact capillary discharge laser makes it possible to ablate craters with diameters as small as 120 nm and a depth of 3.5 nm in organic materials. Moreover, the single shot ablation of organic materials produces craters with none or little sign of thermal damage to the surroundings of the focal spot. Both positive and negative ion extraction modes provide single shot detection of intact analyte molecules from probing volumes down to 50 zL. We have applied SXR TOF MS to the chemical analysis of antibiotics, aminoacids, organic dyes, and dielectrics. The corresponding mass spectra show protonation is the dominant ionization mechanism in positive extraction mode while electron attachment is predominant in negative mode. The high sensitivity and spatial resolution of SXR TOF MS has enabled the demonstration of composition imaging in organic samples with nanoscale lateral - 75 nm and depth - 20 nm resolutions, without compromising mass resolution. SXR TOF MSI is specifically suited in analysis and imaging of insoluble solid state compounds with low ionization efficiency in ultraviolet range.

9589-5, Session 1

XUV/x-ray laser-induced irreversible changes in solids *(Invited Paper)*

Libor Juha, Institute of Physics of the ASCR, v.v.i. (Czech Republic)

Although irreversible changes occurring in solids exposed to high fluxes of energetic photons (i.e., extreme ultraviolet, soft x-ray and x-ray radiation) were first studied almost forty years ago, particular processes responsible for material alteration were investigated in detail only infrequently until now. Let us consider material removal (erosion) as the most illustrative case of XUV/x-ray-induced irreversible substantial changes in a certain material. The XUV/x-ray sources commonly used for the studies of material removal emit at either low peak power (e.g., synchrotron radiation sources) or high peak power (e.g., free-electron lasers and various sources based on short-lived hot dense plasmas): (a) With low-peak-power sources, material is removed by photon-induced desorption from the irradiated sample surface. (b) High-peak-power sources make possible to expose material to a high local dose of radiation in a short period of time, i.e., at a very high dose rate. It produces an overheated, fragmented region of the sample which tends to blow off (ablate) into the vacuum. Investigating these processes with short-wavelength radiation delivered by various sources, we observed both desorption- and ablation-like behavior. A phenomenological desorption-ablation model has been developed. An influence of wavelength, pulse duration, angle of incidence, and other beam parameters on a course of the above-mentioned phenomena will be treated and summarized in this contribution. Recent results obtained with numerous materials of a very different kind, i.e., from ionic crystals to (bio)molecular solids, will be presented. The role of thermal and non-thermal processes will be discussed.

9589-6, Session 2

Multilayer optics for coherent EUV/X-ray laser sources *(Invited Paper)*

Franck Delmotte, Charles Bourassin-Bouchet, Sébastien de Rossi, Evgueni Meltchakov, Maël Dehlinger, Lab. Charles Fabry (France)

The development of new sources and related applications in the EUV and soft X-ray spectral domain, raises more stringent requirements on the quality of multilayer mirrors. Mirrors with high efficiency, good stability, enhanced selectivity and/or broad bandwidth and phase controlled are key components to manipulate the pulses generated by coherent EUV/X-ray laser sources like X-ray lasers, High Harmonic Generation or X-ray Free Electron Laser sources.

After a brief description of the theoretical principles and history of multilayer mirrors, we present the state of the art of multilayer optics for coherent EUV/X-ray laser sources. First, we focus on the specificities of multilayer mirrors for pico- and femto-second sources, in terms of reflectivity, selectivity and stability. Then, we report the recent advances in the design, deposition and characterization of multilayer mirrors for attosecond sources. Phase controlled multilayer mirrors provide a powerful tool towards transporting or even compressing attosecond pulses. Pulse compression down to sub-50 as duration has already been demonstrated in the extreme ultraviolet (EUV) domain (30 – 100 eV). The design and the phase characterization of such mirrors in the soft X-ray domain (100 – 500 eV) remain challenging and will be discussed.

9589-7, Session 2

X-ray diffractive optics *(Invited Paper)*

Anne E. Sakdinawat, Sharon Oh, Chieh Chang, Jeongwon Park, SLAC National Accelerator Lab. (United States); Michael J. Rooks, Yale Univ. (United States); Richard C. Tiberio, Stanford Univ. (United States)

X-ray diffractive optics provide one of the most versatile ways to shape and manipulate an x-ray beam which is important for areas such as x-ray imaging. One of the barriers to practical use of x-ray diffractive optics, especially for the hard x-ray region, is the low efficiency of these optics, stemming from the difficulty in fabricating very high aspect ratio, high resolution dense features. We will describe the use of metal assisted chemical etching schemes to address and solve problems in the area of x-ray optics.

9589-8, Session 3

EUV laser photoelectron spectroscopy of mass selected neutral clusters *(Invited Paper)*

Elliot R. Bernstein, Shi Yin, Colorado State Univ. (United States)

A long standing set of goals for the study of a system of inhomogeneous, neutral clusters (e.g., MmXn or (molecule)p) has been to mass sort and select them individually for determination of physical and chemical properties of each neutral cluster by spectroscopic techniques. We have constructed appropriate instrumentation to achieve these important goals employing photoelectron spectroscopy (PES), driven by both visible (for MmXn -) and EUV (for MmXn0) radiation. Our 26.5 eV/photon EUV laser can ionize any neutral cluster or molecule (EUV PES) that can be identified and isolated. The algorithm includes the following steps: 1. generation of cluster negative ions in a laser ablation supersonic source with the addition, as required, of low energy electrons from a Y2O3 disk; 2. separation of these anionic clusters in a reflectron time of flight mass spectrometer (RTOFMS); 3. selection and slowing of specific, chosen clusters in a mass gate/momentum deceleration stage; 4. threshold photo-detachment of the sorted and selected negative ion clusters with a tunable VIS/UV laser to generate neutral, isolated clusters; and 5. EUV PES of these neutral clusters. Such studies generate vibrational and structural information on the ground states of the neutral clusters (through VIS/UV PES), and information on the ion states of the clusters (through EUV PES). The presentation will include PES results on various metal oxides, sulfides, and other cluster systems and molecules.

9589-9, Session 3

The observation of a transient surface morphology in the femtosecond laser ablation process by using the soft x-ray laser probe

Noboru Hasegawa, Masaharu Nishikino, Masahiko Ishino, Japan Atomic Energy Agency (Japan); Takuro Tomita, The Univ. of Tokushima (Japan); Naofumi Ohnishi, Tohoku Univ. (Japan); Atsushi M. Ito, National Institute for Fusion Science (Japan); Takashi Eyama, Naoya Kakimoto, Rui Idutsu, The Univ. of Tokushima (Japan); Yasuo Minami, The Univ. of Tokyo (Japan); Motoyoshi Baba, Tohru Suemoto, The Univ. of Tokyo (Japan); Anatoly Y. Faenov, Osaka Univ. (Japan); Nail A. Inogamov, Russian Academy of Sciences (Russian Federation); Tetsuya Kawachi, Mitsuru Yamagiwa, Japan Atomic Energy Agency (Japan)

The dynamics of the femto-second laser ablation process is a key issue for the understanding of the sub-micron scale processing. In previous works, the formation of an expansion front with a thin filmy structure outer the ablating surface (= ablation front) was observed by using a probe laser at the wavelength of 400 nm. However the details of both the fronts were not observed because they were covered with plasmas, which interrupted the penetration of the probe beam. We have succeeded in simultaneous observation of the expansion front and the ablation front of the gold which was irradiated by Ti:Sapphire laser with 80 fs duration by using the 13.9 nm soft x-ray laser interferometer. The dynamics of the ablation front was obtained by using the soft X-ray interferometer. The surface roughness of the ablation front was better than a few nm until t = 1 ns of the laser irradiation, and the height of it increased to only 30 nm. The dynamics of the expansion front was obtained from the Newton's rings generated between both the fronts within the time of 200 ~ 800 ps. It implies the expansion front worked as the soft X-ray beam splitter. The expansion speed of the expansion front strongly depended on the local fluence of the pump laser. These results implies that the potential of the expansion front as the novel transient soft x-ray optics because the spatial profile of the expansion front will be controlled by the spatial profile of the pump laser.

9589-10, Session 3

Overview of warm dense matter experiments at SLAC *(Invited Paper)*

Eric C. Galtier, SLAC National Accelerator Lab. (United States)

Warm dense matter (WDM) is found in numerous astrophysical systems, from giant planets to Brown dwarves or cool dense stars. Being this intermediate regime where condensed matter or plasma theories do not apply, it is produced in all laser produced plasma experiments on earth. As a consequence, understanding its properties is fundamental and the whole community is investigating this extreme state of matter.

With the advent of the 4th generation of light sources, namely the Free Electron Lasers (FELs), a new way of producing and diagnosing warm dense matter becomes available. In 2009, the Linac Coherent Light Source (LCLS) at SLAC was the first FEL to produce X-ray photons to be used by the user community.

Since then, various experiments took place at LCLS to produce and measure specific physical properties of warm dense matter. In this talk, we will present an overview of these experiments as well as ongoing efforts. The LCLS has been used in a variety of configuration: as a principle heating mechanism, as a probe or both at the same time. When used as a probe, high power lasers have been used to shock matter and excite it into the WDM regime. Results will be presented.

The end of the talk will describe exciting perspectives on the WDM research, as the LCLS-II will become available in a 5 years time scale.

9589-11, Session 3

Generation of strongly-coupled plasma using Argon-based capillary discharge lasers

Andrew K. Rossall, Valentin Aslanyan, Sarah Wilson, Gregory J. Tallents, The Univ. of York (United Kingdom)

Argon based capillary discharge lasers operate in the extreme ultra violet (EUV) at 46.9 nm with an output of up to 0.5mJ energy per pulse and up to a 10 Hz repetition rate. Focussed irradiances of up to 10^12 W cm^-2 are achievable and can be used to generate plasma in the warm dense matter regime by irradiating solid material. To model the interaction between such an EUV laser and solid material, the 2D radiative-hydrodynamic code POLLUX has been modified to include absorption via direct photo-ionisation, a super-configuration model to describe the ionisation dependant electronic configurations and a calculation of plasma refractive indices for ray tracing of the incident EUV laser radiation. A simulation study is presented, demonstrating how capillary discharge lasers of 1.2ns pulse duration can be used to generate strongly coupled plasma at close to solid density with temperatures of a few eV and energy densities up to 1?10^5 J cm^-3.

Plasmas produced by EUV laser irradiation are shown to be useful for examining the equation-of-state properties of warm dense matter. One difficulty with this technique is the reduction of the strong temperature and density gradients which are produced during the interaction. Methods to inhibit and control these gradients will be examined.

9589-12, Session 4

Development of an ultrashort plasma-based soft x-ray laser *(Invited Paper)*

Adrien Depresseux, Lab. d'Optique Appliquée (France); Eduardo Oliva, Lab. de Physique des Gaz et des Plasmas (France); Julien Gautier, Fabien Tissandier, Lab. d'Optique Appliquée (France); Jaroslav Nejdl, Michaela Kozlova, Institute of Physics of the ASCR, v.v.i. The development of x-ray free electron lasers allowed a myriad of innovative applications notably in biology, requiring high-energy and ultrashort pulse duration in the femtosecond-range to probe the ultra-fast dynamics of matter in the nanometre scale.

Alongside those large-scale and expensive high-brilliance sources, compact and cheap plasma-based x-ray lasers arouse great interest, notably due to their ability to deliver the highest demonstrated energy per pulse [1] within a narrow linewidth. But also because they display excellent optical properties when seeded with a high-harmonic source [2].

However, those sources have been limited to the picosecond range [3] for more than a decade, which restrained the scope of applications.

We proposed and implemented an original technique, named "Collisional Ionization Gating", which allowed us not only to achieve femtosecond pulse

duration for the first time, but also to report a boost in output energy. The combination of those made possible a remarkable enhancement of total peak intensity by about two orders of magnitude compared to the present state of the art.

Our scheme relies on increasing the plasma density to quench the gain duration of the plasma amplifier, which also leads to an increase in saturation intensity and laser gain [4]. At the reported high densities, guiding techniques prove to be pivotal to counterbalance refraction [5].

The demonstrated plasma-based soft x-ray laser was implemented focusing an ultra-intense IR pule into a krypton gas and pumping the atomic transition of Ni-like species at 32.8nm [6].

Tailoring the plasma waveguide for higher densities and longer amplifiers holds great promises to further outdistance previous performances of plasma-based soft x-ray lasers.

Modeling of dense injection-seeded Ni-like Krypton plasma amplifiers

Eduardo Oliva, Univ. Politécnica de Madrid (Spain); Adrien Depresseux, Fabien Tissandier, Julien Gautier, Stéphane Sebban, Lab. d'Optique Appliquée (France); Gilles Maynard, Lab. de Physique des Gaz et des Plasmas (France)

Plasma amplifiers seeded with High Order Harmonics have demonstrated to be a high-repetition rate, table top source of short (picosecond or less), intense and coherent soft X-ray beams. In the quest for shorter (100 fs or less) and more energetic pulses (several microJoules at least), increasing the density of the amplifier promises to fulfill both goals.

In this work we will present modeling results of the recent experiments using the 60 TW laser "Salle Jaune" at LOA. In these experiments, the lasing ion (Ni-like Krypton) is created by Optical Field Ionization in a dense plasma. To ensure the propagation of the IR pulse through the plasma column, the ignitor+heater technique is used to create a plasma channel that acts as a waveguide, compensating the the defocusing and guiding the pulse over several Rayleigh lengths. Once the population inversion is created via collisional excitation, the 25th harmonic of the driving laser is seeded to be amplified when passing through the plasma.

The propagation of the IR pulse through the plasma channel was modeled using the Particle In Cell code WAKE-EP. The results uncover a self-regulating mechanism between the overionization induced refraction at the central part of the channel and the focusing at the channel borders. The amplification of the seeded harmonic is modeled with our Maxwell-Bloch model DeepOne. The code is benchmarked over a huge range of electron densities, confirming the unprecedented duration of 64 fs FWHM (123 fs RMS). DeepOne also gives information about the polarization of the amplified beam.

FEL seeding at FERMI: a root to table-top laser-like FEL performance *(Invited Paper)*

Miltcho B. Danailov, Paolo Cinquegrana, Alexander A. Demidovich, Gabor Kurdi, Ivaylo P. Nikolov, Paolo Sigalotti, Elettra-Sincrotrone Trieste S.C.p.A. (Italy)

Free Electron Lasers (FELs) have made remarkable progress in the last decades. In this paper we show that one important direction of the Extreme UV and Soft X-ray FEL development, i.e. the use of seeding by an external laser, is already allowing to generate pulses having the high coherence, stability of the pulse intensity, wavelength and timing of table-top ultrafast lasers. This work presents some of the novel schemes developed and under development at the FERMI FEL. The work will first describe some key points in the use of High Gain Harmonic Generation (HGHG) seeding at FERMI that have led to the generation of highly stable nearly transform limited FEL pulses. We then concentrate on the recently developed modalities allowing pump-probe experiments with practically no jitter between the pump and probe pulses. One of the presented techniques relies on the use of pulses generated by the seed laser, optically transported to the experimental stations. the seed laser light for pump-probe experiments. We are presenting the design of a scheme implementing this idea at the FERMI FEL. Another new technique described is based on the use of twin-seed pulses and delivers twin FEL pulses with tunable time delay and wavelengths. Some examples from pump-probe measurements based on the above two approaches will be presented and near future development will be discussed.

9589-15, Session 4

Chirped-pulse amplification in x-ray free-electron lasers

Benoît Mahieu, Hugo Dacasa, Lab. d'Optique Appliquée (France); Marta Fajardo, Instituto Superior Técnico (Portugal); Thuy T. T. Le, Lab. d'Optique Appliquée (France); Lu Li, Queen's Univ. Belfast (Ireland); Eduardo Oliva, Univ. Politécnica de Madrid (Spain); Philippe Zeitoun, Lab. d'Optique Appliquée (France)

X-ray Free-Electron Lasers (FEL's) are powerful tools for probing matter properties down to sub-nanometer scales with femtosecond dynamics, allowing a growing number of physical, chemical, biological and medical investigations to be carried out. FEL's operating in seeding mode intrinsically present enhanced temporal coherence properties with respect to those relying on the self-amplified spontaneous emission process. They are however limited, for the moment, to extreme-ultraviolet wavelengths, or with hardness to soft X-rays, and durations of tens of femtoseconds. We studied how these limits can be overcome by means of X-ray chirped-pulse amplification schemes, inspired from infrared lasers.

As a matter of fact, the use of a seed enables a fine control of the chirp and a spectro-temporal shaping of the FEL emission. Moreover, ultrashort wavelengths can be envisaged through high-gain harmonic generation and echo-enabled harmonic generation configurations. We will present FEL simulations coupled with the design of stretcher/compressor in both classical and conical diffraction geometries.

9589-16, Session 4

EIS-TIMER, mini-TIMER, and nano-TIMER: present and future experimental facilities for VUV/soft x-ray transient grating experiments

Cristian Svetina, Nicola Mahne, Lorenzo Raimondi, Filippo Bencivenga, Riccardo Cucini, Flavio Capotondi, Elettra-Sincrotrone Trieste S.C.p.A. (Italy); Andrea Battistoni, Elettra-Sincrotrone Trieste S.C.p.A. (Italy) and Univ. degli Studi di Trieste (Italy); Riccardo Mincigrucci, Elettra-Sincrotrone Trieste S.C.p.A. (Italy) and Univ. degli Studi di Perugia (Italy); Erika Giangrisostomi, Elettra-Sincrotrone Trieste S.C.p.A. (Italy) and Univ. degli Studi di Trieste (Italy); Alessandro Gessini, Michele Manfredda, Ivaylo Petrov Nikolov, Emanuele Pedersoli, Emiliano Principi, P.

Parisse, F. Casolari, Miltcho B. Danailov, Maya Kiskinova, Claudio Masciovecchio, Elettra-Sincrotrone Trieste S.C.p.A. (Italy); Marco Zangrando, Elettra-Sincrotrone Trieste S.C.p.A. (Italy) and IOM-CNR Lab. TASC (Italy)

FERMI, the Italian Free Electron Laser user facility, provides VUV/soft x-ray photons pulses with unprecedented high brilliance and coherence. The EIS-TIMER beamline is foreseen to be installed in 2015-2016 and will be dedicated to perform transient grating experiments. The unique design of EIS-TIMER is conceived to exploit such kind of non-linear coherent experiments to probe collective vibrational and electronic properties of matter at the nanoscale. Lately a proof of principle experiment has been successfully carried out at the DiProI beamline employing a simplified and compact setup: the “mini-TIMER”. Meanwhile we are studying a new and even more compact optical configuration (the “nano-TIMER”) able to extend this approach to a wider wavevector range and to employ ultra-short FEL pulses.

In this seminar we will briefly describe the FERMI user facility, the EIS-TIMER beamline and its scientific case. We will also report on the experimental results obtained with “mini-TIMER” and will focus to the “nano-TIMER” set-up.

Design challenges to photon diagnostics and beam line components under high-repetition-rate x-ray FEL operation

Yiping Feng, SLAC National Accelerator Lab. (United States)

Future high repetition rate X-ray FEL’s such as the European XFEL and LCLS-II presents new challenges to photon diagnostics as well as essential beamline components. In addition to these devices having to sustain the high peak power of a single-pulse FEL radiation, they must also be capable of handling the enormous power density of tens to hundreds of watts over a small area as small as 0.1 mm2. In this talk, I will discuss the potential impact of high power FEL operation on performance of a gas attenuator and the design challenges to beam intercepting components such as a collimator or stopper.

9589-36, Session PWed

Soft x-ray source based on the high-current capillary-discharge system

Jiri Schmidt, Karel Kolacek, Oleksandr Frolov, Jaroslav Straus, Institute of Plasma Physics of the ASCR, v.v.i. (Czech Republic)

Our department has been studying high-current capillary discharge as a prospective XUV laser source since 1998. Among others we have built two experimental apparatuses CAPEX (since 1998) and CAPEX-U (since 2005). On both these devices we have observed lasing at 46.9 nm (Ne-like argon line). While the experimental apparatus CAPEX-U has laser-triggered spark gap, which enables exact synchronization with diagnostics or with other attached experiments, the apparatus CAPEX is capable to run at a higher repetition rate (up to ~ 1 Hz). Some laser beam characteristics have already been measured (e.g. laser pulse energy, laser beam profile and divergence). However, these devices are not only lasing at 46.9 nm, but also they are used for testing a possibility of amplification at the wavelength below 20 nm, that have more practical applications.

Nowadays, the fast high-current capillary-discharge experiments with nitrogen-filled capillary are in progress as well. In this paper the recent results obtained from both these discharge systems (argon-, nitrogen-filled capillaries) will be presented.

Acknowledgement.

This work was performed under auspices and with the support of the Grant Agency of the Czech Republic (contract 14-29772S) and of the Ministry of Education, Youth, and Sports, CR (contract LG13029).

Ultra-broadband ptychography with self-consistent coherence estimation from a high harmonic source

Michal Odstr?il, Univ. of Southampton (United Kingdom) and RWTH Aachen Univ. (Germany); Peter Baksh, Univ. of Southampton (United Kingdom); Hyun-su Kim, RWTH Aachen Univ. (Germany) and Univ. of Southampton (United Kingdom); William S. Brocklesby, Jeremy G. Frey, Univ. of Southampton (United Kingdom)

The ptychography method for coherent diffractive imaging (CDI) is gaining significant popularity over the last few years in the synchrotron science community because of its advantages over simpler CDI schemes. However, for imaging applications in the extreme ultraviolet (XUV), the ability to perform ptychography with table top setups is limited by requirements on coherence and overall beam quality.

With the aim of improving imaging using table top XUV apparatus, we demonstrate an improved ptychography method that can tolerate a relative bandwidth of ~20% for achromatic objects. Further, our algorithm is able to reconstruct diffraction patterns blurred by low beam pointing stability. The coherence and blurring properties of the illumination probe are automatically identified during the ptychographic reconstruction. This improved method allows the use of fewer monochromating optics, obtaining higher flux at the sample and reaching higher resolution for semi-opaque objects. This is critical in the case of ptychography when a large number of diffraction patterns needs to be collected compared to the standard coherent diffraction method with compactness constraints. Our method is tested on reconstruction of partly transparent samples to show the improved reconstruct quality.

9589-17, Session 5

Towards milliwatt average power table-top soft x-ray lasers *(Invited Paper)*

Jorge J. Rocca, Brendan Reagan, Cory Baumgarten, Yong Wang, Shoujun Wang, Alex Rockwood, Liang Yin, Mario Marconi, Vyacheslav Shlyaptsev, Carmen Menoni, Colorado State Univ. (United States)

We will discuss advances in the development of high repetition rate, table-top soft x-ray lasers operating at wavelengths between 10 nm and 20 nm. Combining newly developed diode-pumped high energy ultra-short pulse laser technology with efficient plasma generation techniques we have demonstrated a new generation of compact high average power soft x-ray lasers. Recent results include the first table-top soft x-ray lasers to operate at 100 Hz repetition rate, that have made possible the generation of record 0.2 mW average power at ? = 18.9 nm, 0.1 mW at ? = 13.9nm, and 20 ?W at ? = 11.9nm. These lasers are enabled by a compact chirped pulse amplification laser based on diode-pumped, cryogenically-cooled Yb:YAG power amplifiers that produces 1 Joule, 5 ps FWHM duration pulses at 100 Hz repetition rate. Operation of these lasers with rotating targets has allowed the uninterrupted high repetition rate operation of the ? = 18.9nm soft x-ray laser for hundreds of thousands of consecutive shots, making it suitable for applications in nanoscience and nanotechnology that require high photon flux at short wavelengths. A high energy Ti:Sa driver laser to pump sub-10 nm table top lasers at multi-Hz repetition ray will also be discussed.

9589-18, Session 5

Single-shot phase-controlled diffraction imaging using an Ag x-ray laser at 13.9 nm

Kyoung Hwan Lee, Hyeok Yun, Institute for Basic Science (Korea, Republic of); Jae Hee Sung, Seong Ku Lee, Institute for Basic Science (Korea, Republic of) and Advanced Photonics Research Institute (Korea, Republic of); Hwang Woon Lee, Institute for Basic Science (Korea, Republic of); Hyung Taek Kim, Institute for Basic Science (Korea, Republic of) and Advanced Photonics Research Institute (Korea, Republic of); Chang Hee Nam, Institute for Basic Science (Korea, Republic of) and Gwangju Institute of Science & Technology (Korea, Republic of)

Single-shot x-ray coherent diffraction imaging (CDI) is an emerging technology developed to observe the ultrafast dynamics of nanometer-scale objects without objective lenses. In spite of the potential to achieve wavelength-limited single-shot CDI, the spatial resolution of the CDI has been limited due to practical reasons of illumination flux, the dynamic range of x-ray detectors, noise, and the steep scaling of diffraction signal. Through a detailed analysis of factors limiting the spatial resolution of single-shot CDI, we could substantially improve the achievable spatial resolution of CDI by the sharp phase edges.

We devised a new method to improve the spatial resolution of x-ray CDI by implementing the sharp phase variation in a sample. In our experiment, the spatial resolution of 22 nm was achieved using a single Ag X-ray laser pulse, very close to the diffraction-limited resolution of 21 nm. The achieved spatial resolution was only 1.5 times the wavelength, 13.9 nm, of the x-ray laser. The introduction of the sharp phase edge modified the power scaling of the diffraction signal by inducing an asymmetric diffraction pattern, efficiently extending the diffraction signal to the region of high spatial frequencies. We also performed a simulation to examine the experimental result and confirmed that the sharp phase edge enhanced the resolution compared to the case of a pure absorption edge. Since this phase controlled CDI makes use of a fundamental phenomenon of diffraction, it is a general approach applicable to other lensless imaging methods.

9589-19, Session 5

X-ray characterization of short-pulse laser illuminated hydrogen storage alloys having very high performance

Hiroyuki Daido, Japan Atomic Energy Agency (Japan)

At present, hydrogen starage alloys are more and more important in the fields of electric energy production and strage, automobiles and so on. The initial rates of hydrogen absorption and desorption of a hydrogen storage alloy are one of the important performances to be improved. On the basis of the previous experimental study using accelerators (1), charged particles cause surface modifications on the alloys resulting in improvement of the hydrogen absorption rate while these machines also cause radioactivity. The vacancies introduced into a hydrogen absorption alloy are found to be positive effect on the improvement of the initial hydrogen absorption rate. We also have made improvement of the absorption rate using an ultra-high intensity laser driven proton beam (2). Here, we report on the characterization of the hydrogen absorption rate using direct illumination technique with a femoto second laser as well as nano second laser instead of rather complicated bigger illumination sytems. A laser illuminates the whole surface sequentially on a tip of a few cm sequre LaNi4.6Al0.4 alloy resulting in significant improvement of the hydrogen absorption rate. The expected scenario of this improvement is following. Firstly, the laser hits the surface with appropirate laser intensity and duration, next the ablation occurs. The strong pressure applied to the interior of the sample makes suitable defects in the surface layer of the sample. In order to characterize the surface layer, we perform x-ray diffraction experiment using SPring-8 synchrotron radiation facility. We also discuss useful x-ray techniques for understading the mechnism.

Coherent diffractive imaging employing a laboratory-scale, spatially partially-coherent discharge plasma EUV light source

Jan Bussmann, Forschungszentrum Jülich GmbH (Germany) and RWTH Aachen Univ. (Germany) and JARA-Fundamentals of Future Information Technology (Germany); Michal Odstr?il, Univ. of Southampton (United Kingdom) and RWTH Aachen Univ. (Germany); Raoul Bresenitz, Forschungszentrum Jülich GmbH (Germany) and JARA-Fundamentals of Future Information Technology (Germany) and RWTH Aachen Univ. (Germany); Denis Rudolf, Forschungszentrum Jülich GmbH (Germany); William S. Brocklesby, Univ. of Southampton (United Kingdom); Jianwei Miao, Univ. of California, Los Angeles (United States) and California NanoSystems Institute (United States); Detlev Grützmacher, Forschungszentrum Jülich GmbH (Germany); Larissa Juschkin, RWTH Aachen Univ. (Germany) and Forschungszentrum Jülich GmbH (Germany)

Diffraction limited microscopy in the EUV and soft X-ray spectral region requires expensive either low roughness reflective optics or diffractive optics structured on the nanometer scale. Alternatively, coherent diffraction imaging (CDI) offers the possibility to replace the optics completely by image reconstruction algorithms.

Experimentally, a sufficiently coherent beam shines on the test object which diffraction pattern is recorded on the detector. Then, the object can be reconstructed from its diffraction pattern down to the diffraction limit by means of phase retrieval techniques.

So far, most experiments were performed at synchrotron and free electron laser facilities. Only few laboratory based CDI experiments employing either a high harmonic or a soft X-ray laser source were conducted so far. In our work, we demonstrate CDI with laboratory based high radiance plasma sources with partial spatially coherence developed for EUV lithography. Experimentally, a 10 μm cross-like structured silicon nitride sample is imaged with light of the O VI emission line (17.3 nm). To account for spatial and temporal incoherence a dynamical adapting deblurring kernel is used during reconstruction. This modified modulus constraint method in combination with the small bandwidth of the plasma emission line, allows spectral filtering without transmission filters and only by one multilayer mirror. Steps to push the resolution closer to the diffraction limit and utilizing multiple wavelength will be presented.

3D nanoscale imaging of biological samples with laboratory-based soft x-ray sources

Aurélie Dehlinger, Berlin Lab. for Innovative X-ray Technologies (Germany) and Technische Univ. Berlin (Germany) and Max-Born-Institut (Germany); Anne Blechschmidt, Technische Univ. Berlin (Germany); Birgit Kanngießer, Technische Univ. Berlin (Germany) and Berlin

Lab. for Innovative X-ray Technologies (Germany); Martina C. Meinke, Fiorenza Rancan, Charité Universitätsmedizin Berlin (Germany); Kai Reineke, Leibniz-Institut für Agrartechnik Potsdam-Bornim e.V. (Germany); Christian Seim, Berlin Lab. for Innovative X-ray Technologies (Germany) and Max-Born-Institut für Nichtlineare Optik und Kurzzeitspektroskopie (Germany); Holger Stiel, Berlin Lab. for Innovative X-ray Technologies (Germany); Stephan Werner, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany)

In microscopy, where the theoretical resolution limit depends on the wavelength of the probing light, radiation in the soft X-ray regime can be used to analyze samples that cannot be resolved with visible light microscopes. In the case of soft X-ray microscopy in the water-window, the energy range of the radiation lies between the absorption edges of carbon and oxygen. As a result, carbon-based structures, such as biological samples, possess a strong absorption, whereas e.g. water is more transparent to this radiation. Microscopy in the water-window therefore allows the structural investigation of aqueous samples with resolutions of a few ten nanometers and a penetration depth of up to 10 μm.

In this contribution we present a Laboratory Transmission X-ray Microscope (LTXM) which runs with a laser produced nitrogen plasma that emits radiation at 500 eV. The mentioned high penetration depth can be exploited to analyze biological samples in their natural state and with several projection angles. The obtained tomogram is the key to a more precise and global analysis of samples originating from various fields of life science. The application of this method for the investigation of nanoparticles in human skin and of high-pressure treated bacterial endospores will be presented.

In conclusion we compare our results with other nanoscale imaging methods using coherent laboratory based sources like plasma based X-ray lasers or radiation from high harmonic generation.

9589-22, Session 6

Output beam polarisation of x-ray lasers with transient inversion *(Invited Paper)*

Karol A. Janulewicz, Gwangju Institute of Science and Technology (Korea, Republic of); Chul Min Kim, Gwangju Institute of Science and Technology (Korea, Republic of) and Institute of Basic Science (Korea, Republic of); Holger Stiel, Max-Born-Institut für Nichtlineare Optik und Kurzzeitspektroskopie (Germany); Tetsuya Kawachi, Masaharu Nishikino, Noboru Hasegawa, Japan Atomic Energy Agency (Japan)

Polarisation of the generated radiation is a parameter of paramount importance for application of any radiation source. X-ray lasers work nearly exclusively in the regime of amplified spontaneous emission (ASE) and it is frequently expected that the polarization state of the output radiation should stay undefined. A few attempts to clear the situation did not put much light on the effect giving contradictory conclusions. In fact, it is little consideration on how the amplification process changes the polarization state. The theoretical analysis within the uniform (single-mode) approximation, focusing on the dynamics of X-ray laser generation, suggested that in such a case the output radiation should show some level of polarization but randomly changing from shot-to-shot. To verify this hypothesis we have conducted relevant experiment using traditional double-pulse scheme of transient inversion and a membrane beam-splitter as a polarization selector. It was found that the output radiation has a significant, but fluctuating as far as its amplitude is concerned, s-polarisation component (parallel to the target surface) in each shot. However, it was also found that this result does not gives ultimate answer due to simplified measurement technique and the traditional formula used to determine the degree of polarisation (DOP). The expression, used also in other experiments, is under conditions of these experiments no more valid. More detailed analysis shows that the correlations between the mutually perpendicular components generated in the amplification process are responsible for this fact. This justification will be explained in detail, along with the relation between both treatments.

9589-23, Session 6

Spectral interferometric methods for the complete characterization of femtosecond extreme-ultraviolet pulses

Benoît Mahieu, Hugo Dacasa, Lab. d'Optique Appliquée (France); Lu Li, Queen's Univ. Belfast (Ireland); Eduardo Oliva, Univ. Politécnica de Madrid (France); Philippe Zeitoun, Lab. d'Optique Appliquée (France)

The advent of powerful extreme-ultraviolet coherent sources such as free-electron lasers, high-order harmonic generation or plasma-based lasers is opening opportunities in numerous applications at temporal femtosecond and spatial nanometer resolutions. For these applications, spectral phase and temporal intensity profile are precious pieces of information of the source. Nevertheless, they are regrettably lacking. This is mainly due to the strong absorption of extreme-ultraviolet light in crystals, commonly used at longer wavelengths for pulse characterization.

In this presentation, we will show how spectral interferometric methods have the potential to overcome this barrier. Since a spectrum measurement represents an accessible task, the possibility to encode the complete spectro-temporal information in the frequency domain represents an attractive solution. We will discuss three possible methods relying on the same basis. First, Fourier-transform spectral interferometry using a reference pulse; second, spectral phase interferometry for direct electric field reconstruction applied to seeded free-electron lasers; third, two-dimensional beatings of spatially-shifted replicas. Principle, simulations and first experimental results will be shown.

9589-24, Session 6

Influence of the partial temporal coherence of XUV laser pulses on the measurement of their spectral properties

Andréa Le Marec, Institut des Sciences Moléculaires d'Orsay (France) and Ctr. National de la Recherche Scientifique (France); Olivier A. Guilbaud, Univ. Paris-Sud 11 (France) and Ctr. National de la Recherche Scientifique (France); Pierre Chavel, Ctr. National de la Recherche Scientifique (France) and Univ. Paris-Sud II (France); Olivier Larroche, Commissariat à l'Énergie Atomique (France); Annie Klisnick, Univ. Paris-Sud 11 (France)

The temporal coherence and related spectral properties of the four types of collisional XUV lasers currently operational worldwide were experimentally characterized in the past few years. This comprehensive work has been carried out using the same instrument, a variable path-difference interferometer. The coherence time was inferred from a linear autocorrelation of the XUV pulse, by measuring the variation of the fringe visibility with the path difference, which yields the modulus of the degree of coherence. The spectral profile and the associated linewidth of the XUV laser is obtained through a Fourier transform of the degree of coherence, following the Wiener-Khintchin theorem.

In this work we investigate the role of the partial temporal coherence of the XUV pulse on the measurements. More specifically we will present numerical simulations that help to understand how the partial coherence of the pulse, represented by the ratio of the coherence time to the pulse duration, can influence the measured fringe visibility curve and affect the estimation of the coherence time.

9589-25, Session 6

Wigner distribution measurement of the spatial coherence properties of FELs

Tobias Mey, Bernd Schäfer, Klaus Mann, Laser-Lab. Göttingen e.V. (Germany); Barbara Keitel, Elke Plönjes, Marion Kuhlmann, Deutsches Elektronen-Synchrotron (Germany)

Free-electron lasers deliver VUV and soft x-ray pulses with the best brilliance available and a high degree of spatial coherence. Users of such facilities have high demands on phase and coherence properties of the beam, for instance when working with coherent diffractive imaging. Thus, detailed knowledge of these parameters is of great importance and provides the possibility for advanced machine studies.

The Wigner distribution function (WDF) describes the entire propagation properties of an electromagnetic beam including all information on its spatial coherence. It can be reconstructed from beam profiles taken at different positions along its propagation direction. Here, we present measurements of the WDF conducted at the Free-electron laser FLASH at DESY. As a result, we derive the entire four-dimensional mutual coherence function, the coherence lengths and the global degree of coherence. Additionally, we provide an estimation of the possible error that our algorithm might produce for the derived quantities.

In comparison to existing studies that characterize the photon beam of FLASH, we find significantly lower values for the global degree of coherence. This difference cannot be explained by our error estimation. We explore the possible reasons for this discrepancy and their effect on the value of the global degree of coherence.

9589-26, Session 6

Cross-correlation measurement of femtosecond hard x-ray pulses from a laser plasma source: approaching 100 fs benchmark

Mazhar Iqbal, Muhammad Ijaz, Gwangju Institute of Science and Technology (Korea, Republic of); Holger Stiel, Max-Born-Institut für Nichtlineare Optik und Kurzzeitspektroskopie (Germany); Do Young Noh, Karol A. Janulewicz, Gwangju Institute of Science and Technology (Korea, Republic of)

X-ray pulse duration measurement from laser plasma source is done using cross correlation scheme exploiting ultrafast response of x-ray absorption in Ni metal. We measured the shortest pulse duration of 110 ± 6 fs for high energy bremsstrahlung fulfilling the theoretical prediction of 100 fs.

9589-27, Session 7

Applications of EUV high-harmonics for probing molecular structure and ultrafast dynamics *(Invited Paper)*

Chang Hee Nam, Institute for Basic Science (Korea, Republic of) and Gwangju Institute of Science and Technology (Korea, Republic of); Hyeok Yun, Institute for Basic Science (Korea, Republic of); Hyung Taek Kim, Kyung Taec Kim, Institute for Basic Science (Korea, Republic of) and Gwangju Institute of Science and Technology (Korea, Republic of)

High harmonic light sources possess unique characteristics of attosecond duration in the EUV and soft x-ray spectral range. High harmonic light sources can be applied to probe ultrafast dynamics of atoms and molecules. By tuning harmonic wavelength a specific state of an atom or molecule can be excited, which can be further excited or ionized by applying a time-delayed femtosecond laser pulse. This process of combining harmonic pulses and time-delayed femtosecond laser pulses can reveal the dynamics of photoexcitation and photoionization processes. In addition high-harmonic radiation generated from molecules contains the information on the structure of molecules. When multiple molecular orbitals are exposed to a strong laser field, the highest-occupied molecular orbital (HOMO) is mostly ionized and thus emits strong high-harmonic radiation containing the characteristics of HOMO. The radiation from the energetically lower-lying molecular orbital (HOMO-1) is often too weak in investigating the characteristics of the HOMO-1, necessitating special techniques to observe the radiation from the HOMO-1. In the case of CO2 the ϖg symmetry of the HOMO does not exhibit directional dependence along either the molecular axis or its perpendicular direction. In order to resolve multiple orbitals of such molecules we employ two-dimensional high-harmonic spectroscopy (HHS) by applying an orthogonally polarized two-color laser field, consisting of the fundamental frequency (1?) and its second harmonic (2?). In this case odd and even harmonics carry the characteristics of the HOMO and HOMO-1, respectively. The multi-orbital characteristics are thus revealed in the two-dimensional spectroscopy employing the two-color laser field.

9589-28, Session 7

The MEL-X project at the Lawrence Livermore National Laboratory: a multilayer delay line for x-rays

Tommaso Pardini, Randolph M. Hill, Jennifer B. Alameda, Regina Soufli, Lawrence Livermore National Lab. (United States); Andy Aquila, Sébastien Boutet, SLAC National Accelerator Lab. (United States); Stefan P. Hau-Riege, Lawrence Livermore National Lab. (United States)

At the Lawrence Livermore National Laboratory we are developing a multilayer delay line for x-rays (MEL-X) to enable all-x-ray pump-and-probe experiments at Free Electron Lasers (FELs). The goal of this project is the development and deployment of a proof-of-principle delay line featuring coated x-ray optics. The four- mirror design of the MEL-X is motivated by the need for ease of alignment and use. In order to simplify the overlap of the pump and the probe beam after each delay time change, a scheme involving super-polished rails and mirror-to-motor decoupling has been adopted. The MEL-X features a high intensity pump beam. Its Iridium coating allows it to work at soft and hard x-ray energies all the way up to 9keV, with a probe beam transmission as high as 35% at 8keV, and 14% at 9keV. The delay time can be tailored to each particular experiment, with a nominal range of 70 – 350 fs for this prototype. The MEL-X, combined with established techniques such as x-ray diffraction, absorption or emission, could provide new insights on ultra-fast transitions in highly excited states of matter.

High-harmonics generation and applications *(Invited Paper)*

Jens Biegert, Seth L. Cousin, Stephan Teichmann, Michael Hemmer, Barbara Buades, Noslen Suarez, Francisco Silva, Nicola Di Palo, ICFO - Institut de Ciències Fotòniques (Spain)

Isolated attosecond pulses at the Carbon K-edge (284 eV) hold the promise to image, probe and control the most fundamental electronic processes with

extreme temporal and spatial resolution. Extension of current attosecond pulse generation techniques into the so called water window (284-543 eV) is possible by ponderomotive scaling of the generated attosecond bursts in high-harmonic generation using an intense long wavelength driving laser. We demonstrate for the first time the attosecond lighthouse effect at 300 eV in neon to isolate an attosecond pulse at the water window. The attosecond lighthouse is then compared with spectrally filtered high harmonic generation, which reveals that given the same driving laser both techniques lead to comparable photon flux in conditions leading to isolated attosecond pulses. We will also demonstrate the first near-edge x-ray absorption fine-structure (NEXAFS) measurement in the solid state on a 200 nm free-standing polyimide film at the carbon K-shell edge with our source. The individual fine structure peaks with the known orbitals in polyimide are identified and are in good agreement with state of the art synchrotron data. These results are a first decisive step towards attosecond time resolved soft-X-ray spectroscopy with element selectivity for the condensed phase [1].

Koga, Yuji Fukuda, Akito Sagisaka, Masaharu Nishikino, Takashi Imazono, Noboru Hasegawa, Tetsuya Kawachi, Hiroyuki Daido, Japan Atomic Energy Agency (Japan); Yoshiaki Kato, The Graduate School for the Creation of New Photonics Industries (Japan); Paul R. Bolton, Sergei V. Bulanov, Kiminori Kondo, Japan Atomic Energy Agency (Japan)

Relativistic laser plasma is a known source of XUV and x-ray radiation generated via various mechanisms. We have recently discovered high-order harmonic emission from gas jet targets driven by relativistic-irradiance multi-terawatt femtosecond lasers [Phys. Rev. Lett. 108, 135004 (2012); New J. Phys. 16, 093003 (2014)]. The harmonics constitute short-pulse high-frequency coherent radiation, desirable for many applications. According to the model developed on the basis of catastrophe theory corroborated by 3D and 2D PIC simulations using the REMP code [Comput. Phys. Comm. 135, 144 (2001)], the harmonics are emitted by structurally stable, oscillating electron spikes (cusps), which are the density singularities resulting from catastrophes of a multi-stream relativistic plasma flow [Phys. Rev. Lett. 101, 265001 (2008)]. In this presentation we report results of experiments performed with the J-KAREN laser [Opt. Lett. 35, 1497 (2010)]. We measured dependences of the harmonic yield on several parameters, including the gas jet density and laser pulse energy. We also found a very steep dependence of the yield on the focal spot quality.

Attosecond pulses formation via switching of resonant interaction by tunnel ionization *(Invited Paper)*

Timur R. Akhmedzhanov, Texas A&M Univ. (United States); Vladimir A. Antonov, Institute of Applied Physics (Russian Federation); Yevgeny V. Radeonychev, Institute of Applied Physics (Russian Federation) and Russian Academy of Sciences (Russian Federation); Olga Kocharovskaya, Texas A&M Univ. (United States)

We investigate a new method to produce attosecond pulses from resonant XUV radiation in an atomic gas which is simultaneously irradiated by an IR laser field. Around the crests of IR field all the excited atomic energy levels are strongly broadened due to rapid tunnel ionization from the corresponding excited states and atoms are not able to resonantly absorb the incident vacuum ultraviolet radiation. Vice verse, around zeroes of IR field, ionization is slow and atoms effectively absorb the vacuum ultraviolet radiation. As a result, interaction between atoms and XUV field is switched on and off resulting in formation of attosecond pulses.

We present analytically solvable model of ultrashort pulses formation using two-level at-om and stepwise ionization time dependence approximations. Using many-level atomic model and tunneling ionization rates, we also numerically calculate the result of propagation of XUV field through the optically thin layer of atomic gas (H, He and Ne). Finally, we perform numerical solution of full time-dependent Schrodinger equation for IR-dressed He atoms interacting with quasi-resonant XUV radiation. The results of all three approaches prove the possibility of formation of trains of pulses with a pulse duration in the range of hundreds of attoseconds.

9589-32, Session 8

Using the XFEL to drive the gain of inner-shell x-ray lasers using photo-ionization and photo-excitation processes

Joseph Nilsen, Lawrence Livermore National Lab. (United States)

For the last four decades many photo-pumped X-ray laser schemes have been proposed but demonstrating these schemes in the laboratory has proved to be elusive because of the difficulty of finding a strong resonant pump line or X-ray source. With the availability of the X-ray free electron lasers (X-FEL) at several facilities a tunable X-ray laser source can be used to replace the pump line or X-ray source in previously proposed laser schemes and allow researchers to study the physics and feasibility of photo-pumped laser schemes. Many of these photo-pumped schemes are driven by photo-excitation from a resonant line source but others are driven by photo-ionization from a strong non-resonant X-ray source.

Three years ago an inner-shell X-ray laser was demonstrated at 849 eV in singly ionized neon gas using the LCLS X-FEL at 960 eV to photo-ionize the 1s electron in neutral neon followed by lasing on the 2p – 1s transition in singly-ionized neon. It took many decades to demonstrate this scheme because it required a very strong X-ray source that could photo-ionize the 1s (K shell) electrons in neon on a time scale comparable to the intrinsic auger lifetime in the neon, which is typically 2 fsec.

In this work we model the neon inner shell X-ray laser under similar conditions to those used at LCLS and investigate how we can improve the efficiency of the neon laser and reduce the drive requirements by tuning the X-FEL to the 1s-3p transition in neutral neon in order to create gain on the 2p-1s line in neutral neon. We also explore using the XFEL to drive gain on 3-2 transitions in singly-ionized Ar and Cu plasmas.

9589-33, Session 8

Enhancement of laser-driven betatron radiation *(Invited Paper)*

Liming Chen, The Instiute of Physics (China)

A new method is demonstrated for generating intense betatron x-rays using a clustering gas target irradiated with an ultra-high contrast laser of 3 TW only [1]. The yield of the Ar x-ray betatron emission has been measured to be 2?10^8 photons/pulse, which is over ten-fold enhancement compared to the emission yield produced by using a normal gas target. Simulations point to the existence of clustering as a contributor to the DLA mechanism, thereby finally enhancing the betatron x-ray photons and improving conversion efficiency over 40 times. Another concept of generation of bright betatron radiation during electron acceleration was newly studied [2]. Two electron bunches with different qualities were injected sequentially into the wakefield driven by a super-intense laser pulse. The first one is a mono-energetic electron bunch with peak energy of GeV level, and the second one is injected continuously with large charge and performs transverse oscillation with large amplitude during the subsequent acceleration. The enhancement of transverse resonant oscillation of the inonization injected electron bunch which results in the betatron radiation would lead to Gamma-ray photon energy and peak brilliance beyond that of 3rd generation synchrotron facilities [3].

Multi-stage Auger pumping of atomic EUV lasers in Xe and Kr by a soft x-ray free-electron laser

Laurent Mercadier, Clemens Weninger, Ctr. for Free-Electron Laser Science (Germany) and Max-Planck-Institut für Physik komplexer Systeme (Germany); Sven Bernitt, Michael Blessenohl, Hendrick Bekker, Stepan Dobrodey, Max-Planck-Institut für Kernphysik (Germany); Alvaro Sanchez-Gonzalez, Imperial College London (United Kingdom); Cedric Bomme, Deutsches Elektronen-Synchrotron (Germany); Benjamin Erk, Deutsches Elektronen-Synchrotron (Germany); Philipp Schmidt, Martin Wilke, Andre Knie, Univ. Kassel (Germany); Wen Te Liao, Ctr. for Free-Electron Laser Science (Germany) and Max-Planck-Institut für Physik komplexer Systeme (Germany); Artem Rudenko, Kansas State Univ. (United States); Jan P. Müller, Technische Univ. Berlin (Germany); Zhong Yin, Deutsches Elektronen-Synchrotron (Germany); Rebecca Boll, Evgeny Savelyev, Rolf Treusch, Andrey Sorokin, Deutsches Elektronen-Synchrotron (Germany); Daniel Rolles, Deutsches Elektronen-Synchrotron (Germany); Arno Ehresmann, Univ. Kassel (Germany); Jose R. Crespo Lopez-Urrutia, René Steinbrügge, Max-Planck-Institut für Kernphysik (Germany); Nina Rohringer, Ctr. for Free-Electron Laser Science (Germany) and Max-Planck-Institut für Physik komplexer Systeme (Germany)

The advent of X-ray free-electron lasers (FELs) makes it possible to pump new atomic x-ray lasers with short pulse duration, extreme spectral brightness and full temporal coherence. One of the advantages of such a laser is the spectral stability as compared to the self-amplified spontaneous emission (SASE) used to generate it. We present results on Auger-decay pumping of EUV lasing emission of highly charged Xe and Kr ions. We use a soft x-ray FEL with photon energy between 72 eV and 100 eV to photoionize the inner shells of Xe (4d) and Kr (3d) in an elongated gaseous medium with pressures ranging from 1 mbar to almost 1 atmosphere. Using high-resolution spectroscopy, we observe several lasing lines for both gases, ranging from 56 nm to 120 nm. These lines arise from population inversions of highly charged ions after a sequence of inner-shell photoionization events and Auger decays. Varying the pump-photon energy in the range of the giant 4d and 3d resonances in Xe and Kr allows the change of ionization rates, so that plasmas of different ionic charge-state distributions can be created and certain emission lines can be quenched, others enhanced. We measure a strong dependence of the emission-line strength on both pulse energy and pressure, and find an optimum pressure close to 6 mbar. Bleaching and the large variation of the intensity along the strongly diverging focus of the FEL beam result in a highly nonuniform plasma. This in turn results in different line-emissions along the elongated plasma channel.

Hard x-rays from a table-top all-laser-driven synchrotron light source *(Invited Paper)*

Donald P Umstadter, Univ. of Nebraska-Lincoln (United States)

We discuss the experimental development of a compact, tunable hard x-ray light source. The repetitive petawatt-class Diocles laser system at the University of Nebraska, Lincoln, serves dual purposes. First, it drives a laser-plasma wakefield when it is focused to high intensity (I ~ 10^19W/cm^2) onto a gas jet. The electrostatic field of the relativistically propagating laser-wakefield accelerates electrons to highly relativistic energy, up to 0.5 GeV. Another high intensity laser pulse (I ~ 10^17W/cm^2), from the same laser system, is focused in a counter-propagating direction onto the relativistic electron beam, which generates x-rays by inverse Compton scattering. This is the first all-laser-driven hard x-ray source with a peaked photon spectrum. It is shown to be tunable from 70 keV to 9 MeV, and thus suitable for both atomic and nuclear research and applications. Femtosecond x-ray pulse duration also makes this novel light source suitable for research into ultrafast phenomena.

9590-2, Session 1

The compact light source: A miniature synchrotron producing x-rays via inverse Compton scattering *(Invited Paper)*

Ronald D. Ruth, SLAC National Accelerator Lab. (United States) and Lyncean Technologies, Inc. (United States); Rod Loewen, Lyncean Technologies, Inc. (United States)

The Compact Light Source concept was first developed as a spin off from work at Stanford Linear Accelerator Center towards very small electron storage rings for beam cooling in linear colliders.[1] Later, further research at SLAC explored a miniature storage ring and high-finesse cavity optimized for the hard x-ray regime.[2] These studies led to the formation of a corporation, Lyncean Technologies, Inc., which developed the Compact Light Source (CLS) [3]. The CLS is a near-monochromatic, tunable, homelab-size x-ray source with beamlines that can be used like the x-ray beamlines at the synchrotrons--but it is about 200 times smaller than a conventional synchrotron light source. The compact size is achieved using a “laser undulator” and a miniature electron-beam storage ring. In other words, the x-rays are produced via inverse Compton scattering of electrons circulating in a miniature storage ring interacting with an IR photon pulse stored in a high-finesse cavity. The CLS can produce a photon flux on sample that is comparable to highly-productive synchrotron beamlines. The production-prototype CLS and the Beta CLS operated for many years at Lyncean Technologies, Inc.[3]. The first delivery and commissioning of a commercial CLS took place in the spring of 2015. This presentation will introduce the Compact Light Source showing the injector, linac, storage ring and laser/cavity system. We then present selected results of grating-based imaging and tomography experiments.[4]

Liquid-metal-jet and ultra-high resolution x-ray tube technology including microscopy applications *(Invited Paper)*

Emil Espes, Björn A. M. Hansson, Oscar Hemberg, Mikael Otendal, Per Takman, Tomi Tuohimaa, Excillum AB (Sweden)

The power and brightness of electron-impact micro-focus X-ray tubes have long been limited by thermal damage in the anode. This limit is overcome by the liquid-metal-jet anode (MetalJet) technology that has previously demonstrated brightness in the range of one order of magnitude above current state-of-the art sources. This is possible due to the regenerative nature of this anode and the fact that the anode is already molten, which allows for significantly higher e-beam power density than on conventional solid anodes.

Over the last years, the MetalJet technology has developed from prototypes into fully operational and stable X-ray tubes running in many labs over the world. Key applications include X-ray diffraction and scattering.

To be able to benefit from the higher power-loading capability of the liquid-metal-jet anode, advanced electron optics had to be developed. Based on this advanced electron optics, a new nanofocus x-ray tube (NanoTube) is under development. The foundation of the NanoTube is the advanced electron optics, combined with a tungsten coated diamond transmission target. The NanoTube is designed to reach spot sizes of 100 nm, and by doing so, achieving line-spacing resolution of 50 nm.

This presentation will review the current status of the MetalJet technology specifically in terms of stability, lifetime, flux and brightness. It will also discuss details of the liquid-metal-jet technology with a focus on the fundamental limitations of the technology and refer to some recent data from relevant applications. Furthermore, it will review the state of the development of the NanoTube.

9590-4, Session 1

A novel technique to produce x-rays for XRF, medical, and scientific purposes *(Invited Paper)*

Carlos Camara, Tribogenics (United States)

Since the discovery of X-rays by Wilhelm Roentgen in 1895 X-ray have been produced in basically the same way, using a high voltage power supply attached to an X-ray vacuum tube. In 2008 Seth Putterman, Carlos Camara, Jonathan Hird and Juan Escobar discovered that one could generate enough X-rays to capture an image by peeling scotch tape inside a vacuum. This lead to the formation of Tribogenics in 2011. Since then we have improved our technology by 6 orders of magnitude. Currently we are focused on our first commercial product, a hand held X-ray fluorescence (XRF) instrument. This is the first step towards the development of other x-ray solutions utilizing our technology. We will discuss this new method for producing X-rays, the challenges we face, and some of the products that will be enabled by our efforts.

Development of an adaptable shield wall design for the CSU Linac

Joel Williams, Tejas Doshi, Madhuri Ravikumar, Jeff Ngyn, Sandra G. Biedron, Stephen V. Milton, Josh Einstein, Colorado State Univ. (United States)

When designing an accelerator radiation enclosure, both current demands and any future modifications must be taken into account. At CSU, the initial design for radiation shielding calls for protection from the radiation produced by a 6 MeV electron beam with a current of 1.2188A. In order to ensure the design of the accelerator meets government regulatory specifications for radiation safety under all operational scenarios, we have ran simulations to estimate the necessary shielding required. After determining the ideal materials, we proceeded to design a CAD model and reiterate through the design to ensure all guidelines are still followed. Further, we are planning for upgrades for additional accelerator engineering tests, including a compact light source device. Discussions of the facility and its light source test will be discussed.

9590-8, Session 2

Liquid jet target x-ray tube with field emission cathode

Gennadiy Karpinskiy, Siemens Russia (Russian Federation) and National Research Nuclear Univ. MEPhI (Russian Federation); Taras Bondarenko, Stepan Polikhov, Siemens Russia (Russian Federation); Alexandra Botyachkova, Siemens Russia (Russian Federation) and National Research Nuclear Univ. MEPhI (Russian Federation); Sergey Frolov, Vyacheslav Ivanov, N.N. Semenov Institute of Chemical Physics (Russian Federation); Andreas Geisler, Oliver Heid, Siemens AG (Germany)

Over the last years microfocus X-ray sources faced two main restrictions that substantially limited the enhancement of their performances. The first one is a limited brightness of the electron source and the second is a limitation concerned with anode thermal loads. Our research is concerned with the development of high power X-ray source that is based on the carbon nanostructure field emission cathode as an electron source and high speed liquid metal jet as a target for X-ray generation to solve both these restrictions. The liquid jet of the source is based on the alloys of two metals: heavy atom weight and light atom weight. Besides the high thermal load durability this alloys allows to obtain high characteristics spectrum relative to bremsstrahlung X-ray. CFD simulations were performed to estimate break-up length and behavior of a micrometer jet at velocities up to 500 m/s. High brightness cold emission electron source based on carbon nanostructures and electrostatic extraction grid is designed. Electron beam dynamics simulations are performed. To verify the electron beam dynamics calculations the experimental setup with bulk metal anode is designed and under construction now. The experimental setup for verification of the jet dynamics simulation is as well designed and built. This setup also implies the mounting of the conventional electron gun to analyze the generation of the X-ray radiation from the jet.

9590-9, Session 3

A review of formed optics for lab-based x-ray systems *(Invited Paper)*

Ladislav Pina, Czech Technical Univ. in Prague (Czech Republic)

Imaging in EUV and X-ray region plays important role in radiography, tomography, spectroscop and lithography. Imaging includes also collectors of radiation working as condensers for sample illumination or for intermediate focus formation in EUV lithography exposure systems. One class of optics consist of electroformed mirrors and mechanically bent multifoil mirrors. Formed optical systems and their main characteristics are presented. Comparison of theoretical results obtained by ray-tracing with experimental results is presented. Examples of various optical systems and their applications in the field of X-ray microscopy and tomography, EUV metrology, lithography and spectroscopy are presented.

NanoCT imaging with a prototype nanofocus source

Mark Müller, Simone Ferstl, Sebastian Allner, Martin Dierolf, Technische Univ. München (Germany); Björn Hansson, Tomi Tuohimaa, Per Takman, Excillum AB (Sweden); Franz Pfeiffer, Technische Univ. München (Germany)

n the last decade X-ray microCT (μCT) has gained importance in many research domains and is becoming a routine microscopy technique. Due to the recent development of transmission X-ray tubes with very small focal spot sizes, laboratory-based CT imaging with submicron resolution is possible nowadays.

We present a novel microCT setup featuring a prototype nanofocus X-ray source and a single-photon counting detector. The system relies on mere geometrical magnification and can reach resolutions around 300 nm at its current state.

The nanofocus X-ray tube (Excillum AB, Sweden) consists of a tungsten transmission target on a diamond layer and can so far reach focal spot sizes down to about 300 nm.

The X-ray camera is a PILATUS 300K-W 20Hz detector with a 1000 μm silicon sensor, 1475 x 195 pixels, and a pixel size of 172 x 172 ?m?.

First results demonstrate that the focal spot of the tube is stable enough to permit CT imaging with submicron resolution. The small focal spot size also results in sufficient spatial coherence to exploit edge enhancement effects

and to apply phase contrast imaging methods.

Moreover, the first images indicate that image acquisition with a practically noise-free photon counting detector combined with a low-flux nanofocus tube can result in enhanced contrast compared to similar setups.

We will show first applications comprising stained soft tissue samples as well as bone and tooth samples; e.g. a 3D data set of a piece of tooth, where the dentin tubules, are clearly resolved.

9590-12, Session 3

The best of both worlds: automated CMP polishing of channel-cut monochromators

Elina Kasman, Argonne National Lab. (United States)

The use of a channel-cut monochromator is the most straightforward method to ensure that the two reflection surfaces maintain alignment between crystallographic planes without the need for complicated alignment mechanisms. Three basic characteristics that affect monochromator performance are: subsurface damage which contaminates spectral purity; surface roughness which reduces efficiency due to scattering; and surface figure error which imparts intensity structure and coherence distortion in the beam. Standard chemical-mechanical polishing processes and equipment are used when the reflecting surface is easily accessible, such as for single-bounce monochromators. Due to the inaccessibly of the surfaces inside a channel-cut monochromator for polishing, these optics are generally wet-etched for their final processing. This results in minimal subsurface damage, but very poor roughness and figure error. A new CMP channel polishing instrument design is presented which allows the internal reflecting surface quality of channel-cut crystals to approach that of conventional single-bounce monochromators.

9590-13, Session 3

Possibility for new PolyCO imaging: stroboscopic imaging based on vibrating capillary optics

Andrea Liedl, Univ. degli Studi di Roma Tre (Italy) and Infn-LNF (Italy); Dariush Hampai, Istituto Nazionale di Fisica Nucleare (Italy); Sultan B. Dabagov, Istituto Nazionale di Fisica Nucleare (Italy) and P.N. Lebedev Physical Institute (Russian Federation) and National Research Nuclear Univ. MEPhI (Russian Federation); Claudia Polese, Istituto Nazionale di Fisica Nucleare (Italy) and Univ. degli Studi di Roma La Sapienza (Italy)

Polycapillary lenses are a well known optical devices for radiation and charged particles. These lenses consist of thousands channels through which the signal is transmitted by Total External Reflection phenomenon. Their application have made possible technical improvements in different fields such as Imaging, Fluorescence analysis, channeling studies etc...

In particular, application of this optics coupled on conventional sources such as x-ray tube has open a new season for potential application of desktop instrumentation. For instance, usage of lenses has enhanced spatial coherence and brilliance over the sample allowing better resolution and contrast for imaging purpose. Likewise improved focusing power and confocal configuration of more lenses has improved resolution, from energy and spatial point of view, in fluorescence mapping analysis.

Recent work has studied the behavior of transmitted radiation through a single capillary in vibrating regime. In this work a utilization of vibrating capillary for stroboscopic imaging is presented. A sample characterized by a known periodic event is studied with synchronized vibrating capillary.

The same sample is then analyzed, without optics, by synchronization of detector image acquisition. A comparison between these two results is discussed.

9590-14, Session 4

A triboelectric closed loop band system for the generation of x-rays

Eli Van Cleve, Zach Ganlieli, Ben Lucas, Dan Cudra, Eric W. Wong, Mark Valentine, Pedro Cortes Jr., David Kamkar, Gilberto Jimenez, Andreas Magnusson, Rebecka Jacobsson, Timothy Baxendale, Nikhil Mehta, Jon Fong, Steve Hansen, Andy Kotowski, Dale Fox, Carlos Camra, Justen Harper, Tribogenics (United States)

In 2008 Seth Putterman, Carlos Camara, Jonathan Hird and Juan Escobar discovered that one could generate X-rays by peeling scotch tape inside a vacuum. Since, Tribogenics has developed multiple architectures to generate X-rays from tribocharging. One such design is realized by sliding a polymer band across a metal cylinder and using a target to collect the triboelectric generated electrons from the polymer to generate X-rays. This new architecture is capable of generating x-rays for the purposes of X-ray fluorescence (XRF). In this talk we will describe this architecture and discuss important insights into the generation of x-rays through tribocharging that has resulted from the development of the device.

9590-15, Session 4

Thermal analysis of high-power microfocus x-ray target-scaling effect

Xi Zhang, Vance Robinson, Mark Frontera, GE Global Research (United States)

High resolution X-ray systems require small focal spots which, depending on the application, range from 1 ?m for defect detection to 1 mm for medical CT. Often in opposition to the demand for small spot sizes is the need for faster scan times. The high X-ray flux required for fast scan times and small focal spots required for high resolution result in extremely high power densities and temperature at the focal spot. This is critical because the focal spot temperature is often the limiting factor in both performance and life of imaging system. In this paper, a finite element model is developed to compute the temperature of a stationary x-ray target. This model is used to demonstrate the effect of focal spot size – diameter, on the heat dissipation capability. As the spot size reduces, a higher power density may be sustained by the target. This effect is explained by increased in-plane heat conduction. The peak temperature of a small focal spot also becomes more sensitive to the current density distribution of the incident electron beam. The relationship of the peak power and electron beam profile, power deposition inside the X-ray target and focal spot aspect ratio are discussed. Some experimental data demonstrating such scaling effects is included. General design rules for higher-flux capable targets leveraging these scaling effects are also proposed.

9590-16, Session 4

X-ray tube thermal management

Ali M. Khounsary, Illinois Institute of Technology (United States)

This paper presents an overview of the various fixed X-ray tube designs and the target's thermal management challenges that limit the intensity of the generated X-ray beams. Analytical and numerical results for various sources size/power are presented and methods to further increase the beam intensity are discussed.

Complete time-resolved polarimetry of scattered light on the NIF *(Invited Paper)*

David Turnbull, Joseph E. Ralph, Robert Chow, Pierre A. Michel, Gene Frieders, Robin L. Hibbard, Kenn M. Knittel, Joel R. Stanley, James L. Vickers, Ziad M. Zeid, John D. Moody, Lawrence Livermore National Lab. (United States)

The polarization of 3? scattered light has been measured in the full aperture backscatter (FABS) diagnostic on a 30° incidence quad at the National Ignition Facility (NIF) since June 2013. The initial scoping stage was capable of measuring the time-integrated Jones vector of the collected signal. Two key insights were derived from early experiments. First, laser "glint" (a specular reflection from the inner hohlraum wall), which could cause early time capsule imprint and has been found to seed stimulated Brillouin scattering (SBS) later in time, is observed in near-vacuum hohlraums. Second, the polarizations of the incident laser beam and its backscatter are affected by crossed-beam energy transfer (CBET) in gas-filled hohlraums, and backscatter polarization might therefore serve as a quantitative CBET diagnostic. To more definitively assess the latter possibility, the diagnostic is currently being upgraded to complete time-resolved polarimetry, which means it will measure the full Stokes vector and its evolution over time. Insights derived to date, as well as the new diagnostic design, will be presented. Time-resolved polarimetry will also be used to diagnose Faraday rotation induced by magnetic fields in collisionless shock experiments that are planned this year.

Upgrades to the VISAR-streaked optical pyrometer (SOP) system on NIF

Anastacia M. Manuel, Marius Millot, Peter M. Celliers, Eugene O. Vergel de Dios, Glen James, Philip Datte, Lynn G. Seppala, Lawrence Livermore National Lab. (United States)

The Velocity Interferometer System for Any Reflector (VISAR) is a critical diagnostic in Inertial Confinement Fusion and High Energy Density research as it allows the ability to track shock fronts or interfaces moving 0.1-100 km/s with great accuracy. At the National Ignition Facility (NIF), the VISAR has recently been used successfully for implosion tuning and equation of state measurements. However, the initial design of the companion streaked optical pyrometer (SOP) to measure spectral radiance - hence shock temperature - suffers from large background levels and poor spatial resolution. The SOP upgrade improves spatial resolution in the 560-640nm band by using custom lenses and K-mirrors, and a gating-circuit for the streak camera to reduce background signal. The upgraded SOP now allows high quality data collection matching NIF VISAR's standards.

Radiation test results for a megapixel CMOS charge dump and read camera at the National Ignition Facility

Joseph R. Kimbrough, Perry M. Bell, Alexander A. Lumbard, Mai S. Thao, Lawrence Livermore National Lab. (United States)

A prototype radiation tolerant camera based on a 2k by 2k CMV4000 sensor from CMOSIS Inc. was tested for total dose and neutron damage effects at the National Ignition Facility. Camera electronic parts were selected to operate up to 10 krad(Si). The CMOS based camera incorporate a fast charge and dump of the sensor, followed by image readout. This allows dumping the charge in the pixel due to the prompt radiation and then readout of the longer persistence phosphor image from the x-ray streak camera or gated imaging detector. Characterization results of the camera's performance before and after the radiation test are compared

Lawrence Livermore National Laboratory is operated by Lawrence Livermore National Security, LLC, for the U.S. Department of Energy, National Nuclear Security Administration under Contract DE-AC52-07NA27344. LLNL-ABS-666586

Design and implementation of a gated-laser entrance hole imaging diagnostic (G-LEH-1) at NIF

Nathan E. Palmer, Hui Chen, Jarom Nelson, Joe Kimbrough, Marilyn B. Schneider, Perry M. Bell, Lawrence Livermore National Lab. (United States); Eric Huffman, National Security Technologies, LLC (United States); John L. Porter, Marcos O. Sanchez, Liam D. Claus, Mark W. Kimmel, Sandia National Labs. (United States); John W. Stahoviak, Sandia Staffing Alliance, LLC (United States); Terance J. Hilsabeck, Joseph D. Kilkenny, General Atomics (United States)

Gated x-ray images through the laser entrance hole (LEH) of a hohlraum can provide critical information for ICF experiments at the National Ignition Facility (NIF), such as the size of the LEH vs time, the growth of the gold bubble [1], and the change in the brightness of inner beam spots due to time-varying cross beam energy transfer [2]. Incorporating a high-speed multi-frame CMOS x-ray imager developed by Sandia National Laboratories [3] into the existing Static X-ray Imager (SXI) diagnostic [4] at NIF, the new Gated LEH Imager #1 (G-LEH-1) diagnostic is capable of capturing two to

four LEH images per shot on its 1024x448 pixel photo detector array, with integration times as low as 2 ns per frame. The design of this diagnostic and its implementation on NIF will be presented.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Security, LLC, (LLNS) under Contract No. DE-AC52- 07NA27344. LLNL-ABS-666596. Sandia National Laboratories is a multi-program laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy's National Nuclear Security Administration under Contract No. DE-AC04-94AL85000.

Gated x-ray camera microchannel plate gain droop investigation

Bart Beeman, Jorge Carrera, John M. Chesser, John B. Lugten, Fred V. Allen, Alex A. Lumbard, Charles G. Brown Jr., Joe P. Holder, Joseph R. Kimbrough, Lawrence Livermore National Lab. (United States)

We present measurements and modeling results of the electrical conductor "strips" deposited on microchannel plate (MCP) x-ray detectors. Short pulse mode response of the MCP is extremely sensitive with the output intensity related to the applied voltage by up to V23. Thus any voltage drop as the pulse travels along the strip due to conductor losses, surface roughness, etc. leads to significant changes in recorded signal intensity. This is commonly referred to as gain droop with typical variations of >3x over a 7mm x 34mm strip (3% change in voltage ~2x change in gain). In an effort to minimize this gain droop we investigate electrode material choice, material thickness, and effects of annealing on the DC ohmic loss of the strip.

Additionally any reflected energy due to impedance mismatches at the output of the MCP, or crosstalk between strips, may superimpose on the incident voltage pulse, again causing gain variations. Impedance matching measurement tools and techniques for ~10ohm MCP's will be discussed.

Lawrence Livermore National Laboratory is operated by Lawrence Livermore National Security, LLC, for the U.S. Department of Energy, National Nuclear Security Administration under Contract DE-AC52-07NA27344.

Mirrored low-energy channel for the MiniXRD

Eric C. Dutra, Larwence P. MacNeil, National Security Technologies, LLC (United States); Steven M. Compton, Barry A. Jacoby, Lawrence Livermore National Lab. (United States); Mark L. Raphaelian, National Security Technologies, LLC (United States)

X-ray Diodes (XRD) are currently used for spectroscopic measurements, measuring x-ray flux, and estimating spectral shape of the VUV to soft x-ray spectrum. A niche exists for an inexpensive, robust x-ray diode that can be used for experiments in hostile environments on multiple platforms, including explosively driven experiments that have the potential for destroying the diode during the experiment. A multiple channel stacked filtered array was developed with a small field of view where a wider parallel array could not be used, but filtered channels for energies lower than 1000 eV were too fragile to deploy under normal conditions. To achieve both the robustness and the required low-energy detection ability, we designed a small low-energy mirrored channel with a spectral sensitivity from 30 to 1000 eV. The stacked MiniXRD x-ray diode system design incorporates the mirrored low-energy channel on the front of the stacked filtered channels to allow the system to work within a small field of view. We will present results that demonstrate this is a promising solution for low-energy spectrum measurements.

This work was done by National Security Technologies, LLC, under Contract No. DE-AC52-06NA25946 with the U.S. Department of Energy and supported by the Site-Directed Research and Development Program. DOE/NV/25946--2316

Disposable blast shields for use on NIF imaging diagnostics

Cal A. Smith, Lawrence Livermore National Lab. (United States); Karen M. Wang, Lawrence Livermore National Lab. (United States) and Stanford Univ. (United States); Marion J. Ayers, Robbin L. Hibbard, Kim Christensen, Nathan D. Masters, Lawrence Livermore National Lab. (United States)

The 192 lasers deliver 2MJ of energy to Target Chamber Center (TCC) that produces an intense amount of energy to a single small volume. Along with The National Ignition Facilities (NIF) scientific experimental results come the harsh consequences to the experimental equipment and supporting diagnostic structures, which include hohlraums, support packages, target positioners, diagnostic equipment, and laser optics. Of these, the hohlraum and support packages are typically quickly vaporized and are transformed into an expanding spherical shell of high-hypersonic gases referred to as "Debris Wind". During an experimental event, such as fusion implosion, the target diagnostic components used to measure key observables on NIF are subjected to extreme pressures and impact shocks due to incident "Debris Wind" loading. As diagnostics are positioned closer to TCC, the diagnostic pinhole stacks, and other components along the diagnostic structure are become more likely to be at or above the yield strength of the materials commonly used. Of these, the pinhole stack components and data recording instruments behind the pinholes are the most costly to replace. A conceptual configuration for a pinhole shield has been proposed, analyzed and tested with the hopes that it will be able to mitigate damage to the pinhole stack and imaging equipment and allow immediate re-use of the diagnostic equipment. The shield would be a single use, disposable window that could be replaced quickly by inserting and removing it before and after each experimental laser shot. This will allow NIF to benefit from significant material and labor costs.

9591-9, Session 3

3? beam timing diagnostic for the OMEGA laser facility

Joseph D. Katz, W. Donaldson, R. Huff, E. Hill, J. Kelly, J. Kwiatkowski, R. Brannon, Univ. of Rochester (United States)

The OMEGA laser at the University of Rochester's Laboratory for Laser Energetics is a 60-beam system used for inertial confinement fusion (ICF) experiments. Uniform drive of the target surface requires precise beam timing to achieve accurate power balance. A new diagnostic has been implemented to measure the relative beam-to-beam time of arrival of each of the 60 beamlines. An 860-?m spherical diffuser placed at the target chamber center serves as a quasi-isotropic scattering source, making it possible for a fixed optical detector to view light from of any individual beamline. During a beam-timing run, the OMEGA laser is configured to generate frequency-tripled, 351-nm, ultraviolet (UV) pulses with energies of ~100 pJ at a repetition rate of 5 Hz. Light from the scattering target is optically relayed to a fast photomultiplier tube and recorded on a digital oscilloscope. A portion of the original infrared (IR) seed pulse is fiber

optically delivered the beam-timing oscilloscope and recorded using a photodiode. By recording the scattered UV pulse and the IR seed on the same oscilloscope trace, a jitter-free measurement of the beam arrival time can be made. Discrepancies in beam timing are corrected by adjusting the total optical path length of the beamlines. Typical variation in the measured arrival times of all 60 OMEGA beams after adjustment is 5-ps rms (root mean square).

Digitizer architecture analysis for target diagnostics on the National Ignition Facility

Arthur Carpenter, Todd J. Clancy, Bart Beeman, Perry Bell, Lawrence Livermore National Lab. (United States)

This paper covers a systems engineering analysis of existing scope-based Target Diagnostics (TD) on the National Ignition Facility (NIF) at Lawrence Livermore National Laboratory (LLNL), for the purpose of selecting standard digitizer architectures for NIFs future use. Key performance criteria and a summary of test results is presented.

Currently of the 60+ Target Diagnostics, at least fifteen use a type of high speed electrical signal data read-out device leading to over 200 digitization channels spread over six types of CRT and digital oscilloscopes, each with multiple models and versions. The proposed standard architectures discussed in this paper allow the NIF to efficiently and reliably operate digitizers that meet the required performance metrics for the lifetime of the NIF.

The systems engineering analysis identifies key stakeholders for multiple subsets of scope-based diagnostics including but not limited to the nToFs (neutron Time of Flight), DANTE a broadband, time-resolved x-ray spectrometer, SPBT (South Pole Bang Time), GRH (Gamma Reaction History), and FFLEX (Filter Fluorescer Diagnostic). From these stakeholders, key performance metrics are derived and drive a test plan that evaluates different digitizers and architectures. The results of this work allows for the selection of several architectures to be used in future diagnostics.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Materials characterization of irradiated spectralon from the NIF target chamber

Robert Chow, Gene Frieders, Wayne Jensen, Mark Pearson, Phil Datte, Lawrence Livermore National Lab. (United States)

The Near Backscatter Imager (NBI) participates in nearly every kind of experiment conducted at NIF and measures backscatter, the result of the interaction between incident laser light and plasma waves at a target. Large Spectralon plates, on the order of a hundreds of mm per side, are used as Lambertian scatter components for the NBI diagnostics. The plates were deployed in 2009 and replaced in April of 2014. All NBI assemblies suffered reflectivity degradation, and some changes were spatially localized. The growth of some defects was correlated to the cumulative fusion energy and the cumulative neutron yield created from the Deuterium-Tritium target shots.

Spectralon plates were extracted from the NIF target chamber in April of 2014 after irradiation to a cumulative neutron fluence of 3.53E8 neutrons/mm2 and cumulative total fusion energy from energetic particles of 0.92 mJ/mm2. These plates were characterized for materials and mechanical changes with the following techniques: RBS, FTIR, XPS, SEM, EDX and tensile tests. These tests indicate that the bulk Spectralon has not degraded but there are the defects created that significantly change the reflectivity of the Spectralon. The analysis shows that the surface loses F atoms and the C bonds to H, O, N and other C-F molecules.

Gated photocathode design for the P510 electron tube used in the National Ignition Facility (NIF) optical streak cameras *(Invited Paper)*

Philip S Datte, Glen James, Daniel Kalantar, Gene Vergel de Dios, Lawrence Livermore National Lab. (United States)

The optical streak cameras currently used at the National Ignition Facility (NIF) implement the P510 electron tube from Photonis1. The existing high voltage electronics provide DC bias voltages to the cathode, slot, and focusing electrodes. The sweep deflection plates are driven by a ramp voltage. This configuration has been very successful for the majority of measurements required at NIF. New experiments require that the photocathode be gated or blanked to reduce the effects of undesirable scattered light competing with low light level experimental data. The required 2300V gate voltage is applied between the photocathode and the slot electrode in response to an external trigger, to allow the electrons to flow. Otherwise the slot electrode is held at near the same potential as the photocathode, preventing electron flow. This article reviews the implementation and performance of the gating circuit that applies an electronic gate to the photocathode with a nominal 50ns rise and fall time, and a pulse width between 50ns and 2000ns.

9591-13, Session 4

Multi-axis neutron imaging at the National Ignition Facility *(Invited Paper)*

David N. Fittinghoff, Gary P. Grim, Robin L. Hibbard, Donald R. Jedlovec, Lawrence Livermore National Lab. (United States); Frank E. Merrill, Petr L. Volegov, Carl H. Wilde, Los Alamos National Lab. (United States)

Inertial Containment Fusion (ICF) experiments at the National Ignition Facility (NIF) rely on a Neutron Imager (NI) to measure the 2D size and shape of the neutrons produced by the burning deuterium-tritium plasma. Since the NI is located on the equator of the NIF chamber, it provides only one view of the plasma, which complicates understanding the inherently three-dimensional nature of the implosion. Attempts to use x-ray images combined with the neutron image to improve our understanding of the 3D neutron-burn volume have proved to be inconsistent with the fuel mass. This result is understandable since neutrons and x-rays are not produced or propagated in the same manner. Thus, it is desirable to use multiple NIs, and we are designing two NIs nearly orthogonal to the current imager, one near the pole of the chamber and one near the equator, for fielding on the NIF in the next five years. In this paper, we will discuss the current designs, including the resolution, field of view and placement in the facility as well as the analysis that will be required to use the three orthogonal neutron imagers to measure the neutron burn volume of plasmas at NIF. Prepared by LLNL under Contract DE-AC52-07NA27344.

Upgrades to the Radiochemistry Analysis of Gas Samples (RAGS) diagnostic at the National Ignition Facility

Donald R. Jedlovec, Kim Christensen, Lawrence Livermore National Security, LLC (United States); Carol Velsko,

William Cassata, Wolfgang Stoeffl, Dawn Shaughnessy, Lawrence Livermore National Security, LLC (United States)

The Radiochemical Analysis of Gaseous Samples (RAGS) diagnostic apparatus operates at the National Ignition Facility (NIF). At the NIF, Xenon is: injected into the target chamber as a tracer, is used as an analyte in the NIF targets, and is also generated as a fission product from fast 14Mev neutron fission of uranium contained in the NIF hohlraum. Following a NIF shot, the RAGS is used to collect the gas from the NIF target chamber and then to cryogenically fractionate Xenon gas. Radio Xenon and other collected activation products are counted via gamma spectroscopy, with the results used to determine critical physics parameters including: capsule areal density, fuel-ablator mix, and nuclear cross sections.

We will discuss the following performance upgrades to the system:

1) Modification of the Xenon fractionator to allow collection of Krypton. Krypton is an important target analyte and is also generated as fission gas in NIF shots. We have modified the cryostat to enable fractionation of Xenon, Krypton, or both, and

2), a translatable detector for quantification of the Xenon activity. An in situ Germanium detector is used to count the radio isotopes collected on the cold head. NIF shots that incorporate uranium in the hohlraum generate large amounts of fission gas, the radioactivity of which swamps the detector. We have designed a system that will adjust the detector to cold head distance based upon either the count rate or the time after the NIF shot.

9591-15, Session 4

Vast Area Detection for Experimental Radiochemistry (VADER) at the National Ignition Facility

Justin D. Galbraith, Ron Bettencourt, Dawn Shaughnessy, Bahram Talison, Kevin Morris, Lawrence Livermore National Lab. (United States)

At the National Ignition Facility (NIF), the flux of neutrons and charged particles at peak burn in an inertial confinement fusion capsule induces measureable concentrations of nuclear reaction products in the target material. Radiochemistry analysis of post-shot debris can be used to determine diagnostic parameters associated with implosion of the capsule, including fuel areal density and ablator-fuel mixing. Additionally, analysis of debris from specially doped targets can provide realistic debris samples for nuclear forensics.

We have developed and are deploying the Vast Area Detection for Experimental Radiochemistry (VADER) diagnostic to collect shot debris at the NIF. VADER uses quick release collector panels that are easily reconfigured for different collector materials and geometry. The VADER collectors are located 50 cm from the NIF target; each of nine collectors views approximately 25 square degrees solid angle. Dynamic loading of the NIF target debris field was modelled using LS-DYNA. Three dimensional printing was utilized to expedite the design process. Model-based manufacturing was used throughout.

We will describe the design and operation of this diagnostic as well as some initial results.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

9591-16, Session 4

Implementation of an enhanced permanently-installed neutron activation diagnostic hardware in NIF

Donald R. Jedlovec, Lawrence Livermore National Security. LLC (United States); Charles B. Yeamans, Ellen R. Edwards, Jorge A. Carrera, Lawrence Livermore National Security, LLC (United States)

Neutron activation diagnostics are commonly employed as baseline neutron yield and flux measurement instruments. Much insight into implosion performance has been gained by deployment of up to 19 identical activation diagnostic samples distributed around the target chamber at unique angular locations. Their relative simplicity and traceability provide neutron facilities with a diagnostic platform that is easy to implement and verify. However, the current NIF implementation relies on removable activation samples, creating a 1-2 week data turn-around time and considerable labor costs. The system described here utilized a commercially-available lanthanum bromide (cerium-doped) scintillator with integrated MCA emulator as the counting system and a machined zirconium-702 cap as the activation medium. The device is installed within the target bay and monitored remotely. Yield values are returned within 10 minutes after a NIF shot. Additionally, this system allows the placement of any activation medium tailored to the specific measurement needs. We discuss the design and function of a stand-alone and permanently installed neutron activation detector unit to measure the yield and average energy of a nominal 14 MeV neutron source with a pulse length less than 1 nanosecond.

9591-17, Session 5

Design of a spectrometer for opacity experiments at the National Ignition Facility *(Invited Paper)*

Patrick W. Ross, Jeffrey A. Koch, Michael J. Haugh, Wayne C. Stolte, National Security Technologies, LLC (United States); Robert F. Heeter, Marilyn B. Schneider, Duane A. Liedahl, Theodore S. Perry, Lawrence Livermore National Lab. (United States); Greg S. Dunham, Sandia National Labs. (United States)

The National Ignition Facility (NIF) Opacity Spectrometer (OpSpec) is a modular spectrometer designed initially for opacity experiments on NIF. The design of the OpSpec will be presented in light of the requirements and constraints. Potential dispersing elements and detector configurations will be presented, and the advantages and disadvantages of each configuration will be discussed. The full OpSpec design covers the energy range from approximately 550 eV to 2 keV. The energy resolution of the OpSpec is E/?E > 500. Applications of the OpSpec will be discussed, including relevant astrophysical applications for NIF experiments, and will compliment recently published work on the Z machine. (Bailey, et al., Nature 517, 56-59 (2015).)

This work was done by National Security Technologies, LLC, under Contract No. DE-AC52-06NA25946 with the U.S. Department of Energy.

9591-18, Session 5

Calibration results for first NIF Kirkpatrick-Baez diagnostic

Nicolai F. Brejnholt, Louisa A. Pickworth, Jay J. Ayers, David K. Bradley, Todd A. Decker, Stefan P. Hau-Riege, Randolph M. Hill, Thomas J. McCarville, Tommaso Pardini, Julia K. Vogel, Chris C. Walton, Lawrence Livermore National Lab. (United States)

The Lawrence Livermore National Laboratory (LLNL) has been developing a series of novel x-ray imagers for the National Ignition Facility (NIF) utilizing Kirkpatrick-Baez (KB) geometry. A fully assembled imager contains four KB optic pairs featuring cylindrical mirrors with custom-designed single or multi-layer coatings applied to them. Multiple interchangeable mirror packs have been commissioned for various experimental campaigns, with spatial resolution as low as 5 ?m at the center of the field of view and 12x magnification.

Tight tolerances on the grazing angles of the x-ray mirrors require precision

alignment of each component via a coordinate measuring machine (CMM), and a comprehensive off-line calibration of each optic pair at x–ray wavelengths. The first fully assembled imager is currently being aligned and tested. The main goals of the calibration are to validate the CMM alignment of the optic pairs, and measure the spatial resolution as a function of position in the field of view. Here we report first results of the calibration effort.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. LLNL-ABS-666488

9591-19, Session 5

Determining the diffraction properties of a cylindrically-bent KAP crystal from 1 to 4.5 keV

Michael J. Haugh, National Security Technologies, LLC (United States); Ming Wu, Sandia National Labs. (United States); Kenneth D. Jacoby, Cindy Christensen, National Security Technologies, LLC (United States); Joshua J. Lee, National Security Technologies, LLC (United States) and Sandia National Labs. (United States)

Bent KAP crystals are frequently used in spectroscopic diagnostics for plasma studies on the Z machine at Sandia National Laboratories and the National Ignition Facility at the Lawrence Livermore National Laboratory. For an anisotropic crystal, like KAP, bending the crystal can produce distortions of the planar spacing in other directions. The bending can alter the diffraction properties significantly compared to the corresponding flat crystals. These diffraction properties affect the throughput and the resolving power of the spectrometer. The KAP crystal is a valuable tool for the X-ray spectral energy range from 500 to 5000 eV, and a better understanding of the effect of bending will be valuable to spectrometer designers and users. We have measured reflectivity curves for cylindrically bent KAP crystals for the energy range from 1000 to 5000 eV for bent crystals that range from 5 to 23 cm radii of curvature. The measurements were made using the NSTec dual goniometer X-ray source, with a flat KAP crystal as the monochromator. The method used to analyze the data and the conclusions obtained will be presented.

9591-20, Session 5

Optimizing the input and output transmission lines that gate the microchannel plate in a high-speed x-ray framing camera

John B. Lugten, Charles G. Brown Jr., Bart V. Beeman, Alex A. Lumbard, Fred V. Allen, Douglas R. Kittle, Lawrence Livermore National Lab. (United States)

We present new designs for the launch and receiver boards used in a high speed x-ray framing camera at the National Ignition Facility. The new launch board uses a Klopfenstein taper to match the 50 ohm input impedance to the ~10 ohm microchannel plate. The new receiver board incorporates design changes resulting in an output monitor pulse shape that more accurately reproduces the pulse shape at the input and across the microchannel plate; this is valuable for assessing and monitoring the electrical performance of the assembled framing camera head. The launch and receiver boards maximize power coupling to the microchannel plate, minimize cross talk between channels, and minimize reflections. We discuss some of the design tradeoffs we explored, and present modeling results and measured performance. We also present our methods for dealing with the non-ideal behavior of coupling capacitors and terminating resistors. We compare the performance of these new designs to that of some earlier designs.

9591-21, Session 6

Exploration of high Miller index Ge crystals in flat and bent geometries for imaging high-energy x-rays *(Invited Paper)*

Joshua J. Lee, Michael J. Haugh, Jeffery A. Koch, National Security Technologies, LLC (United States)

Near normal-incidence spherically-bent crystals are used as x-ray imaging optics for a variety of applications at HEDP (high-energy-density physics) facilities worldwide. The combination of constraints from geometric optics, requiring operating near normal incidence, as well as limited inter-atomic spacings, typically at least several angstroms, limits the upper useful energy range to several keV. Accessing energies in excess of 10 keV have been achieved by using higher-order reflections where the 2d lattice spacing happens to match an integral number of wavelengths. We propose using high Miller-index crystals, operated in the first diffraction order, as an alternative to high-order reflections from low Miller-index crystals. We have tested a Ge (15, 7, 7) crystal for integrated reflectivity and will present comparisons of experimental results to theoretical predictions for both flat and cylindrically-bent geometries. This work was done by National Security Technologies, LLC, under Contract No. DE-AC52-06NA25946 with the U.S. Department of Energy.

9591-22, Session 6

Shot-time photography at the National Ignition Facility

Donald R. Jedlovec, Kim Christensen, Lawrence Livermore National Lab. (United States)

The Nation Ignition Facility (NIF) conducts a variety of experiments to study matter at the extremes, including studies of material properties, hydrodynamics, and the interaction of intense radiation fields with matter. The NIF supports the users by operating twenty-four hours a day, with a laser shot rate averages roughly one per day.

We have developed a shot time camera that has the capability to provide an image of each shot for the users. While initially more of promotional tool, recent improvements show potential as a shot diagnostic. The shot time camera is a time integrated, shot- triggered, digital camera that images visible light generated at shot time in the NIF target chamber. It is selectable by the user and operates automatically with the NIF shot cycle. We will discuss the system design, recent results, and plans for the future.

9591-23, Session 6

Precision fabrication of large-area silicon-based geometrically-enhanced x-ray photocathodes using plasma etching

Yekaterina P. Opachich, National Security Technologies, LLC (United States); Ning Chen, Ashwini Gopal, Salah Uddin, Nanoshift, LLC (United States); Eric Huffman, Jeffrey A. Koch, National Security Technologies, LLC (United States); Andrew MacPhee, Lawrence Livermore National Lab. (United States); Terance J. Hilsabeck, General Atomics (United States); Sabrina R. Nagel, Perry M. Bell, David K. Bradley, Otto L. Landen, Lawrence Livermore National Lab. (United States)

Geometrically enhanced photocathodes are currently being developed for use in applications that seek to improve detector efficiency in the visible to X-ray ranges. Various photocathode surface geometries are typically chosen based on the detector operational wavelength region, along with requirements such as spatial resolution, temporal resolution and dynamic

range. Recently, a potential structure has been identified for use in the X-ray region. This anisotropic high aspect ratio structure has been produced in silicon using inductively coupled plasma (ICP) etching technology. The process is specifically developed with respect to the pattern density and geometry of the photocathode chip to achieve the desired sidewall profile angle. The tapered sidewall profile angle precision has been demonstrated to be within ±2.5° for a ~12° wall angle, with feature sizes that range between 4-9 μm in diameter and 10-25 μm depth. Here we present the method used to produce a set of geometrically enhanced high yield X-ray photocathodes in silicon.

9591-24, Session 6

An overview of the Ultrafast X-ray Imager (UXI) program at Sandia Labs

Liam Claus, Lu Fang, Mark W. Kimmel, Joel Long, John L. Porter, Gideon Robertson, Marcos Sanchez, Sandia National Labs. (United States); Douglas Trotter, Douglas Trotter Consulting (United States); Randolph R. Kay, Sandia National Labs. (United States)

The Ultra-Fast X-ray Imager (UXI) program is an ongoing effort at Sandia National Laboratories to create high speed, multi-frame, time gated Readout Integrated Circuits (ROICs), and a corresponding suite of photodetectors to image a wide variety of High Energy Density (HED) physics experiments on both Sandia's Z-Machine and National Ignition Facility (NIF). The program is currently fielding a 1024 x 448 prototype camera with 25 ?m pixel spatial resolution, 2 frames of in-pixel storage and the possibility of exchanging spatial resolution to achieve 4 or 8 frames of storage. The camera's minimum integration time is 2 ns. Minimum signal target is 1500 e- rms and full well is 1.5 million e-. The design and initial characterization results will be presented as well as a description of future imagers.

Conference 9592: X-Ray Nanoimaging: Instruments and Methods II

SPIE. OPTICS+ PHOTONICS OPTICAL ENGINEERING+ APPLICATIONS

Wednesday - Thursday 12–13 August 2015

Part of Proceedings of SPIE Vol. 9592 X-Ray Nanoimaging: Instruments and Methods II

9592-1, Session 1

Science capabilities of the Hard X-ray Nanoprobe (HXN) at NSLS-II *(Invited Paper)*

Yong S. Chu, Hanfei Yan, Xiaojing Huang, Sebastian Kalbfleisch, Evgeny Nazaretski, Nathalie Bouet, Juan Zhou, Li Li, Weihe Xu, Hui Yan, Kenneth Lauer, Kazimierz J. Gofron, Brian Mullany, Dennis Kuhne, James Biancarosa, Michael Maklary, Nikolaos Simos, Brookhaven National Lab. (United States)

The Hard X-ray Nanoprobe (HXN) beamline at the NSLS-II has been designed and constructed to explore new frontier of the x-ray microscopy, by offering a suite of scanning microscopy techniques at an initial spatial resolution of 10 nm. The designed scanning microscopy techniques include x-ray fluorescence, x-ray diffraction, x-ray absorption, x-ray scattering, phase-contrast imaging, spectroscopy, and ptychography. Aggressive R&D on multilayer Laue lens and nanopositioning have resulted in instrument capabilities to focus hard x-rays down to 11 nm and to perform scanning x-ray microscopy experiments with excellent precision. Innovative approaches have been implemented in the beamline design to achieve required stability for x-ray beam and experiment environment. Commissioning measurements provide preliminary evidences that the HXN beamline is performing as designed. Presentation will summarize key instrument designs supporting the science capabilities and commissioning data.

9592-2, Session 1

Fast scanning multi-technique imaging and tomography at Nanoscopium (Synchrotron Soleil)

Andrea Somogyi, Kadda Medjoubi, Gil Baranton, François A. Polack, Jean-Pierre Samama, Synchrotron SOLEIL (France)

The 155 m long Nanoscopium beamline of Synchrotron Soleil is dedicated to scanning multi-technique hard X-ray imaging and tomography. It aims to reach 30-200 nm resolution in the 5-20 keV energy range for routine user experiments. The beamline design tackles the tight stability requirements of such a scanning nano-probe by creating an overfilled secondary source, implementing all horizontally reflecting main beamline optics, applying high mechanical stability equipments and constructing a dedicated high stability building envelope. The beamline aims to provide high sensitivity elemental and sample morphology mapping by fast scanning spectro-microscopy combined with absorption, differential phase contrast and dark field imaging and electron density mapping by coherent imaging techniques.

The typical scientific fields to be covered by the beamline are biology and life sciences, earth- and environmental sciences, geo-biology and bio-nanotechnology. The beamline is especially well suited for studies seeking information about highly heterogeneous systems at multiple length scales also in natural or in operando conditions. In this presentation we report on the optical design of Nanoscopium and the measured operational characteristics. Then we present the proof of principle multimodal fast scanning imaging and 3D tomography experiments performed with ms/pixel dwell time.

9592-3, Session 1

Hard x-ray nanoprobe by Montel KB mirrors at Taiwan Photon Source

Gung-Chian Yin, Shi-Hung Chang, Bo-Yi Chen, Huang-Yeh Chen, Bi-Hsuan Lin, Shao-Chin Tseng, Chien-Yu Lee, Jian-Xing Wu, National Synchrotron Radiation Research Ctr. (Taiwan); Shao-Yun Wu, National Tsing Hua Univ. (Taiwan); Mau-Tsu Tang, National Synchrotron Radiation Research Ctr. (Taiwan)

The hard X-ray nanoprobe beamline at TPS acquires a large numerical aperture by utilizing a pair of diffraction-limited Montel nested Kirkpatrick-Baez mirrors. The beamline, despite with a moderate length of 69 meters, can accordingly achieve similar performances compared to those beamlines longer than 100 meters. The Montel KB mirrors made of silica are places symmetrically with a 45 degrees cut to reduce the gap and unintentional crack between the mirrors. The size and the divergence of the focus spot are simulated to be less than 40 nm and 6.29 mrad, respectively, as the slope errors for the mirrors are expected less than 0.05 ?rad. An ultra precise ten-axis mirror holder is designed and fabricated to meet the critical requirement for the mirror alignment.

The beamline optics, thus designed to take the advantage of the geometry of Motel mirrors, brings about a symmetrical focal spot at the sample. The design feature of the beamline optics includes a horizontal double crystal monochromator, and a two stage horizontally focusing mirrors before the Montel mirrors.

For the endstation, multimodal probes will be provided, including XRF, XAS, XEOL, XRD, CDI, etc. An SEM in close cooperation with laser interferometers is equipped to precisely position the samples and perform the fly scanning. The updated progress of the endstation will be reported in the presentation.

9592-4, Session 1

A next-generation in-situ nanoprobe beamline at the APS MBA lattice

Jörg Maser, Barry Lai, Argonne National Lab. (United States); Mariana Bertoni, Arizona State Univ. (United States); Tonio Buonassisi, Massachusetts Institute of Technology (United States); Si Chen, Lydia Finney, Sophie-Charlotte Gleber, Ross Harder, Curt Preissner, Ruben Reininger, Chris Roehrig, Xianbo Shi, Volker Rose, Deming Shu, David Vine, Stefan Vogt, Argonne National Lab. (United States)

The Upgrade of the Advanced Photon Source's Storage Ring with a multibend achromat (MBA) magnetic lattice will yield a 4th Generation Hard X-ray Synchrotron with massively increased brilliance and source dimensions perfectly suited for nanofocusing and coherent imaging. To exploit the new source's 100x increase in coherent hard x-ray flux and its almost symmetric x-ray shape, we are developing a new flagship hard x-ray microscopy beamline, the In-Situ Nanoprobe (ISN).[1] The ISN is dedicated to the study of materials and devices for generation, storage and transmission of energy, such as photovoltaic systems,[2] batteries[3] and fuel cells. The ISN will provide in-situ and operando characterization of advanced materials and devices under change of temperature, gases, and under applied fields, at

previously unattainable spatial resolution and throughput. The ISN will use nanofocusing mirrors to focus hard x-rays into a probe of as small as 20 nm size. Use of mirror as nanofocusing optics will yield an increase in focused flux to 1.6?1011 Phot/s at 25 keV, into an energy band of ΔE/E = 10-4. The achromatic properties of mirror optics will allow fast spectroscopic studies at very high spatial resolution. To fully exploit the powerful source properties, the ISN beamline will have a length of approximately 180 m. This will yield large working distances of around 50 mm at a resolution of 20 nm, critical to deploying a wide variety of in-situ environments. The combination of very large focused flux and flux density, nano-spectroscopy and large working distance will enable very high-speed scanning of complex materials and devices at physically relevant time scales, and characterization through multidimensional parameter spaces. This will, for example, enable materials discovery and materials or device optimization efforts. To enable the potential of the ISN, the beamline will be designed with view to user friendliness, batch-scan capability and efficiency of operation. We will present the conceptual design of the ISN beamline, and discuss initial studies of advanced photovoltaic systems.

9592-5, Session 1

High-speed x-ray mapping using the FalconX4 at extremely-high count rates

Peter Grudberg, XIA LLC (United States); Paul A. Scoullar, Southern Innovation (Australia)

As synchrotron fluxes continue to increase and the beam spot size decreases at nanoscale beam lines, there is unprecedented need for the ability to perform very high rate X-ray spectroscopy with the ability to do very fast mapping. The FalconX4 (with family members FalconX1 and FalconX8) is the latest of the next generation pulse processors that allow for extremely high throughput while maintaining good resolution; the FalconX4 offers a highly flexibly control architecture that allows for high-speed mapping with a wide range of different detectors and control signals. We present the results of a variety of sample experiments, illustrating what can be done with this new technology.

9592-6, Session 2

Resolution limits of projection x-ray microscopy and tomography

Michael Feser, Carl Zeiss X-ray Microscopy, Inc. (United States)

High-resolution x-ray microscopy can be realized by projection microscopy or by use of x-ray lenses to produce magnified images. Both types of microscopes suffer fundamental and practical limitations to the resolution achievable. Contrary to intuition, the limit to the resolution of both types of microscopes is given by the diffraction limit. In the projection microscope this takes the form of blurring due to propagation Fresnel diffraction. This effect is energy dependent and gets severe at low x-ray energies which are preferred for high-resolution imaging due to the increased contrast. In many practical cases this establishes the resolution limit for projection microscopy. X-ray lens based microscopes on the other hand are limited by the diffraction limit of the optics employed putting more emphasis on the ability of manufacturing these optics. The role of practical limitations such as imaging time and sample working distance to realize tomographic or in-situ imaging are discussed and it is shown that for practical purposes for most cases below one micrometer spatial resolution it is preferable to use a x-ray lens based microscope. The reason for this are the requirement for sufficient sample working distance to carry out measurements and the requirements for practical exposure times to conduct the experiments.

9592-7, Session 2

Development of achromatic full-field hard x-ray microscopy with two monolithic imaging mirrors

Satoshi Matsuyama, Hidetoshi Kino, Shuhei Yasuda, Osaka Univ. (Japan); Yoshiki Kohmura, RIKEN/SPring-8 (Japan); Hiromi Okada, JTEC Corp. (Japan); Tetsuya Ishikawa, RIKEN/SPring-8 (Japan); Kazuto Yamauchi, Osaka Univ. (Japan)

We developed an achromatic and high-resolution full-field hard X-ray microscope based on advanced Kirkpatrick-Baez mirror optics that comprises two monolithic one-dimensional Wolter mirrors. The monolithic imaging mirrors were figured to have an elliptical shape and a hyperbolic shape on a single substrate, which can function as a one-dimensional imaging optics. The monolithic structure of the imaging mirror can make the mirror alignment easy, leading to keep the arrangement very stable. The mirror fabrication was performed with a shape accuracy of 2 nm using our home-built techniques of elastic emission machining (EEM), microstitching interferometry (MSI) and relative-angle-determinable stitching interferometry (RADSI). The constructed microscope consists of a polycapillary lens as a condenser, the imaging mirrors as an objective and a CMOS camera coupled with a phosphor screen and a relay lens. It has a numerical aperture of ~1.5 and magnification of 634x and 195x in vertical and horizontal directions, respectively. The first performance test, in which a Siemens star chart with a 100-nm pattern was observed at an X-ray energy around 10 keV, was performed at BL29XUL of SPring-8. The 100-nm pattern was clearly observed. The contrast analysis revealed that the microscope achieved the spatial resolution less than 100 nm.

9592-8, Session 2

FXI: a full-field x-ray imaging beamline at NSLS-II

Wah-Keat Lee, William Loo, Yong S. Chu, Jun Wang, Richard Gambella, Zhong Zhong, Brookhaven National Lab. (United States); Ruben Reininger, Argonne National Lab. (United States)

The Full Field X-ray Imaging (FXI) beamline at the NSLS-II will enable x-ray microscopy with 30 nm spatial resolution and very high speed image acquisition, using a Transmission X-ray Microscope (TXM). The TXM will operate in the 5-11 keV range and the data collection time for a complete 3D tomographic data set will be < 1 minute. Single image acquisition times will be < 100 ms. The TXM has also been designed with nano-XANES capability, incorporating automated alignment during nano-XANES measurements. The beamline has been designed to tackle the very high power loads from the NSLS-II damping wigglers, with the sole purpose of delivering maximum photon flux for the TXM to enable high speed data acquisition. This paper will discuss the technical details of the FXI beamline.

9592-9, Session 3

Ptychographic x-ray nanotomography at the Swiss Light Source *(Invited Paper)*

Manuel Guizar-Sicairos, Ana Diaz, Mirko Holler, Julio C. da Silva, Oliver Bunk, Andreas Menzel, Paul Scherrer Institut (Switzerland)

Ptychography combines elements of scanning probe microscopy with coherent diffractive imaging and has been developed to be a robust high-resolution imaging technique that finds today applications in X-ray, electron and optical microscopy. It provides reconstructions of the beam and the specimen's complex-valued transmissivity which allows for instance to

fully characterize focused X-ray beams, images with elemental specificity, quantify mixtures of known components, or combine with fluorescence microscopy for complementary imaging contrast.

The extension of ptychography to 3D, often named ptychographic X-ray computed tomography (PXCT), was originally demonstrated at the Swiss Light Source (SLS) in 2010. This technique provides a nanoscale 3D map of the sample's complex-valued refractive index. It is amenable for use with hard X-rays which gives access to the interior of samples with several tens of microns thickness and has great potential for high-resolution due to the high sensitive phase contrast and the small wavelength below 1 nm.

We present here progress in reconstruction and post-processing algorithms as well as implementation and development of dedicated instrumentation for fast and precise 3D scanning at the SLS. Compared to the first demonstration in 2010, such developments have already allowed an improvement of one order of magnitude in resolution and two orders of magnitude in imaging speed. We showcase results of in situ measurements under varying environmental conditions, quantitative imaging of bio-mineralized specimens, frozen hydrated cells, and nanoscale characterization of catalyst materials.

9592-10, Session 3

Development of a soft x-ray ptychography beamline at SSRL and its application in the study of energy storage materials

Anna M. Wise, Hendrik Ohldag, SLAC National Accelerator Lab. (United States); William Chueh, Stanford Univ. (United States); Joshua J. Turner, Michael F. Toney, Johanna L. Nelson Weker, SLAC National Accelerator Lab. (United States)

Ptychography is an emerging high resolution coherent imaging technique which can improve the resolution of scanning transmission X-ray microscopy (STXM) by over ten-fold. Development of this capability is underway at SSRL to establish sub-5 nm resolution in situ ptychography with near-edge X-ray absorption fine structure (NEXAFS) imaging. This is being achieved via an upgrade of the current soft X-ray STXM chamber on beamline 13-1, involving the installation of an area detector and an interferometer system for high precision sample motor control. The undulator source on beamline 13-1 provides the spatially and temporally coherent X-ray beam required for ptychographic imaging in the energy range 500 – 1200 eV. This energy range allows access to the oxygen chemistry and the valence states of 3d transition metals found in energy storage materials, making soft x-ray ptychography a particularly powerful tool to study the chemical states and structure of battery materials at relevant length scales. The implementation of in situ ptychographic imaging can therefore provide a wealth of additional information on battery operation and failure, with measurements possible at comparable imaging resolutions to TEM with a lower radiation dose. The development of this in situ ptychography capability will be described, along with its application to the study of energy storage materials.

9592-11, Session 3

Imaging strain in SiGe thin films at the nanoscale by x-ray Bragg ptychography

Wen Hu, Xiaojing Huang, Brookhaven National Lab. (United States); Conal E.. Murray, IBM Thomas J. Watson Research Ctr. (United States); Zhonghou Cai, Argonne National Lab. (United States); Evgeny Nazaretski, Yong S. Chu, Brookhaven National Lab. (United States); Hanfei Yan, National Synchrotron Light Source II, Brookhaven National Lab. (United States)

Strain is known to play a crucial role in determining the performance of semiconductor devices, thereby the control of strain is a key issue in their design and fabrication. Conventional x-ray diffraction techniques, although capable of measuring strain at very high accuracy, do not offer the spatial resolution needed for microelectronics. X-ray Bragg ptychography is a new emerging technique to image strain noninvasively in an extended crystalline specimen with a resolution better than the beam size of the x-ray probe, ultimately enabling a 3D strain measurement at the nanoscale. In this work, we present a theoretical study on the effects of partial coherence, the overlap ratio and position uncertainty in Bragg Ptychography, using synthetic data generated from forward simulation. The convergence of the reconstruction and the detection sensitivity of the strain field under various conditions are discussed. We also report a Bragg Ptychography experiment on a SiGe thin film feature for 3D strain reconstruction by performing spiral 2D scans at different rocking angles. Reconstructed strains are compared to previously reported values and results obtained from theoretical modeling. Issues and challenges in the reconstruction are discussed as well.

9592-29, Session 3

Fast strain mapping of nanoLED devices using nano-focused x-ray beams

Tomas Stankevic, Univ. of Copenhagen (Denmark); Dmitry Dzhigaev, Max Rose, Anatoly Shabalin, Deutsches Elektronen-Synchrotron (Germany); Zhaoxia Bi, Lund Univ. (Sweden); Juliane Reinhardt, Deutsches Elektronen-Synchrotron (Germany); Anders Mikkelsen, Lars Samuelson, Lund Univ. (Sweden); Gerald Falkenberg, Ivan A. Vartanyants, Deutsches Elektronen-Synchrotron (Germany); Robert K. Feidenhans'l, Univ. of Copenhagen (Denmark)

Strain engineering applied on the semiconductor core-shell nanowires opens new possibilities in the fields of solid state lightning and nanoelectronics. Better elastic strain relaxation in 3D geometry allows growing heterostructures of lattice mismatched materials without introducing misfit dislocations. It is crucial to be able to measure local strain variations in each individual nanodevice with nanometer resolution. X-rays are the only tool that provides such possibility and can be used on the samples thicker than 200 nm. In this paper we show results of the nanoscale strain mapping performed on a single, 400 nm thick and 2μm long core-shell InGaN/GaN nanowire. The thickness of the shell with 30% In concentration was 25 nm thick, which highly exceeds the critical dimensions for such heterostructure and thus both plastic and elastic strain relaxation was expected. We scanned the sample with 40 nm steps in the X-ray beam, focused down to 100 nm at full width at half maximum. At each step diffraction pattern was measured, which contained signals from the core and the shell of the nanowire. By measuring positions of the Bragg peaks we were able to extract local strain and tilt of the crystal planes. We observed inhomogeneous strain distribution caused by the asymmetric strain relaxation of the InGaN shell. One side of the shell was still fully strained with respect to the core, while the other was nearly fully relaxed. Moreover, large tilt and strain gradients were seen at the interface with the substrate.

9592-13, Session 4

Progress on multi-order hard x-ray imaging with multilayer zone plates *(Invited Paper)*

Markus Osterhoff, Christian Eberl, Robin Wilke, Jesper Wallentin, Florian Döring, Hans-Ulrich Krebs, Georg-August-Univ. Göttingen (Germany); Michael Sprung, Deutsches Elektronen-Synchrotron (Germany); Tim Salditt, Georg-August-Univ. Göttingen (Germany)

Today's technical developments and challenges often involve particles and phaenomena on the nano metre scale. In the field of x-ray imaging, a wide variety of techniques has been developed to gather highly resolved data on shape, density distribution, local order, or x-ray induced changes in the

sample. While techniques like ptychography overcome the resolution limit on beam size, other contrast mechanisms like fluorescent maps, local stimuli, or nano-diffraction are limited by the quality and size of the probing beam.

We present our latest results in hard x-ray imaging using multilayer zone plates (MZPs) that can focus down well below 10?nm in two dimensions. A combined optics set-up constisting of prefocusing optics (by, e.g., Kirkpatrick-Baez mirrors or compound refractive lenses) that adapt the coherence area of synchrotron radiation (depending on beamline and energy, about 50 to 500?micro metre) to the MZP diameter, about 1.5 to 15?micro metre in our case.

With the experience of first imaging experiments using high-resolution MZPs at 18?keV, we identify and tackle challenges in the experimental set-up and the imaging experiment itself. The experimental side is accompanied by recent developments in data analysis methods.

M. Osterhoff et al., J. Appl. Crystallogr. (accepted, 2015)

9592-14, Session 4

High-resolution high-efficiency multilayer Fresnel zone plates for soft and hard x-rays

Umut T. Sanli, Kahraman Keskinbora, Corinne Grévent, Max-Planck-Institut für Intelligente Systeme (Germany); Keith Gregorczyk, CIC nanoGUNE Consolider (Spain); Mato Knez, CIC nanoGUNE Consolider (Spain) and IKERBASQUE, Basque Foundation for Science (Spain); Gisela Schütz, Max-Planck-Institut für Intelligente Systeme (Germany)

X-ray microscopy enables high spatial resolutions, high penetration depths and characterization of a broad range of materials. Calculations show that nanometer range resolution is achievable in the hard X-ray regime by using Fresnel zone plates (FZPs) if certain conditions are satisfied. However, this requires, among other things, aspect ratios of several thousands. The multilayer (ML) type FZPs, having virtually unlimited aspect ratios, are strong candidates to achieve single nanometer resolutions. Our research is focused on the fabrication of ML-FZPs which encompasses deposition of multi-layers over a glass fiber via the atomic layer deposition (ALD), which is subsequently sliced in the optimum thickness for the X-ray energy by a focused ion beam (FIB). We recently achieved aberration free imaging with an efficiency of up to 12.5 % and resolved 21 nm features. This is the highest imaging resolution achieved by an ML-FZP. We also showed efficient focusing of 7.9 keV X-rays down to 30 nm focal spot size (FWHM). For resolutions below ~10 nm, efficiencies would decrease significantly due to wave coupling effects. To compensate this effect high efficiency, low stress materials have to be researched, as lower intrinsic stresses will allow fabrication of larger FZPs with higher number of zones, leading to larger light collecting area. As a first step we fabricated an ML-FZP with a diameter of 62 μm, an outermost zone width of 12 nm and over 400 active zones. Further strategies for fabrication of high resolution high efficiency multilayer FZPs will also be discussed.

9592-15, Session 4

Stacking multiple zone plates for efficient hard x-ray focusing at the Advanced Photon Source

Michael Wojcik, Sophie-Charlotte Gleber, Deming Shu, Christian Roehrig, Barry Lai, David J. Vine, Stefan Vogt, Argonne National Lab. (United States)

Zone plates are diffractive focusing optics capable of nanometer focusing but limited focusing efficiency at hard x-ray energy. A smaller focus spot is possible by reducing the outer zone width (OZW) while increasing the zone height will generally increase focusing efficiency. The combination of thick zones with small outer zone width, or high aspect ratio, for better performing zone plates is not feasible with state-of-the-art fabrication methods and requires other methods to achieve the aspect ratio desired.

Near field stacking involves two zone plates with the same dimensions and aligning them within the depth of focus in the beam direction and one third of the OZW in the transverse direction. Due to the depth of focus limitation, stacking more than 2 zone plates is extremely difficult, so a new method was proposed and developed to stack zone plates in the intermediate field. Zone plates were designed for intermediate field stacking and fabricated. Multiple stacking apparatuses were assembled and tested. We will report on results from stacking up to 6 zone plates with sub-100-nm OZW, e.g. 28% focusing efficiency at 27 keV x-ray energy, as well as applications using the stacking apparatus.

This research used resources of the Advanced Photon Source and Center for Nanoscale Materials, U.S. Department of Energy (DOE) Office of Science User Facilities operated for the DOE Office of Science by Argonne National Laboratory under Contract No. DE-AC02-06CH11357.

9592-16, Session 4

Fabrication and x-ray testing of true kinoform lenses with high efficiency

Kahraman Keskinbora, Umut T. Sanli, Corinne Grévent, Gisela Schütz, Max-Planck-Institut für Intelligente Systeme (Germany)

Fresnel zone plates have been very successful in focusing of X-rays enabling high resolution X-ray microscopy. However, FZPs are limited to a theoretical maximum of 40 % diffraction efficiency and in practice much less efficient than this. However, a refractive/diffractive optical device with a three dimensional surface structure called the kinoform lens enables focusing X-rays with a theoretical diffraction efficiency of 100 %. The fabrication of kinoform type lenses have been pursued by utilizing step-approximated geometries via gray scale optical lithography or overlay electron lithography among other methods, while the realization of true continuous kinoform surface remained elusive. Recently, we have succeeded in fabricating true kinoforms with an effective gray scale ion beam lithography route. The fabricated kinoforms showed high focusing efficiencies (>14 % absolute and ~ 90 % relative) and were used for imaging in a scanning soft X-ray microscope. Results demonstrate that almost ideal kinoform profile was achieved through this process and the efficiency was dominated by absorption of soft X-rays which was used for testing. Efficiency calculations show that the kinoforms can reach very high efficiencies at EUV and hard X-ray energies. Especially in the hard X-ray range where the absorption is low kinoforms can in principle achieve tremendous focusing efficiencies when the material constraints are satisfied. We also discuss, the prospects and challenges of kinoform lenses including materials issues and micro-structural design, efficiency considerations at low and high energies and possible applications as focusing optics in laboratory sources where efficiency is crucial.

9592-26, Session PWed

Extending x-ray imaging with current nanofabrication techniques for fabrication of high-yield Fresnel zone plate optics

Robert Peters, Mirwais Aktary, Luis Gutierrez-Rivera, Cameron Horvath, Applied NanoTools Inc. (Canada)

Advances in sources for x-ray nanoimaging have led to an increased demand for focusing optics that can provide both nanoscale resolution and high efficiency. Nanofabrication challenges in producing x-ray optics are one of the limitations in furthering the widespread reception of x-ray nano-imaging. Fresnel zone plates in particular, due to the requirements for nanoscale features with high aspect ratios on nano-thin membranes, can suffer from low yield, high-costs, and short lifetimes, especially for hard x-ray designs. We demonstrate a fabrication process that allows

for the production of low-cost, high yield, and increased-lifetime zone plates. Diffraction efficiency experiments have been shown to provide near theoretical efficiency for the first order along with high resolution imaging. A several micrometer thick gold central stop process also significantly improves contrast in imaging by limiting the 0th order light, while adding structural integrity to the fragile membrane without additional film stress, reducing the risk of damaging the optics during handling and imaging. Nanofabrication methods, including cold development with vibration regulation, and anti-charging films have extended the normal capabilities of traditional nanofabrication of Fresnel zone plates. These techniques have allowed the fabrication of zone plates with high resolution for soft to hard x-ray imaging. Work involving state-of-the art reactive ion etching to further increase the aspect ratio for 20 keV energies and above is also presented.

9592-27, Session PWed

High-resolution strain mapping of single nanowires with x-ray Bragg ptychography

Dmitry Dzhigaev, Deutsches Elektronen-Synchrotron (Germany); Tomas Stankevic, Univ. of Copenhagen (Denmark); Zhaoxia Bi, Lund Univ. (Sweden); Max Rose, Anatoly Shabalin, Juliane Reinhardt, Deutsches Elektronen-Synchrotron (Germany); Anders Mikkelsen, Lund Univ. (Sweden); Ulf Lorenz, Univ. Potsdam (Germany); Ruslan Kurta, European XFEL GmbH (Germany); Andrei Singer, Univ. of California, San Diego (United States); Frank Seiboth, Technische Univ. Dresden (Germany); Lars Samuelson, Lund Univ. (Sweden); Christian G. Schroer, Deutsches Elektronen-Synchrotron (Germany); Robert Fedenhans'l, Univ. of Copenhagen (Denmark); Ivan A. Vartanyants, Deutsches Elektronen-Synchrotron (Germany)

Strain analysis at the nanoscales is crucial for understanding physical, electrical, and photonic properties and fabrication processes of crystalline structures such as nanowires. For structural studies we considered individual nanowires. These were InP nanowire with applications in solar cells technology and core-shell GaN/InGaN nanowire with applications in light emitting diodes. Diameters of investigated samples were 100 nm and 400 nm, respectively.

Recently developed X-ray Bragg ptychography technique allows reconstruction of the crystal displacement field from coherently scattered intensities by solving the phase problem iteratively. Bragg ptychography experiments were performed at P06 nanoprobe end-station of PETRA III synchrotron source. By using X-ray nano-beam with the size below 100 nm (FWHM) it was possible to map quantitatively the internal strain field of a single InP and GaN/InGaN core-shell nanowires without destructive sample preparation.

Our results show inhomogeneous strain distribution in the core of the NW, which is caused by asymmetric strain relaxation in the shell. Finite Element Model (FEM) simulations based on the elasticity theory were performed in order to ensure the reliability of experiments. Values and profiles of the strain field from FEM simulations are consistent with the experimental results.This technique permitted a non-destructive determination of strain with a spatial resolution better than 20 nm.

Presented results extend the possibilities of nano-crystals in situ characterization in order to improve the efficiency of fabrication and performance of the future nanowire-based devices.

9592-28, Session PWed

Transmission x-ray microscopy at Diamond Light Source I13 Beamline

Joan Vila Comamala, Diamond Light Source Ltd. (United Kingdom); Jeroen Borgra, Paul Scherrer Institut (Switzerland); David S. Eastwood, The Univ. of Manchester (United Kingdom) and Research Complex at Harwell (United Kingdom); Ulrich H. Wagner, Andrew J. Bodey, Miryam Garcia-Fernandez, Diamond Light Source Ltd. (United Kingdom); Christian David, Paul Scherrer Institut (Switzerland); Christoph Rau, Diamond Light Source Ltd. (United Kingdom)

To date, full-field Transmission X-ray Microscopy (TXM) has shown to be a powerful method for obtaining quantitative internal structural and chemical information from materials at the nanoscale. The installation of a full-field TXM station will extend the current microtomographic capabilities of Diamond-Manchester BL-I13 Beamline Imaging Branch at Diamond Light Source into the sub-100 nm spatial resolution range using photon energies from 8 to 15 keV. Preliminary full-field TXM experiments demonstrate a spatial resolution of about 50 nm in both transmission and Zernike phase contrast modes at 8.3 keV photon energy. The tomographic capabilities using Zernike phase contrast were tested using a Nickel particle from a solid oxide fuel cell (courtesy of R. Bradley, University of Manchester) and the fibres of a coir-based supercapacitor material (courtesy of C. P. Gray and N. Trease, University of Cambridge). The dedicated Full-Field TXM station will be built in-house with the contributions of Diamond Light Source support divisions in collaboration of the X-ray Optics Group of the Paul Scherrer Institut (Switzerland) developing state-of-the-art diffractive X-ray optical elements. The full-field TXM will become an important direct imaging asset for material science, energy science and biology at the nanoscale at the Diamond Light Source.

9592-30, Session PWed

Fly-scan ptychography

Junjing Deng, Northwestern Univ. (United States); Youssef S. G. Nashed, Si Chen, Argonne National Lab. (United States); Nicholas W. Phillips, La Trobe Univ. (Australia); Tom Peterka, Rob Ross, Stefan Vogt, Argonne National Lab. (United States); Chris J. Jacobsen, Northwestern Univ. (United States); David J. Vine, Argonne National Lab. (United States)

Ptychography is a coherent diffraction imaging method which offers powerful tools to image extended objects at a spatial resolution limited only by the scattering strength of the object and the detector geometry. Most ptychography experiments to date employ a move-settle-measure mode for data acquisition, which is often referred as step-scan mode. In this mode, data acquisition can be very slow when the move and settle steps take longer to complete than the measure step. We describe here the use of a continuous "fly-scan" mode for ptychographic data collection in which the sample is moved continuously for fast scan, while multiple probe mode reconstruction methods are used to obtain the sample complex transmission function as well as the illumination functions. We show in simulations, and in x-ray imaging experiments, some of the characteristics of fly-scan ptychography, including the reduction in the data acquisition time. This approach will become increasingly important as brighter x-ray sources are developed, such as diffraction limited storage rings.

9592-31, Session PWed

Layer tilt analyses of MLLs using diffraction efficiency versus rocking angle for defect mapping

Adam Kubec, Fraunhofer IWS Dresden (Germany) and Argonne National Lab. (United States); Raymond Conley, Argonne National Lab. (United States) and Brookhaven National Lab. (United States); Nathalie Bouet, Hanfei Yan, Juan Zhou, Brookhaven National Lab. (United States);

Albert T. Macrander, Jörg Maser, Argonne National Lab. (United States)

With new and improved fabrication of Multilayer Laue lenses (MLL) analyses of these structures becomes more important to identify remaining challenges in the fabrication. This is especially necessary when large aperture and wedged MLLs are introduced as their fabrication must meet increasingly stringent precision requirements.

We have developed a method to quantitatively determine defects in an MLL structure such as local bending, twisting, possible discontinuities, or local delamination. Using Coupled-Wave-Theory, we calculated expected diffraction patterns for a particular lens. These are then compared to measured diffraction data. The results show absolute bending in a lens structure, where the resolution is only limited by instrumentation parameters. We used a representation of the data, where diffracted intensity is shown as a function of the rocking angle.

9592-32, Session PWed

MAPStoTomoPy: a workflow for synchrotron-based fluorescence tomography

Young Pyo Hong, Northwestern Univ. (United States); Si Chen, Advanced Photon Source, Argonne National Lab. (United States); Chris Jacobsen, Northwestern Univ. (United States) and Advanced Photon Source, Argonne National Lab. (United States)

Analyzing fluorescence tomographic data aquired from 2IDE and BioNanoprobe(BNP) was rather complex and time-consuming. One had to collect per-pixel-fitted data from MAPS, align the dataset respect to common rotation axis, do the reconstruction, and attain visualization of the data. There was no dedicated program for the dataset from the beamlines. Moreover, most of the users of beamlines are experts on their fields but had a little knowledge about 3d reconstruction. Thus, users had to wait for beamline scientists to analyzing 3d tomographic data while beamline scientists other workloads. Consequently, we developed a program, MapsToTomoPy, that provides a workflow from image registration to reconstruction.

The program would take an output of MAPS as an input and generates slices of a reconstructed 3d image by utilizing TomoPy. While some users of the beamlines are also interested in the process of image registration and reconstruction, most of users are interested in reconstructed data rather than the process. The goal of the program is to provide a comprehensive 3d tomographic data analyzing tool even for the users with a little knowledge of how image registration and/or reconstruction works.

9592-33, Session PWed

Refractive lens-based full-field x-ray imaging at 50 keV with sub-micron resolution

Sarvjit D. Shastri, Peter Kenesei, Argonne National Lab. (United States); Robert M. Suter, Carnegie Mellon Univ. (United States)

Combining sub-micron resolution imaging with the penetration property of high-energy x-rays (> 50 keV) offers numerous applications, such as the ability to examine cracks and voids associated with the onset of failure in engineering materials. Progress on the development of this method at the Advanced Photon Source beamline 1-ID is reported. A tested configuration having approximately 20x imaging magnification with compound refractive lenses placed 1.7 m after the specimen, and a two-dimensional detector located 32-37 m further downstream, gave sub-micron resolution with 50 keV x-rays. The subsequent goal of achieving tomographic capability, while compacting the full set-up to a more practical length of a few meters, is discussed.

9592-17, Session 5

Simultaneous x-ray nano-ptychographic and fluorescence microscopy at the bionanoprobe *(Invited Paper)*

Si Chen, Argonne National Lab. (United States); Junjing Deng, Northwestern Univ. (United States); David J. Vine, Youssef Nashed, Argonne National Lab. (United States); Qiaoling Jin, Northwestern Univ. (United States); Stefan Vogt, Argonne National Lab. (United States); Chris J. Jacobsen, Argonne National Lab. (United States) and Northwestern Univ. (United States)

Hard x-ray fluorescence microscopy (XFM) offers unparalleled sensitivity for quantitative analysis of most of the trace elements in biological samples, such as Fe, Cu, and Zn. These trace elements play critical roles in many biological processes. With the advanced nano-focusing optics, nowadays one can focus hard x-rays down to 30 nm or below and probe the trace elements within subcellular compartments. However, XFM does not usually show much ultrastructural information, because main constituents of biomaterials, i.e. H, C, N, and O, have low fluorescence yield and little absorption contrast at multi-keV x-ray energies. An alternative technique for imaging ultrastructure is ptychography. One can record diffraction patterns from a coherently-illuminated sample, and then reconstruct the complex transmission function of the sample. In theory the spatial resolution of ptychography can reach the wavelength limit. In the presentation, we will describe the implementation of ptychography at the Bionanoprobe (a recently development hard x-ray fluorescence nanoprobe at the Advanced Photon Source) and demonstrate simultaneous ptychographic and fluorescence imaging of a frozen green algae cell. This method allows one to locate trace elements within the ultrastructure of biological samples with high spatial resolution. Additionally, both ptychography and fluorescence are compatible with tomographic approach for 3D imaging.

9592-18, Session 5

The hard x-ray nanoprobe beamline and electron microscopy facility at Diamond

Paul Quinn, Julia Parker, Fernando Cacho-Neri, Andrew Peach, Guy Wilkin, Diamond Light Source Ltd. (United Kingdom)

Diamond is currently constructing a new microscopy and imaging facility which will house a hard X-ray nanoprobe beamline (I14) and a new electron microscopy facility.

The I14 nanoprobe beamline is a 185m long beamline which will use a nanofocussing KB system with cryogenic sample handling capabilities for 2D and 3D scanning X-ray fluorescence, X-ray spectroscopy and imaging applications in a range of areas.

The microscopy centre provide 4 electron microscope suites which serve two facilities:

The Electron imaging centre for biology which will provide two cryo electron microscopes and offer single particle analysis of biological macromolecules and cellular tomography, as well as electron crystallography. These techniques will complement the atomic mapping possible with the macromolecular crystallography beamlines, the elemental mapping in cells provided by the X-ray nanoprobe and the larger scale cell imaging capability of the new Full Field Cryo Transmission X-ray Microscope (B24 cryo-TXM). In addition the facility will provide extensive range of cryogenic sample preparation tools.

The Electron microscopy centre for physical sciences which will be used look at the ordering and chemical state of atoms in the sample, through EDX, EELS, atomic scale imaging, and electron diffraction and should also compliment the nanoprobe beamline.

This facility combines staff and expertise from a number of different areas which we believe we will allow us to make exciting progress in correlative

x-ray, optical and electron microscopy studies. Details of the facilities and plans for correlative experimental studies will be discussed.

9592-19, Session 5

Development of differential analysis techniques for multivariate imaging data analysis

Zhonghou Cai, Argonne National Lab. (United States)

Recent technological advances in X-ray detectors and diffraction limited synchrotron storage ring will allow the chemical element, structure, and energy state of a material to be imaged through fast X-ray microscopy with fluorescence emission, diffraction, and spectroscopy. It is anticipated that the fast X-ray microscopy will particularly enable imaging studies of heterogeneous materials that often are of multi-element, multi-phase, and multi-energy state and are complex spatially and compositionally. Once merging multimodal imaging data across various contrasts, the dimension of the imaging variable space increases quickly. When the variances of the imaging variables are widely dispersed, the degree of the image complexity will be beyond the processing capability of a human brain through visual recognition of features. This poses a great challenge on analyzing and extracting scientific information from multivariate imaging data. We are developing at the Advanced Photon Source multivariate descriptive statistical analysis tools that hierarchically differentiate image pixels based on their composition in the multivariable space and differentiate imaging variables based on their associations with principal components along which the image pixels exhibit statistically significant variances. These numerical methods can sensitively summarize all meaningful composition features in images with the level of differentiation controllable to as small as that of noise and reveal inherent relations among imaging variables of elemental contents, phases concentrations, and energy states. Since it imposes no limitation in the dimension of the variable space, the developed tools are particularly suited for data analysis across different imaging platforms. We will present the differential analysis method, demonstrate its applications, and discuss the direction of future development.

9592-20, Session 5

Chemical speciation imaging at environmentally-relevant concentrations using x-ray fluorescence microscopy

David J. Paterson, Daryl L. Howard, Martin D. de Jonge, Kathryn M. Spiers, Australian Synchrotron (Australia); Chris G Ryan, Robin Kirkham, CSIRO (Australia); Barbara E. Etschmann, Monash Univ. (Australia); Enzo Lombi, Erica Donner, Univ. of South Australia (Australia); Peter M. Kopittke, The Univ. of Queensland (Australia)

X-ray fluorescence microscopy (XFM) can be used for elemental and chemical microanalysis across length scales ranging from millimeter to nanometer. XFM is ideally suited to quantitatively map trace elements within whole plant and other biological specimens, environmental and soil samples. The elemental sensitivity of the X-ray fluorescence probe provides valuable information for investigations in a diversity of environmental sciences, and the high penetration of hard X-rays enables measurement of whole cells and tissue sections with a minimum of preparation.

Advances in X-ray fluorescence detection methods such as the Maia detector now enable high definition images at mega-pixel per hour rates. The ability to rapidly acquire 2D images enables 3D information such as fluorescence tomography to be obtained in realistic times. Chemical speciation (valence) imaging (CSI) is a 3D technique where the third dimension is spectroscopic detail. CSI produces an X-ray Absorption Near Edge Structure (XANES) spectra from the X-ray fluorescence signal at each pixel in the spatial image. Fitting of spectra with incident X?ray beam energy tracking has been developed in GeoPIXE software using the Dynamic Analysis method.

CSI has been demonstrated at the Australian Synchrotron XFM beamline with micron resolution and moderate definition (10K pixels) across a diverse range of sciences and applications from environmental chemistry to arsenic toxicity in crop production. Recent studies probing and optimising the efficiency and sensitivity of the CSI technique to achieve measurements at environmentally relevant concentrations will be presented.

9592-25, Session 5

Nano Investigator: a versatile tool for nm-scale spatial resolution x-ray imaging with MLL nanofocusing optics

Evgeny Nazaretski, Brookhaven National Lab. (United States)

The Hard X-ray Nanoprobe (HXN) beamline at the NSLS-II has been designed and constructed to address questions related to scientific and technological challenges at the nm-scale. The HXN X-ray Microscope is a key instrument for the beamline, providing a suite of experimental capabilities which includes scanning fluorescence, diffraction, differential phase contrast and ptychography utilizing Multilayer Laue Lenses (MLL) and zoneplate (ZP) as nanofocusing optics. To enable higher impact and explore the phase space in materials research studies, the instrument is equipped with a temperature regulation system capable of varying specimen temperature between 100 K and 1000 K. During this presentation, different phases of the x-ray microscope development process will be discussed, various prototype systems designed and constructed will be reviewed. Preliminary data demonstrating nm-scale spatial resolution imaging using MLL optics will be presented.

9592-21, Session 6

Chemical and tomographic microscopy of energy materials in action *(Invited Paper)*

Johanna L. Nelson Weker, Yijin Liu, Joy C. Andrews, SLAC National Accelerator Lab. (United States)

Using the rapid imaging rate and penetrative power of full-field hard X-ray transmission microscopy (TXM), we are able to track morphological [1] and chemical [2] changes of energy materials under realistic conditions. High resolution, in situ microscopy allows the visualization of dynamic systems in time, capturing a wealth of information inaccessible to ex situ imaging methods. In situ TXM is fundamental to understanding of the standard operation and failure mechanisms of energy materials such as catalysts and battery electrodes, as well as the nucleation and growth of nanostructures, which directly affect the properties of the final structure. In addition to in situ microscopy, energy materials benefit greatly from mapping elemental and chemical information in 3D. By mapping this information, the surface chemistry, which often dominates the functionality of these materials, can be visualized and understood.

We will discuss recent results on battery electrodes tracking the morphological and chemical changes in 2D and density and volume changes in 3D. Additionally, we will present and discuss results on visualizing the nucleation and growth of nanostructures with unique electrical, optoelectronic and luminescent properties. Finally we will show our latest results of in situ and ex situ imaging on catalytic materials used in petroleum refinery.

9592-22, Session 6

Synchrotron-based transmission x-ray microscopy for improved extraction in shale during hydraulic fracturing

Andrew M. Kiss, Adam D. Jew, Stanford Synchrotron Radiation Lightsource (United States); Claresta Joe-Wong, Stanford Univ. (United States); Kate M. Maher, Yijin Liu, Gordon E. Brown, John Bargar, Stanford Synchrotron Radiation Lightsource (United States)

Engineering topics which span a range of length and time scales present a unique challenge to researchers. Hydraulic fracturing (fracking) of oil shales is one of these challenges and provides an opportunity to use multiple research tools to thoroughly investigate a topic. Currently, the extraction efficiency for hydrocarbons from source rock is low but can be improved by carefully studying the processes at the micro- and nano-scale. Fracture fluid induces chemical changes in the shale which can have significant effects on the microstructure morphology, permeability, and chemical composition. These phenomena occur at length scales from nanometer to hundreds of microns and times from days to months which require different instrumentation to properly study. Synchrotron-based techniques such as fluorescence tomography provide high sensitivity elemental mapping and an in situ micro-tomography system records morphological changes with time. Since typical pores sizes can be less than 100 nm, the transmission X-ray microscope (TXM) at the Stanford Synchrotron Radiation Lightsource (SSRL) beamline 6-2 is utilized to collect a nano-scale three-dimensional representation of the sample morphology with elemental and chemical sensitivity. We present the study of model shale system containing quartz and pyrite, in which particles are mixed and exposed to oxidizing solution, to establish the basic understanding of the more complex geology-relevant oxidation reaction. The spatial distribution of the production of the oxidation reaction, ferrihydrite, is retrieved via full-field XANES tomography showing the reaction pathway. Further correlation between the high resolution TXM data and the high sensitivity micro-probe data provides insight into potential morphology changes which can decrease permeability and limit hydrocarbon recovery.

9592-23, Session 6

Magnetic contrast nanotomography

Robert P. Winarski, Argonne National Lab. (United States)

We are using the X-ray polarization selectivity (linear, right and left circularly polarized) available at the Hard X-ray Nanoprobe Beamline to examine magnetic materials in three dimensions using magnetism as a contrast mechanism [1,2,3]. X-ray magnetic circular dichroism (XMCD) refers to the differential absorption of left and right circularly polarized (LCP and RCP) X-rays, induced in a sample by an applied magnetic field. By closely analyzing the difference in the XMCD absorption spectra, information can be obtained on the magnetic properties of the elements in the system, such as spin and orbital magnetic moments. Differences in the near-edge X-ray absorption spectra are proportional to the differences in spin densities of the unoccupied electron bands in the sample. We are measuring these differences in absorption contrast while controlling the polarization during nanotomography acquisition.

9592-24, Session 6

X-ray microscopy for in situ characterization of 3D microstructure evolution in the laboratory

Benjamin Hornberger, Hrishikesh Bale, Arno Merkle, Michael Feser, William Harris, Carl Zeiss X-ray Microscopy, Inc. (United States)

X-ray microscopy (XRM) has emerged as a powerful technique that reveals 3D images and quantitative information of interior structures. XRM executed both in the laboratory and at the synchrotron have demonstrated critical analysis and materials characterization on meso-, micro-, and nanoscales, with spatial resolution down to 50nm in laboratory systems. The non-destructive nature of X-rays has made the technique widely appealing, with potential for “4D” characterization, delivering 3D micro- and nanostructural information on the same sample as a function of sequential processing or experimental conditions. Understanding volumetric and nanostructural changes, such as solid deformation, pore evolution, and crack propagation are fundamental to understanding how materials form, deform, and perform. We will present recent instrumentation developments in laboratory based XRM including a novel in situ nanomechanical testing stage. These developments bridge the gap between existing in situ stages for micro scale XRM, and SEM/TEM techniques that offer nanometer resolution but are limited to analysis of surfaces or extremely thin samples whose behavior is strongly influenced by surface effects. Several applications will be presented including 3D-characterization and in situ mechanical testing of polymers, metal alloys, composites and biomaterials. They span multiple length scales from the micro- to the nanoscale and different mechanical testing modes such as compression, indentation and tension.

Conference 9593: Hard X-Ray, Gamma-Ray, and Neutron Detector Physics XVII

SPIE. OPTICS+ PHOTONICS OPTICAL ENGINEERING+ APPLICATIONS

Monday - Wednesday 10–12 August 2015

Part of Proceedings of SPIE Vol. 9593 Hard X-Ray, Gamma-Ray, and Neutron Detector Physics XVII

9593-1, Session 1

Physics of spectral resolution in gamma-ray scintillator detectors *(Invited Paper)*

Stephen A. Payne, Nerine J. Cherepy, Steven L. Hunter, Erik L. Swanberg, Patrick R. Beck, Zachary M. Seeley, Lawrence Livermore National Lab. (United States)

For scintillators, the fundamental limit to achieving better spectral resolution is due to the so-called nonproportionality. To understand this limit better, we have recorded hundreds of curves of the light yield against the energy of a single high-energy electron injected into the scintillator (using an instrument known as SLYNCI). By employing this single high-energy electron we are able to measure and model the interplay between the electron stopping behavior (which mediates the initial carrier concentration) and the subsequent dynamics where the electrons and holes can form excitons, annihilate or be trapped, and can be captured by activators to lead to luminescence. Scintillators including binary halides and oxides and ternary compounds have been characterized, as well as organics (crystals, liquids, plastics). Further studies of the impact of codopants, temperature variation and atmospheric processing conditions have been conducted. These experimental data have been modeled to fit the light yield curves versus the electron energy and to predict the resolution. We also attended to the formation of delta-rays, resulting from high-energy collisions between electrons, and to the initial distribution of electrons (rather than a single electron) arising from gamma excitation of scintillators (i.e. from photoelectric absorption and Compton scattering). We compare the gamma and electron nonproportionality curves, as well as their measured and predicted values of resolution.

9593-2, Session 1

Co-doping effects in halide scintillators: density-functional calculations

Koushik Biswas, Arkansas State Univ. (United States); Richard T. Williams, Wake Forest Univ. (United States)

Understanding the behavior of dopants and codopants and their consequences on material properties is an important area in scientific research. Recently aliovalent doping or codoping of activated scintillator crystals has generated substantial interest. Some scintillators showed remarkable improvement in energy resolution e.g., LaBr3:Ce (Sr, Ca), while others did not produce desired outcome, SrI2:Eu (La). We report our density functional theory based studies of codoping in scintillator materials and their interactions with other defect centers.

9593-3, Session 1

Linearity response of Ca2+-doped CeBr3 as a function of gamma-ray energy

Paul P. Guss, National Security Technologies, LLC (United States); Michael E. Foster, Sandia National Labs. (United States); Bryan M. Wong, Univ. of California, Riverside (United States); F. P. Doty, Sandia National Labs. (United States); Kanai S. Shah, Michael R. Squillante, Urmila Shirwadkar, Rastgo Hawrami, Joshua P. Tower, Radiation Monitoring Devices, Inc. (United States); Thomas G. Stampahar, Sanjoy Mukhopadhyay, National Security Technologies, LLC (United States)

An aliovalently calcium-doped cerium tribromide (CeBr3:Ca2+) crystal was prepared with a gamma-energy resolution (FWHM) of 3.2% at the 137Cs 662 keV gamma energy. We completed a crystal assessment and calculated the predictive performance and physical characteristics using density functional theory (DFT) formalism. Detector performance, characteristics, calcium doping concentration, and crystal strength are reported. The structural, electronic, and optical properties of CeBr3 crystals were investigated using the DFT within generalized gradient approximation. Specifically, we see excellent linearity of photons per unit energy with the aliovalent CeBr3:Ca2+ crystal. Proportionality of light yield is one area of performance in which Ce-doped and Ce-based lanthanide halides excel. Maintaining proportionality is the key to producing a strong, high-performance scintillator. Relative light yield proportionality was measured for both doped and undoped samples of CeBr3 to ensure no loss in performance was incurred by doping. The light output and proportionality for doped CeBr3, however, appears to be similar to that of undoped CeBr3. The new crystal was subjected to additional testing and evaluation, including a benchmark spectroscopy assessment. Results, which present energy resolution as a function of energy, are summarized. Typical spectroscopy results using a 137Cs radiation source are shown for our crystallites with diameters <1 cm. We obtain energy resolution of 3.2% before packing the crystallite in a sealed detector container and 4.5% after packing. Spectra were also obtained for 241Am, 60Co, 228Th, and background to illustrate the spectrosocopic quality of CeBr3:Ca2+ over a broader energy range.

9593-4, Session 1

Versatile rate equation and transport model for proportionality of light yield in electron tracks: undoped and Tl-doped CsI at 295 K, undoped CsI at 100 K, and YAP:Ce vs [Ce] *(Invited Paper)*

Richard T. Williams, Xinfu Lu, James L. Drewery, Wake Forest Univ. (United States); Gregory A. Bizarri, Lawrence Berkeley National Lab. (United States); Samuel Donnald, The Univ. of Tennessee (United States) and Agile Technologies (United States); Jason Hayward, Merry Koschan, Charles L. Melcher, The Univ. of Tennessee Knoxville (United States); Kan Yang, Saint-Gobain Crystals (United States); Michael Mayhugh, Saint-Gobain Crystals (United States) and Faceted Development, LLC (United States); Peter R. Menge, Saint-Gobain Crystals (United States)

We describe validation tests in pure and Tl-doped CsI vs temperature and in YAP:Ce vs Ce concentration of a versatile numerical model of scintillator nonproportionality based on rate equations including electron, hole, and exciton mutual interaction and transport, solved by a finite element method appropriate to the geometry of electron tracks. The coupled rate equations include hot and thermalized carrier transport as well as charge separation and resulting space charge fields, carrier capture on activators and defects, bimolecular formation of excitons, Auger and dipole-dipole quenching. Coefficients in the equations are physical rate constants and transport coefficients, most of which can be determined from experiments independent of scintillation. The solution of coupled diffusion-limited rate equations for untrapped and trapped electrons, holes, and excitons is combined with Geant4 Monte Carlo simulation of electron tracks to model electron energy response. The employed protocol for testing the model is to first fit the measured proportionality curve of the undoped host at room temperature with most of the rate and transport coefficients set at published values from interband laser z-scan, picosecond absorption, transport, and luminescence lifetime measurements or calculations. The pure-host parameters so determined are then held fixed for modeling the activator-doped host with input from ps absorption, thermoluminescence,

and/or calculation. Temperature dependence of proportionality and light yield in undoped CsI, the different mechanisms determining proportionality, light yield, and decay time between pure CsI and CsI:Tl, and Ce-concentration dependence in YAP:Ce are accounted for with measured and/or physically supportable fitting parameters.

Crystallographic defects in detector-grade CZT crystals: exploring their properties using synchrotron facilities *(Invited Paper)*

Anwar Hossain, Aleksey Bolotnikov, Giuseppe Camarda, Yonggang Cui, Rubi Gul, Utpal Roy, Ge Yang, Ralph James, Brookhaven National Lab. (United States)

At the present status of CZT detector technology, it is true to state that the advancement and commercialization of these technologies mostly depends on the quality of the detector crystals. Over the past decade, many problems have been identified and resolved, taking this technology to a more advanced stage. The remaining critical defects in CZT crystals can mostly be attributed to stress-related sub-grain boundaries or dislocation walls and crystallographic strains, which cause non-uniformities in detector response and eventually degrade the performance of the fabricated detectors. We carried out experiments to identify and understand the roles of such defects in commercial-grade CZT crystals. We employed state-of-the-art tools including high spatial resolution X-ray spectroscopy, micro-diffraction and micro-tomography techniques at the National Synchrotron Light Source (NSLS-I & II) and at the Advanced Light Source (ALS). In this presentation, we describe in detail our acquired data of the material defects, their influence on the detector's performance, and discuss possible resolutions.

9593-6, Session 2

Control of electric field in CdZnTe radiation detectors by above-bandgap light

Jan Franc, Václav Dedic, Martin Rejhon, Charles Univ. in Prague (Czech Republic)

We have studied in details the high-flux induced polarization and above bandgap light induced depolarization in planar CdZnTe detector. We have observed the depolarization of the detector under simultaneous cathode-site illumination with excitation LED at 910nm and above bangap LED at 640nm caused by trapping of drifting photogenerated electrons. Although the detector current is quite high during this depolarization, we have shown that it decreases within ~5ms to its initial value after switching off the depolarizing light. In order to get detailed information about physical processes present during polarization and depolarization and, moreover, about associated deep levels, we have performed the series of infrared spectral scanning measurements of detector without illumination and under illumination in polarized and optically depolarized states. Three deep levels participating on polarization and depolarization have been found. Level at energy Ec-1.13 eV is associated with a strong optical transition of the electrons to the conduction band forming positive space charge. The photogenerated electrons coming from above bandgap light illumination drifting from cathode towards anode fill the electron trap localized at energy Ec-0.88 eV and cause the formation of the negative space charge and the depolarization of the detector operating under high flux. Weaker electron trapping happens also at midgap level with energy Ev+0.75 eV which mainly interacts with the valence band as the hole trap causing polarization of the detector irradiated with high-flux X-rays.

9593-7, Session 2

Study of point defects in As-grown and annealed bridgman grown CZT crystals and their effects on ?-product and resistivity

Rubi Gul, Brookhaven National Lab. (United States) and Alabama A&M Univ. (United States); Stephen Egarievwe, Alabama A&M Univ. (United States); Georgios Prekas, Uri El-Hanany, Redlen Technologies (Canada); Aleksey E. Bolotnikov, Giuseppe Camarda, Yonggang Cui, Anwar Hossain, Utpal Roy, Ge Yang, Brookhaven National Lab. (United States); Adam Densmore, Redlen Technologies (Canada); Ralph B. James, Brookhaven National Lab. (United States)

In this research, we report on the presence of point defects and their abundance in as-grown and annealed CdZnTe radiation detectors grown under different conditions using travelling heater method (THM). We used Deep Level Transient Spectroscopy (I-DLTS) to determine the activation energy, capture cross-section, and density for different traps. The deepest observed trap has a binding energy of around 1.1 eV, and the shallowest is at a few meV. 1.1 eV trap and Cadmium vacancies are extensively studied in the detectors, before and after different annealing processes. The electrical resistivity and carrier-transport properties (??? of the detectors are studied as a function of the concentration for the 1.1-eV trap. The knowledge gained from the DLTS of point defects and ??-products is used to understand the effects of traps on the performance of CdZnTe detectors. The results indicate that the concentration of 1.1-eV trap causes non-uniformity in the E-field, and also causes a change in the resistivity and the ??e-product, and hence, it is a dominant feature in the degradation of detector performance.

9593-8, Session 2

Correcting response inhomogeneity of CdZnTe detectors

Aleksey E. Bolotnikov, Giuseppe S. Camarda, Yonggang Cui, Gianluigi De Geronimo, Jack Fried, Anwar Hossain, Utpal N. Roy, Emerson Vernon, Ge Yang, Ralph B. James, Brookhaven National Lab. (United States)

We describe the techniques for correcting the charge losses caused by defects in CdZnTe (CZT) detectors fabricated from unselected off-the-shelve CZT crystals. The techniques are based on implementing a correction method for high-granularity position-sensitive detectors to enhance their performance by dividing the active volumes of the detectors into small voxels and applying corrections to the charge-signals generated from them. We present the results obtained from testing position-sensitive virtual Frisch-grid detectors and 3D position-sensitive pixelated detectors with small pixel sizes.

9593-9, Session 2

Towards a post-growth annealing approach to mitigate material defects: case analysis of CdZnTe, CdMnTe, and CdTeSe

Ge Yang, Aleksey E. Bolotnikov, Yonggang Cui, Giuseppe S. Camarda, Anwar Hossain, Utpal N. Roy, Rubi Gul, Ralph B. James, Brookhaven National Lab. (United States)

In this work, we investigate post-growth annealing to improve the properties of CdZnTe, CdMnTe and CdTeSe crystals. Defect structures and opto-electronic properties of as-grown and annealed CZT crystals are characterized by IR transmission microscopy, white X-ray beam diffraction topography, current-voltage measurements, and low-temperature photoluminescence spectroscopy. New results from recent long-term annealing experiments at lower temperatures will be presented and discussed.

9593-10, Session 3

Investigations of 6LiIn(1-x)Ga(x)Se2 semi-insulating crystals for neutron detection

Brenden Wiggins, Vanderbilt Univ. (United States); Arnold Burger, Fisk Univ. (United States); Keivan G. Stassun, Vanderbilt Univ. (United States); Ashley C. Stowe, Y-12 National Security Complex (United States)

Neutron detectors are used for illicit material detection, neutron radiography, compositional analysis of stellar bodies, and nuclear power monitoring. Li-containing chalcogenides have the potential to replace 3He detectors for thermal neutron detection. The high density of lithium-6 in the 6LiInSe2 crystal results in high intrinsic thermal neutron efficiency; however, the effective efficiency is limited to 80% due to an 115In neutron capture reaction. In order to improve the overall detection efficiency, gallium has been systematically substituted for indium in the crystal lattice yielding 6LiIn1-xGaxSe2. In addition, gallium addition will be tested as a scintillation activator. A comparison of crystal quality and radiation response will be presented.

9593-12, Session 3

Thermal neutron detectors based on hexagonal boron nitride epilayers

Hongxing Jiang, Jingyu Lin, Texas Tech Univ. (United States)

Solid-state thermal neutron detectors with improved detection efficiencies are highly sought after for the detection of fissile materials. Due to low emission of neutrons by a potential fissile materials as well as decreasing of neutron flux with square of distance, it is difficult in many cases to detect neutron signal at a reasonable distance. A large size high efficiency detector is desired to improve the detector performance and to provide a relatively high counting rate.

Wafer-scale hexagonal boron nitride (h-BN) semiconducting epilayers with a thickness up to 4.5 um have been successfully synthesized by MOCVD on sapphire substrates. Metal-semiconductor-metal thermal neutron detectors with size up to 1.5 cm x 1.5 cm were fabricated. The reaction product pulse-height spectra were measured under thermal neutron irradiation produced by a 252Cf source moderated by high density polyethylene block. The measured pulse-height spectra revealed distinguishable peaks corresponding to the product energies of 10B and neutron reaction. The results indicate that h-BN semiconductor detectors are very sensitive in resolving energies of specific reaction products and have a negligible response to gamma photons produced by 137Cs decay at 0.662 MeV. Our results indicate that h-BN are highly promising for realizing sensitive solid-state thermal neutron detectors with expected advantages resulting from semiconductor technologies, including compact size, light weight, low operating voltage, and low cost.

9593-13, Session 3

Neutron detection with LiInSe2 *(Invited Paper)*

Zane W. Bell, Oak Ridge National Lab. (United States); Arnold Burger, Fisk Univ. (United States); Ashley C. Stowe, Y-12 National Security Complex (United States); Joshua P. Tower, Radiation Monitoring Devices, Inc. (United States); Liviu Matei, Michael Groza, Fisk Univ. (United States); Alireza Kargar, Huicong Hong, Radiation Monitoring Devices, Inc. (United States)

The detection of thermal neutrons has traditionally been accomplished with 3He-tubes, but with the recent shortage of 3He, much research has gone into finding suitable replacements. Both relatively inefficient 10B- and 6LiF-coated silicon diodes and HgI2 have been known for many years, and engineered structures in Si that have been filled with 10B and 6LiF have shown promise. These devices are intended to realize an optimal juxtaposition of neutron-sensitive material and semiconductor and thereby simulate a semiconductor containing B or Li. Such material has been realized for the first time in the form of 6LiInSe2 in which collectable charge from the 6Li(n,t) reaction indicates a neutron event. In this paper, we report neutron, gamma, and alpha responses of 6LiInSe2, Monte Carlo simulations of the responses, and compare the simulations to the measured data. We show pulse height spectra from pure gamma sources and from a thermal neutron source, and the effects of threshold on the separation of neutron and gamma events. We derive the mu-tau product from the position of spectral features as a function of bias voltage. In addition, we demonstrate the observation of the beta decay of 116mIn in samples exposed to thermal neutrons. This feature of the response serves as a confirmation of exposure to neutrons.

This work has been supported by the US Department of Homeland Security, Domestic Nuclear Detection Office, under competitively awarded Cooperative Agreement 2013-DN-077-ER00002. This support does not constitute an express or implied endorsement on the part of the Government.

9593-14, Session 4

Towards stable thallium bromide devices for long-term use *(Invited Paper)*

Amlan Datta, CapeSym, Inc. (United States); Piotr Becla, CapeSym, Inc. (United States) and Massachusetts Institute of Technology (United States); Shariar Motakef, CapeSym, Inc. (United States)

Thallium Bromide (TlBr) is a wide bandgap, compound semiconductor with high gamma-ray stopping power and promising physical properties. However, performance degradation and the eventual irreversible failure of TlBr devices occurs due to ionic polarization. Along with polarization, there are a number of scarcely explored processes which renders the devices unusable for practical purposes. This includes but are not limited to degradation of the electrodes with time, changes in residual stress of the TlBr crystals, and variations in the surface chemistry. Several of these issues will be explored in detail and potential solutions will be provided. For example, we have observed that the reaction of anode metal with Br decreases the lifetime of the device significantly. Different anode materials were tested to find the most resilient candidate. Several other modifications to the TlBr device fabrication techniques were also made and their effects on the long term performance was evaluated. A uniform electric field in TlBr devices is a necessary condition for device stability. We will also present results of direction observation of changes in the electric field for

an extended time in a TlBr, and relate it to residual stresses. We will present most recent lifetime results that we have obtained by employing a number of techniques to stabilize the semiconductor-metal interface.

This is an invited paper.

9593-15, Session 4

Impact of heat treatment on the electrical characteristics and charge collection efficiency of metal-GaAs:Cr-metal x-ray sensors

Anton V. Tyazhev, Andrei N. Zarubin, Vladimir A. Novikov, Oleg P. Tolbanov, Anastasiya D. Lozinskaya, David L. Budnitsky, Maxim S. Skakunov, National Research Tomsk State Univ. (Russian Federation)

The paper presents the results of experimental studies of the resistivity, electron mobility, charge collection efficiency, (mu*tau)n product and the IV characteristics of "metal-GaAs:Cr-metal" X-ray sensors dependences on the heat treatment. Experimental samples were pad sensors with an active area of 0.1-0.25 cm2 and a thickness in the range of 400 - 500 microns.

Resistivity measurements were carried out using both classical methods (Hall measurements) as well as a non-contact measurement technique.

The values of (mu*tau)n were evaluated from measurements of the charge collection efficiency dependences on the bias voltage when exposed to gamma rays from the source of 241Am.

It is shown that the heat treatment in the temperature range 200-500? C does not lead to significant degradation of characteristics of "metal-GaAs: Cr-metal" sensors and can be used in technology of ionizing radiation GaAs:Cr pixel sensors.

9593-16, Session 4

Novel semiconductor radiation detector based on mercurous halides *(Invited Paper)*

Henry Chen, Joo-Soo Kim, Proyanthi Amarasinghe, Feng Jin, Sudhir B. Trivedi, Brimrose Technology Corp. (United States); Arnold Burger, Fisk Univ. (United States); Jarrod Marsh, Marc S. Litz, U.S. Army Research Lab. (United States); James O. Jensen, U.S. Army Edgewood Chemical Biological Ctr. (United States)

The three most important desirable features in the search for RTSD candidate as an alternative material to current COTS material for gamma and/or thermal neutron detection are: low cost, high performance and long term stability. This is especially important for pager form application in homeland security. Yet, despite years of research, no explored RTSD candidate so far can satisfy the above 3 features simultaneously. In this work, we show that mercurous halide materials Hg2X2 (X= I, Cl, Br) is a new class of innovative compound semiconductors that can deliver breakthrough advances to COTS radiation detector materials. These materials are much easier to grow thicker crystals. They can detect gamma and potentially neutron radiation making it possible to detect two types of radiation with just one crystal material. The materials have a wider bandgap meaning higher resistivity and lower leakage current, making this new technology more compatible with available microelectronics. The materials also have higher atomic number and density leading to higher stopping power and better detector sensitivity/efficiency. They are not hazardous so there are no environmental and health concerns during manufacturing and are more stable making them more practical for commercial deployment. Focus will be on Hg2I2. Material characterization and detector performance will be presented and discussed. Initial results show that an energy resolution of 2.45% @ 59.6 keV gamma from Am-241 can be achieved at room temperature.

9593-17, Session 4

Neutron Detection with Noble Gas Scintillation: A Review of Recent Results

Christopher M. Lavelle, Johns Hopkins Univ. Applied Physics Lab., LLC (United States); Michael Coplan, Univ. of Maryland, College Park (United States); Eric C. Miller, Johns Hopkins Univ. Applied Physics Lab., LLC (United States); Alan K. Thompson, National Institute of Standards and Technology (United States); Alex Kowler, Univ. of Maryland, College Park (United States); Rob Vest, Andrew Yue, National Institute of Standards and Technology (United States); Tim Koeth, Johns Hopkins Univ. Applied Physics Lab., LLC (United States) and Univ. of Maryland, College Park (United States); Mohammad Al-Sheikhly, Univ. of Maryland, College Park (United States); Charles Clark, National Institute of Standards and Technology (United States)

Thermal neutron detection is of vital importance to many disciplines, including neutron scattering, workplace monitoring, and homeland protection. We survey recent results from our collaboration which couple low pressure noble gas scintillation with novel approaches to neutron absorbing materials and geometries to achieve potentially advantageous detector concepts. Noble gas scintillators were used for neutron detection as early as the late 1950's. Modern use of noble gas scintillation includes liquid and solid forms of argon and xenon in the dark matter and neutron physics experiments and commercially available high pressure applications have achieved high resolution gamma ray spectroscopy. Little attention has been paid to the overlap between low pressure noble gas scintillation and thermal neutron detection, for which there are many potential benefits. Approaches currently under study include multiple thin films of boron-10, boron carbide dispersed in an open cell foam, and transparent neutron absorbing materials. Experiments have been conducting using neutron beams at the NIST Center for Neutron Research.

9593-58, Session 4

High-barrier Schottky contact on n-type 4H-SiC epitaxial layer and investigation of defect levels by deep level transient spectroscopy (DLTS)

Khai V. Nguyen, Rahmi O. Pak, Cihan Oner, Mohammad A. Mannan, Krishna C. Mandal, Univ. of South Carolina (United States)

High barrier Schottky contact has been fabricated on 20 um n-type 4H-SiC epitaxial layers grown on 350 um thick substrate 4 degrees off-cut towards the [112 0] direction. The 4H-SiC epitaxial wafer was diced into 8 x 8 mm2 samples. The metal-semiconductor junctions were fabricated by photolithography and dc sputtering with metals of various work functions. The junction properties were characterized through current-voltage (I-V) and capacitance-voltage (C-V) measurements. Detectors were characterized by alpha spectroscopy measurements in terms of energy resolution and charge collection efficiency using a 0.1 uCi 241Am radiation source. It was found that detectors fabricated from high work function rare transition metal demonstrated very low leakage current and significant improvement of detector performance. Defect characterization of the epitaxial layers was conducted by deep level transient spectroscopy (DLTS) to thoroughly investigate the defect levels in the active region. The presence of a new defect level induced by this rare transition metal-semiconductor interface has been identified and characterized.

9593-18, Session 5

Novel highly-stable and rugged contact on CdTe-based materials for radiation detector applications *(Invited Paper)*

Utpal N. Roy, Aleksey E. Bolotnikov, Giuseppe S. Camarda, Yonggang Cui, Rubi Gul, Anwar Hossain, Ge Yang, Ralph B. James, Brookhaven National Lab. (United States); Aswini K. Pradhan, Rajeh Mundle, Norfolk State Univ. (United States)

Mechanical degradation of contacts and their poor adhesion to CdZnTe and CdTe is a major and long-standing technological problem for use of this material for detector applications. The contact interfacial layer plays a vital role in detector performance. The main reason for the contact degradation is the large differences in the thermal expansion coefficients of the common metals used for contacts and the CdZnTe. The stress between the contact and CdZnTe causes mechanical degradation and thus affects adversely the detector performance and aging. In this presentation the advantages of a novel contact and the performance of devices with the novel contact for radiation detector applications will be discussed.

9593-19, Session 5

Growth characterization of CdTeSe-based materials and fabrication of devices for radiation detector applications

Utpal N. Roy, Aleksey E. Bolotnikov, Giuseppe S. Camarda, Yonggang Cui, Rubi Gul, Anwar Hossain, Ryan Tappero, Ge Yang, Ralph B. James, Brookhaven National Lab. (United States)

Selenium in the CdTe matrix was found to be very effective in reduction of various defects such as sub-grain boundary networks and the concentration of secondary phases. In addition, the concentration of electrically active defects were also found to be reduced drastically in the CdTe matrix after alloying with Se. Growth of CdTeSe and CdZnTeSe crystals and the effects of Se on the structural defects and the concentration of electrically active defects will be discussed. The charge transport characteristics and the correlation with the electrically active defects will be presented. Finally, preliminary results of the device performance for radiation detector applications will be reported.

9593-20, Session 5

Xenon gamma-ray spectrometer in the experiment Signal on board the spacecraft Interhelioprobe

Alexander S. Novikov, Sergey E. Ulin, Valery V. Dmitrenko, Victor M. Grachev, Viktor N. Stekhanov, Konstantin F. Vlasik, Ziyaetdin M. Uteshev, Irina V. Chernysheva, Alexander E. Shustov, Denis V. Petrenko, National Research Nuclear Univ. MEPhI (Russian Federation)

In the experiment SIGNAL, which is planned to take place on board spacecraft INTERHELIOPROBE, a xenon gamma-ray spectrometer is to be used. The gamma-ray spectrometer in question has been chosen because of its characteristics permitting detailed study of solar gamma-radiation under rough experimental conditions. The equipment is able to provide: high energy resolution (5-6-fold better than that of scintillation detectors), performance at high temperatures, steady operation under significant vibroacoustic load, and high radiation resistance of the working medium. The aforesaid properties of the xenon gamma-ray spectrometer meet goals and objectives of the experiment SIGNAL. The description of ballistics scenario and operation orbit of the spacecraft INTERHELIOPROBE are presented.

Currently development of the scientific equipment SIGNAL is in the stage of preparation of design documentation and SIGNAL device model manufacturing. The equipment in question is being developed at NRNU MEPhI. The established deadline is October 2015.

9593-21, Session 5

First principles studies of the stability and Shottky barriers of metal/CdTe(111) interfaces

Zhen Liu, Dorj Odkhuu, Maosheng Miao, Nicholas Kioussis, California State Univ., Northridge (United States); Suleyman Tari, Fikri Aqariden, Yong Chang, Sivananthan Labs., Inc. (United States); Christoph H. Grein, Univ. of Illinois at Chicago (United States)

CdZnTe and CdTe based semiconductor X-Ray and Gamma-Ray detectors have been intensively studied recently due to their promising potentials for achieving high-resolution, high signal-to-noise ratios and low leakage current, all are desirable features in applications ranging from medical diagnostics to homeland security. Understanding the atomic and electronic structures of the metal/semiconductor interfaces is essential for the further improvements of performance. Using density functional calculations, we systematically studied the stability, the atomic and electronic structures of the interfaces between CdTe (111) surfaces (Te- and Cd- terminated) and the selected metals (Al, Cu and Pt). We also calculated the Schottky barrier height (SBH) by aligning the electrostatic potentials in semiconductor and metal regions. Our calculations revealed the importance of intermixing between semiconductor and metal layers and the formation of Te-metal alloys at the interface. The obtained SBH does not depend much on the choice of metals despite the large variation of the work functions. On the other hand, the interface structure is found to have large effect to the SBH, which is attributed to the metal induced states in the gap. The position of such states is insensitive to the metal work functions, as revealed by the analysis of the electronic structures.

9593-22, Session 6

Potassium-based halide scintillators with high-energy resolution *(Invited Paper)*

Mariya Zhuravleva, Luis Stand, Eric D. Lukosi, Charles L. Melcher, The Univ. of Tennessee Knoxville (United States)

Our goal is to discover and develop low-cost, effective new scintillators that can be used for the detection of illicit radioactive materials. In order to unambiguously identify the specific gamma-ray signatures of radioactive elements, scintillator materials must possess energy resolution approaching 2% at 662 keV. Currently available radiation sensors have either inadequate energy resolution (NaI:Tl), unacceptably high cost (CZT and LaBr3:Ce), or limiting operational burden (HPGe).

We present a summary of crystal growth and scintillation properties of new high-resolution scintillators that were discovered by our group during the past two years. When activated with Eu2+, ternary compounds that belong to the KA2X5 and K2AI4 (A = Sr, Ba; X = I, Br) compositional families demonstrate excellent combinations of scintillation light yield and proportionality. Light yields up to ~95,000 photons/MeV and energy resolution as good as 2.4% at 662 keV were measured. Several of the new compounds display very proportional photon and electron responses. The effect of intrinsic radioactivity due to 40K on their performance in nuclear security applications was evaluated.

Using the vertical Bridgman method, we have demonstrated that KSr2X5:Eu scintillator crystals can be successfully grown at fast pulling rates (up to 10 mm/h) and can have low growth defect density and uniform scintillation performance even for relatively large samples (~1 inch3). We further improved the purity of the raw materials via zone refining and melt-aging.

Improvements of phase homogeneity of K2AI4:Eu crystals via optimization of growth parameters and using off-stoichiometric melt compositions are reported. In order to improve crystal quality and scintillation performance, we implemented co-doping and solid solutions.

9593-23, Session 6

Organic-inorganic scintillator detectors for radiation detection

Nathan T. Shewmon, Paul M. Johns, Weiran Cao, Daken Starkenburg, Shinyoung Yeo, James E. Baciak Jr., Juan C. Nino, Jiangeng Xue, Univ. of Florida (United States)

Organic photodiodes (OPDs) coupled to inorganic scintillator crystals can improve upon photocathode and photomultiplier tube systems to provide low cost, low power consumption, and high collection efficiency photodiodes for portable scintillator radiation detectors. Over the last two decades, developments in organic, polymer-based, semiconductor technology has spurred tremendous interest in their applications for photovoltaics, lighting, and circuitry. In this work we present the coupling of OPDs with nuclear electronic technology to drive the development of scintillator detectors with improved characteristics compared to those used currently. The design and development of integrated scintillator and OPD systems is presented in the context of building detection systems for medical radiology and national security applications.

OPDs fabricated on scintillator crystals offer the design advantages of flexibility, conformability to the morphology of the crystal, and a relative ease of fabrication. In this work, results from the design and analysis of OPDs coupled to scintillators will be presented along with the challenges of integrating organic-inorganic components. By careful selection of device structure and processing, we demonstrate highly sensitive OPDs with specific detectivity (D*) of >1013 Jones as a result of low leakage current <5 nA/cm2 and high responsivity >300 mA/W within a wavelength range that is tunable across the near UV through the full visible spectrum by selection of appropriate photoactive organic materials. Further, we show how OPD compositions can be selected to maximize the absorption efficiency of the device at wavelengths that match the emission range of alkali-halide scintillator crystals.

Highlights of the work presented include results from coupling the organic photodetectors to the surface of CsI(Tl) scintillator crystals, as well as the electronic response of the device from external stimulus sources. The capability for using organic photodetectors in pulse mode operation for the collection and analysis of signals will also be presented for future work on resolving gamma ray spectra.

9593-24, Session 6

Transparent ceramic scintillators *(Invited Paper)*

Nerine J. Cherepy, Zachary M. Seeley, Stephen A. Payne, Patrick R. Beck, Erik L. Swanberg, Brian Wihl, Steven Hunter, Scott E. Fisher, Peter A. Thelin, Daniel J. Schneberk, Gary F. Stone, Randall Thompson, Lawrence Livermore National Lab. (United States); Todd Stefanik, Nanocerox, Inc. (United States); Joel Kindem, Cokiya, Inc. (United States)

Transparent ceramics fabrication offers a new pathway to high melting point oxide scintillators previously considered ungrowable. Fabrication of transparent ceramics begins with high purity oxide nanopowders, consolidated by pressing and sintering to full density to produce a pure-phase polycrystalline optic with no residual porosity. We report here on progress in scaleup and instrumentation of Cerium-doped Gadolinium Yttrium Gallium Aluminum Garnet, or GYGAG(Ce). The Ce-doped GYGAG ceramic scintillators are mechanically rugged and stable in air while providing good light yield (~50,000 Ph/MeV) with an emission peak centered at 550 nm. We have fabricated optically transparent GYGAG(Ce) ceramics as large as 5.3 in3 for PMT-based detectors. The mechanical ruggedness of the GYGAG(Ce) ceramic lends itself to pixelation, as it is readily cut and polished with high yield. A gamma spectrometer incorporating 1024 GYGAG(Ce) pixels, mounted on a photodiode array, offers energy resolution at 662 keV of 3.3% for single pixels, 3.6% for the summed histogram of our 32 best pixels, and 4.0% for a sum of 220 pixels. Another transparent ceramic scintillator, Gd0.3Lu1.6Eu0.103, or "GLO," offers excellent x-ray stopping, due to its Zeff = 68 and density of 9.1 g/cm3. We have recently fabricated a transparent ceramic GLO scintillator plate 11.5" in diameter by 0.1" thick for high energy radiography, and we will report here on its performance in a 9 MeV imager.

9593-25, Session 6

Degradation of deliquescent halide scintillators

Mariya Zhuravleva, Luis Stand, Hua Wei, The Univ. of Tennessee Knoxville (United States); Lynn A. Boatner, Oak Ridge National Lab. (United States); Kanai Shah, Radiation Monitoring Devices, Inc. (United States); Arnold Burger, Fisk Univ. (United States); Charles L. Melcher, The Univ. of Tennessee Knoxville (United States)

Most high-performance inorganic scintillators are halide compounds, which exhibit hygroscopic, or even deliquescent, behavior. Scintillator crystals react with oxygen and moisture from an ambient atmosphere, which results in rapid deterioration of their physical form and is accompanied by degradation of the scintillation properties. The knowledge of relative hygroscopicity alone is not sufficient to in order to assess the requirements for protective packaging.

The goal of this work is to provide a better understanding of the complex mechanisms of hydration and degradation of scintillation performance of various multicomponent scintillators such as SrI2:Eu, CsBa2I5:Eu, KSr2I5:Eu, LaBr3:Eu, CsSrI3:Eu, and Cs2LiYCl6:Ce. We present real-time observations of physical degradation and show that the degradation rate and morphology development are correlated with the composition, crystal structure, and sample history. We have also developed a technique to measure the water solubility of ternary compounds by allowing the samples to absorb moisture from the atmosphere and monitoring their weight in dynamic equilibrium under controlled conditions. The results suggest that dissolution is accompanied with the formation of intermediate decomposition products, and that water solubility is not a quantitative representation of hygroscopicity. We have also studied the effect of surface roughness on physical decomposition and light collection efficiency. The results for various metal halide scintillators are compared with standard commercial scintillators such as NaI:Tl and CeBr3.

9593-26, Session 7

Challenges and future directions for planetary gamma ray and neutron spectroscopy *(Invited Paper)*

Thomas H. Prettyman, Planetary Science Institute (United States); Arnold Burger, Fisk Univ. (United States); James L. Lambert, Julie Castillo-Rogez, Jet Propulsion Lab. (United States); Naoyuki Yamashita, Planetary Science Institute (United States)

The elemental composition of planetary surfaces can be determined using nuclear spectroscopy. Cosmic-ray interactions with planetary surfaces and atmospheres make gamma rays and neutrons, some of which escape into space. Gamma rays are also produced by the decay of long-lived radioelements. The emitted radiation provides a chemical fingerprint from which the concentration of major elements in silicate minerals, selected trace elements and volatiles can be determined. In situ and close-proximity orbital measurements are possible. The origins of planetary gamma ray and

neutron spectroscopy date back to Ranger and Apollo. Nuclear methods were used to characterize the surface composition of the terrestrial planets, the near-Earth asteroid Eros, and the main-belt asteroid Vesta. Nevertheless, rapid developments in other fields have rendered some of the technology obsolete. This is a natural consequence of extreme challenges facing the development of flight hardware, which must survive launch and acquire data in harsh environments. The technology gap for scintillators for gamma ray spectroscopy is striking. Scintillators fill a niche for planetary applications requiring rugged, compact, and low-power sensors. New technologies such as LaBr3, CeBr3, and SrI2 must undergo rigorous testing and demonstrate a competitive edge over heritage technology in order to be considered for flight. Opportunities for more frequent, low-cost missions with miniaturized satellites may help bring new technologies to maturity at a rapid pace, providing planetary scientists with a better selection of tools for composition analysis. The fundamentals of planetary nuclear spectroscopy, the state-of-the-art in instrumentation, current challenges and possibilities for future development are presented.

9593-27, Session 7

Radiation anomaly detection algorithms for field acquired gamma energy spectra

Sanjoy Mukhopadhyay, Richard J. Maurer, Ronald S. Wolff, Paul P. Guss, Stephen E. Mitchell, National Security Technologies, LLC (United States)

The Remote Sensing Laboratory (RSL) is developing a tactical, networked radiation detection system that will be agile, reconfigurable, and capable of rapid threat assessment with high degree of fidelity and certainty. Our design is driven by the needs of users such as law enforcement personnel who must make decisions by evaluating threat signatures in urban settings. The most efficient tool available to identify the nature of the threat object is real-time gamma spectroscopic analysis, as it is fast and has a very low probability of producing false positive alarm conditions. Urban radiological searches are inherently challenged by the rapid and large spatial variation of background gamma radiation, the presence of benign radioactive materials in terms of the normally occurring radioactive materials (NORM), and shielded and/or masked threat sources. Multiple spectral anomaly detection algorithms have been developed by national laboratories and commercial vendors. For example, the Gamma Detector Response and Analysis Software (GADRAS) a one-dimensional deterministic radiation transport software capable of calculating gamma ray spectra using physics-based detector response functions was developed at Sandia National Laboratories. The nuisance-rejection spectral comparison ratio anomaly detection algorithm (or N-SCRAD), developed at Pacific Northwest National Laboratory, uses spectral comparison ratios to detect deviation from benign medical and NORM radiation source and can work in spite of strong presence of NORM and or medical sources. RSL has developed its own wavelet-based gamma energy spectral anomaly detection algorithm called WAVRAD. Test results and relative merits of these different algorithms will be discussed and demonstrated.

9593-28, Session 7

The next generation of crystal detectors for future HEP experiments

Ren-Yuan Zhu, California Institute of Technology (United States)

Crystal detectors have been used widely in high energy and nuclear physics experiments, medical instruments and homeland security applications. Novel crystal detectors are continuously being discovered and developed in academia and in industry. In high energy and nuclear physics experiments, total absorption electromagnetic calorimeters (ECAL) made of inorganic crystals are known for their superb energy resolution and detection efficiency for photon and electron measurements. A crystal ECAL is thus the choice for those experiments where precision measurements of photons and electrons are crucial for their physics missions. For future HEP experiments at the energy and intensity frontiers, however, the crystal detectors used in current ECALs are either not bright and fast enough, or not radiation hard enough. Crystal detectors have also been proposed to build a Homogeneous Hadron Calorimeter (HHCAL) to achieve unprecedented jet mass resolution by duel readout of both Cherenkov and scintillation light, where development of cost-effective crystal detectors is a crucial issue because of the huge crystal volume required. This paper discusses several R&D directions for the next generation of crystal detectors for future HEP experiments at all frontiers.

9593-29, Session 7

Measurements on scintillators and semiconductor detectors at the Advanced Light Source (ALS)

Giuseppe S. Camarda, Aleksey E. Bolotnikov, Yonggang Cui, Rubi Gul, Anwar Hossain, Utpal Roy, Ge Yang, Ralph B. James, Brookhaven National Lab. (United States)

During the transition period between closure of Beamline X27B at BNL's NSLS and opening of Beamline MID at NSLS-II, we began operation of LBNL's ALS Beamline 3.3.2 to carry out our radiation detection materials R&D. Measurements performed at this Beamline include, X-ray Detector Response Mapping and White Beam X-ray Diffraction Topography (WBXDT), among others. We will introduce the capabilities of the Beamline and present the most recent results obtained on CdZnTe and multiple scintillators. The goal of the studies on CdZnTe is to understand the origin and effects of subgrain boundaries and help to visualize the presence of a higher concentration of impurities, which might be responsible for the deterioration of the energy resolution and response uniformity.

9593-30, Session 7

Development of NEUANCE: the neutron detector array at DANCE

Marian Jandel, Bayar Baramsai, Aaron Couture, Shea M. Mosby, Gencho Y. Rusev, John L. Ullmann, Carrie L. Walker, Los Alamos National Lab. (United States)

The Detector for Advanced Neutron Capture Experiments (DANCE) at Los Alamos Neutron Science Center (LANSCE) has been successfully used for numerous measurements of capture cross sections. The DANCE array is a gamma ray calorimeter that consists of 160 BaF2 scintillation arranged in 4ϖ geometry. In recent years, we have carried out also measurements on neutron-induced fission and new results on emission of prompt-fission gamma rays were obtained. To enhance the capabilities of the DANCE array, we are designing a smaller segmented array from liquid scintillators that fits inside a central cavity of the DANCE array. Using a pulse shape discrimination, we have additional information on the gamma-rays and neutrons emitted from neutron-induced fission. Preliminary results from the first experiments at DANCE with the prototype of NEUANCE will be presented for U-235 neutron-induced reactions and Cf-252 spontaneous fission.

We gratefully acknowledge the support of the U.S. Department of Energy through the LANL/LDRD Program. Part of this work was also supported by the U.S. Department of Energy, Office of Science, Nuclear Physics under the Early Career Award No. LANL20135009.

9593-31, Session 8

Hard X-ray camera (HXC) for the FFAST mission

Hiroshi Tsunemi, Kiyoshi Hayashida, Hiroshi Nakajima, Naohisa Anabuki, Ryo Nagino, Osaka Univ. (Japan);

Masanobu Ozaki, Japan Aerospace Exploration Agency (Japan)

We have developed the Hard X-ray Camera (HXC) for the FFAST mission. FFAST is proposed to observe a large sky region to search for heavily obscured AGN. It will cover larger sky region than that by Nustar and detect fainter AGNs than those by Swift/BAT. It consists of two small satellites in formation flight with a 12m distance. One satellite carries a super mirror and the other carries the HXC, which forms a space telescope covering the energy range up to 80 keV. The HXC is similar in structure to that of the CCD camera (SXI) for ASTRO-H. They employ similar type of CCDs. CCDs for HXC is added a thin plate of scintillator attached to the CCD that is called a SDCCD. The soft X-ray (below 15 keV) is absorbed in the CCD while hard X-ray, passing through the CCD, is absorbed in the scintillator. The HXC body is similar to that of the SXI. The SXI employs two mechanical cooler to keep the working temperature around -110C while the HXC employs one mechanical cooler to keep the working temperature around -70C. Surrounding electronics for both cameras are also similar to each other. We will report the results of the radiation hardness, performance results both for X-rays and for charged particles. Various tests have been done so far. ASTRO-H will go in the 2015FY while FFAST is proposing to the scientific small satellite mission.

9593-32, Session 8

A low-noise wide-dynamic-range event-driven detector using SOI pixel technology for high-energy particle imaging

Sumeet Shrestha, Hiroki Kamehama, Keita Yasutomi, Keiichiro Kagawa, Shizuoka Univ. (Japan); Ayaki Takeda, Takeshi G. Tsuru, Kyoto Univ. (Japan); Yasuo Arai, High Energy Accelerator Research Organization, KEK (Japan); Shoji Kawahito, Shizuoka Univ. (Japan)

This paper presents a low-noise wide-dynamic-range pixel design for high-energy particle detector in astronomical application. Silicon on insulator (SOI) based detector is used for the detection of wide range of high energy particle (both soft and hard X-ray). The sensor has thin layer of CMOS readout circuitry and thick layer of high-resistivity detector vertically stacked in a single chip. Pixel circuits are divided into two parts; signal sensing circuit and event detection circuit. Event detection circuit consisting of a comparator and logic circuits detects the incidence of high energy particle, categorizes it into two energy groups using an appropriate energy threshold and generates a two-bit code for an event and energy level. The code for energy level is then used for selection of the gain of the in-pixel amplifier for the detected signal, providing a function of high-dynamic-range signal measurement. The two-bit code for the event and energy level is scanned in the event scanning block and the signals from the hit pixels only are read out. The variable-gain in-pixel amplifier uses a continuous integrator and integration-time control for the variable gain. The proposed design allows the small signal detection and wide dynamic range due to the adaptive gain technique and capability of correlated double sampling (CDS) technique of kTC noise canceling of the charge detector. An experimental chip with an 8 x 8 pixel array designed with the SOI pixel technology is being manufactured and the results of the first sample will be presented at the meeting.

X-CELIV: X-ray-excited charge extraction by linearly increasing voltage: a new method for the electrical charge transport characterization of x-ray detectors

Moses Richter, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); Patric Büchele, Siemens AG (Germany); Gebhard J. Matt, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); Sandro F. Tedde, Oliver Schmidt, Siemens AG (Germany); Christoph J. Brabec, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany)

A novel generation of hybrid X-ray detector, comprising an active material composition of terbium doped gadolinium oxysulfide (GOS) scintillator particles dispersed in a blend of the organic semiconductor poly-3-hexylthiophene (P3HT) and a fullerene derivative (PCBM) is investigated. The active layer is easily processed from solution, e.g. by spraycoating or printing. The achieved X-ray conversion efficiencies are comparable to well established direct converting semiconductors such as a-Se.

Upon X-ray irradiation the GOS scintillator emits green light which is reabsorbed by the P3HT:PCBM blend, where free electron-hole pairs are generated. The electrons (holes) are extracted by an applied electrical field along the PCBM (P3HT) phase. The conversion efficiency of the detector is a trade-off between higher X-ray absorption (i.e. increased GOS content) and the charge carrier extraction efficiency over the organic matrix. The latter is greatly influenced by the layer morphology and thickness. Therefore, key parameters, such as the charge carrier mobility μ and life time ?, are of high interest to optimize the active hybrid blend.

We here demonstrate a new adaptation of the charge extraction by linearly increased voltage method in combination with X-ray excitation (X-CELIV) as a versatile characterization technique for (any) X-ray detector technology. It allows the quantitative device investigation under real operational conditions, meaning a homogeneous excitation of the photo-conducting P3HT:PCBM blend. The measured mobilites agree very well to the literature values for P3HT and PCBM. The lifetime ? is determined by delayed charge extraction and the conversion rate simultaneously derived from the integrated signal.

9593-34, Session 8

Photon counting 3D x-ray CT as a input device for 3D-printers

Toru Aoki, Univ. of Shizuoka (Japan); Akifumi Koike, ANSeeN, Inc. (Japan) and Univ. of Shizuoka (Japan); Kiryu Sugiyama, Univ. of Shizuoka (Japan)

Photon counting X-ray CT has been developed by using CdTe photon counting sensor. We have already reported Photon counting X-ray CT system for material identification system by using dual- and/or multi-energy X-ray CT. In this paper, we have evaluated this system as a input device for 3D-printers. 3D-printers are required the simple binary data for each of voxel without half tone. We have compared with two CdTe detectors system, one is the current integration detector, and the other is the photon counting detector. Photon counting CT shows very high contrast, and it could be separate cross-sectional images by materials. The results data is very suitable for input data for 3D-printer.

9593-35, Session 8

Spectral x-ray imaging performance of a hybrid pixel detector working in data driven read out mode

Erik Fröjdh, Rafael Ballabriga Sune, Jerome Alozy, Michael Campbell, Erik H. M. Heijne, Xavier Llopart, Tuomas Poikela, Lukas Tlustos, Winnie S. Wong, CERN (Switzerland)

Timepix3 is a new hybrid pixel detector readout chip working in data driven read out mode, capable of simultaneously measuring energy and time of arrival of each impinging photon. The pixel size is 55 x 55 um2 and the matrix consists of 256 x 256 pixels. Immediately after a pixel is hit a data packet with the pixel coordinates, the time over threshold (energy) and time of arrival is sent out. The maximum hit rate of Timepix3 is 85.3 Mhits/s/chip. The chip is designed with a super pixel structure, consisting of 2 x 4 pixels. Each super pixel has one 640 MHz oscillator which is activated when

the signal on any of the 8 pixels crosses the analogue threshold, providing a timestamp with a step size of 1.56 ns. The noise of the front end is ~60 e- and with a silicon sensor the energy resolution in time over threshold mode has been measured to be 4.07keV at 60keV (all cluster sizes included).

In this work we investigate the spectral imagining performance of Timepix3 with both CdTe and silicon sensors. Having the energy and time information of each hit enables new correction algorithms for sensor defect and image reconstruction. Results are compared to the Medipix3RX chip, which provides analogue charge summing and four thresholds but not energy information for individual hits. Timepix3 can also be used as a platform for detailed sensor characterization since the time information is detailed enough to resolve the charge drift time for most sensor materials..

9593-36, Session 9

Growth and characterization of self-activated scintillator for dual gamma- and neutron- detector applications

Utpal N. Roy, Aleksey E. Bolotnikov, Giuseppe S. Camarda, Yonggang Cui, Rubi Gul, Anwar Hossain, Ge Yang, Ralph B. James, Brookhaven National Lab. (United States)

Most present-day scintillators are activated by doping with foreign elements that engender striations or a concentration gradient along the direction of growth, so rendering the host non-uniform, and thus degrading the uniformity and energy resolution for large-volume devices. The resolution for doped scintillators suffers serious degradation with increasing volume, thus lowering the yield and increase in the cost of large-volume detectors. Self-activated scintillators possibly are the best choice to resolve this problem. Growth and characterization of self-activated scintillator for dual gamma- and neutron- detector applications will be presented.

9593-37, Session 9

Synthesis of transparent nanocomposite monoliths for gamma scintillation

Yunxia Jin, Chao Liu, Tibor J. Hajagos, David Kishpaugh, Yi Chen, Qibing Pei, Univ. of California, Los Angeles (United States)

Heavy element loaded polymer composites have long been proposed to detect high energy X- and ?-rays via scintillation. The previously reported composite scintillation monoliths have achieved limited success because of the diminished light output resulting from fluorescence quenching and opacity. We report the synthesis of transparent nanocomposite monoliths comprising high-Z nanocrystals uniformly dispersed in polymer matrix at high loading content. The strategies to avoid luminescence quenching and opacity in the nanocomposite have produced transparent monoliths with high loading of nanocrystals while retaining the light yield of the neat polymer matrix. Photoelectric peak for Cs-137 gamma (662 keV) can be obtained from the monoliths.

9593-38, Session 9

Characterization and testing of EJ309 liquid scintillator detector

Bayarbadrakh Baramsai, Marian Jandel, Todd A. Bredeweg, Aaron Couture, Shea Mosby, Gencho Rusev, John L. Ullmann, Carrie L. Walker, Los Alamos National Lab. (United States)

LA-UR-15-21671

This work is part of a new neutron detector array (NEUANCE) development project.

NEUANCE is installed in the central cavity of the 4pi gamma-ray array DANCE located at Los Alamos Neutron Science Center. The detector system with simultaneous neutron and gamma-ray detection capability will provide data to investigate neutron induced capture and fission theory and it's applications.

The EJ309 scintillator was tested with different geometries, each coupled to a Hamamatsu photomultiplier tube (PMT) or a Silicon photomultiplier (SiPM) for the test measurements with standard gamma-ray and {252}Cf sources. GEANT4 was used to understand the light output and the optical photon transport in the scintillator. The detector geometry and optimum parameters for the data acquisition system were determined based on the test results and the simulations.

We gratefully acknowledge the support of the U.S. Department of Energy through the LANL/LDRD Program for the work. Part of this work was also supported by the Department of Energy, Office of Science, Nuclear Physics under the Early Career Award No. LANL20135009.

9593-39, Session 9

Development of a thin scintillation film fission-fragment detector and a novel neutron source

Gencho Y. Rusev, Marian Jandel, Evelyn M. Bond, Audrey R. Roman, Jaimie K. Daum, Rebecca K. Springs, Los Alamos National Lab. (United States)

Investigation of prompt fission and neutron-capture gamma rays from fissile actinide samples at the Detector for Advanced Neutron Capture Experiments (DANCE) requires use of a fission-fragment detector to provide a trigger or a veto signal. Development and testing of a Thin scintillation Film Detector (TFD) will be presented. A layered TFD detector composed of multiple U-235 samples, which served as an active target, has been tested at DANCE with a white-source neutron beam produced at the Los Alamos Neutron Science Center. Results from a systematic study of the performance of this detector will be reported.

In addition, a novel neutron source with fast neutron-emission timing has been designed in help with the TFD characterization. The development and the performance of the neutron source will also be presented.

We gratefully acknowledge the support of the U.S. Department of Energy through the LANL/LDRD Program and the U.S. Department of Energy, Office of Science, Nuclear Physics under the Early Career Award No. LANL20135009.

9593-40, Session 9

Electronic properties of ternary alkali-alkaline earth halide scintillators

Koushik Biswas, Changming Fang, Arkansas State Univ. (United States); Sanjoy Mukhopadhyay, National Security Technologies, LLC (United States)

A class of scintillators comprising of alkali and alkaline earth metal halides having the general formula AiBjXk, where A (alkali metal) = Na, K, Cs; B (alkali earth metal) = Ca, Sr, Ba; and X (halogen) = Cl, Br, I are of interest. Here i-j-k are typically 1-2-5 or 2-1-4 (for charge neutrality). However, basic understanding about these ternary compounds is incomplete. Here, we present the results of a systematic first-principles study on the crystal structures and electronic properties of these halides employing both the standard density-functional theory (DFT) within the local density approximation (LDA) or the generalized gradient approximation (GGA), and 'beyond DFT' methods using hybrid functionals. Role of activator doping (Eu2+) will be discussed.

9593-41, Session PWed

Networked gamma radiation detection system for tactical deployment

Sanjoy Mukhopadhyay, Richard J. Maurer, Ronald S. Wolff, Paul P. Guss, Ethan X. Smith, Stephen E. Mitchell, National Security Technologies, LLC (United States)

A networked gamma radiation detection system with directional sensitivity and energy spectral data acquisition capability is being developed by the National Security Technologies, LLC, Remote Sensing Laboratory to support the close and intense tactical engagement of law enforcement who carry out counterterrorism missions. In the proposed design, three clusters of 2" ? 4" ? 16" sodium iodide crystals ?4 each? with digiBASE-E ?for list mode data collection? would be placed at four corners of a minivan. To enhance localization and facilitate rapid identification of isotopes, advanced smart real-time localization and radioisotope identification algorithms like WAVRAD and NSCRAD will be incorporated. We will test a collection of algorithms and analysis that centers around the problem of radiation detection with a distributed sensor network.

We will study the basic characteristics of a radiation sensor network and focus on the trade-offs between false positive alarm rates, true positive alarm rates, and time to detect multiple radiation sources in a large area. Empirical and simulation analyses of critical system parameters, such as number of sensors, sensor placement, and sensor response functions, will be examined. This networked system will provide an integrated radiation detection architecture and framework with (i) a large nationally recognized search database equivalent that would help generate a common operational picture in a major radiological crisis; (ii) a robust reachback connectivity for search data to be evaluated by home teams; and, finally, (iii) a possibility of integrating search data from multi-agency responders.

9593-42, Session PWed

Possibility of gated silicon drift detector detecting hard x-ray

Hideharu Matsuura, Shinya Fukushima, Shungo Sakurai, Shohei Ishikawa, Akinobu Takeshita, Atsuki Hidaka, Osaka Electro-Communication Univ. (Japan)

One of the authors has proposed a simple-structure Silicon X-ray detector (Gated Silicon Drift Detector: GSDD), whose structure is much simpler than a commercial Silicon Drift Detector (SDD). SDDs contain multiple built-in metal-oxide-semiconductor field-effect transistors (MOSFETs) or implanted resistors whose fabrication processes lower the yield rate of detectors, and require at least two high-voltage sources. On the other hand, GSDDs do not contain the MOSFETs or implanted resistors. Although GSDDs contain multiple gates instead of p-rings in SDDs, no extra fabrication processes are required to form the gates because the metal gates are formed on the passivating oxide layer during the metallization of the anode and the p-ring. Moreover, GSDDs require only one high-voltage source. Therefore, GSDDs greatly reduce the cost of the X-ray detection system.

We fabricate prototype GSDDs that contained 0.625-mm-thick Si substrates with an active area of 18 mm2 operated by Peltier cooling and a single voltage source. Its energy resolution at 5.9 keV from an 55Fe source is 145 eV at -38 °C and -90 V.

The thicker the Si substrate is, the higher the absorption of X-rays by it is. We design GSDDs to detect X-ray photons with energies up to 80 keV for X-ray absorbance higher than 15%. We simulate the electric potential distribution in GSDDs with Si thicknesses from 0.5 to 3.0 mm. We obtain an adequate electric potential distribution in the thickness of 3.0 mm, and the capacitance of the GSDD remains small and its X-ray count rate remain high.

9593-43, Session PWed

Response function of planar Cd(Zn)Te detectors to beta-radiation

Alexandr A. Zakharchenko, Alexandr V. Rybka, Leonid N. Davydov, Vladimir E. Kutny, Manap A. Khazhmuradov, National Science Ctr. Kharkov Institute of Physics and Technology (Ukraine); Petro M. Fochuk, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine); Aleksey E. Bolotnikov, Ralph B. James, Brookhaven National Lab. (United States)

We investigated the response function of a planar CdZnTe detector designed for measurement of electron energy spectra and experimentally measured the response of CdZnTe detector to radiation of 90Sr/90Y reference radiation source. The model of the wide gap semiconductor gamma-ray detector, developed earlier, was used for the simulation of CdZnTe detector response functions by Monte-Carlo method. The simulated response functions of a CdZnTe detector agree well with the experimentally measured one with the use in the detector model of only two fitting parameters: products of mobility and average lifetime for electrons and holes. Other parameters of the model (bias voltage, equivalent noise charge, shaping time, detector unit geometry) correspond to the actual characteristics of the measuring channel. This agreement allows abandoning the measurements and using instead the proposed simulated response functions when the mu-tau products are known. It is expedient in the problem of obtaining beta radiation spectra from the mixed beta and gamma fields (e.g., at in situ determination of 137Cs and 90Sr sources activity). Some insignificant divergences between spectra were explained by a high enough level of noise of the preamplifier in which we did not apply temperature stabilization. The simulation has shown that the increase in the discrimination threshold largely eliminates divergences between measurement and simulation data. A similar effect is achieved at the application of thin metal filters. When exact determination of beta spectra for energy less than 100 keV is needed, it is necessary to use a measuring channel with noise level of 10 keV and below.

9593-44, Session PWed

The effect/influence of crystal thickness on the electrical characteristics of Cd(Zn) Te detectors

Valerii M. Sklyarchuk, Petro M. Fochuk, Ilarii Rarenko, Zinajida Zakharuk, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine); Aleksey E. Bolotnikov, Ralph B. James, Brookhaven National Lab. (United States)

The electrical characteristics of Cd(Zn)Te detectors with rectifying contacts and varying thickness were studied. It was established that the geometric dimensions affect the electrical properties. We find that the maximum value of the operating bias voltage and the electric field in the detector for moderate values of dark current can be achieved at a certain optimum crystal thickness. This observation is due to the combined effect of generation-recombination in the space-charge region and space-charge limited currents. Results of this study will be presented.

9593-45, Session PWed

Temperature-dependent electrical properties of high-resistivity CdTe

Petro M. Fochuk, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine); Yevhen Nykoniuk, National Univ. of Water Management and Natural Resources Application (Ukraine); Valerii M. Sklyarchuk, Zinajida Zakharuk, Serhii Dremlyuzhenko, Ilarii Rarenko, Yuriy Fedkovych Chernivtsi

National Univ. (Ukraine); Aleksey E. Bolotnikov, Ralph B. James, Brookhaven National Lab. (United States)

High-resistivity CdTe crystals were grown by a modified technology. The temperature dependences of the charge-carrier density, ionization energy of the donors, degree of compensation, and dependency of the photo-characteristics of the material on the photo-excitation level were studied. The role of spatial micro-scale inhomogeneities on the electrical properties was identified. Samples showed a high detection resolution for Am-241.

9593-46, Session PWed

Regularities of melting and crystallization in CdTe-Al alloys

Andriy I. Kanak, Oleh Kopach, Petro M. Fochuk, Larysa P. Shcherbak, Igor Nakonechnyj, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine); Aleksey E. Bolotnikov, Ralph B. James, Brookhaven National Lab. (United States)

The differential thermal analysis was used to study CdTe-Al system. We investigated parameters of melting and crystallization processes of this system. Three alloys with different content of aluminum (2, 4 and 6 mol. % Al) were synthesized. Research was conducted by cyclic heating and cooling with isothermal holding during 10-, 30- and 60 minutes. Aluminum concentration on the CdTe phase transitions parameters' was established.

9593-47, Session PWed

Development of wide-band-gap AlGaAs photodiodes for scintillation-based radiation detection applications

Xiao Jie Chen, Erik B. Johnson, Chad M. Whitney, Radiation Monitoring Devices, Inc. (United States); Taehoon Kang, Michigan State Univ. (United States); Mark D. Hammig, Univ. of Michigan (United States); James F. Christian, Radiation Monitoring Devices, Inc. (United States)

The development of high-performance scintillation materials that emit light below 400 nm has prompted the development of improved solid-state UV photodetectors. While silicon provides a mature context for UV photodetectors, the high dark current due to its low band-gap (1.1eV) limits the signal-to-noise performance as the detector is scaled to large areas. Photodetectors fabricated in materials with a larger band-gap have the potential to surmount the performance limitations experienced by silicon. AlGaAs is a material that provides a band gap from 1.55eV to 2.13 eV, depending on Al concentration. Using high Al concentration AlGaAs to engineer a wider bandgap >2eV is very desirable in terms of reducing dark noise, however, due to its strong absorption of UV-light at the material surface, it may limit the quantum efficiency <400 nm due to surface effects. By introducing surface layers that have a longer penetration depth for UV photons, promises a boost in quantum efficiency in the UV while maintaining low dark current

This work describes the development of photodiodes fabricated in AlGaAs. It presents the design of the photodiodes, simulations of their performance, the fabrication process, along with characterization data of fabricated photodiode samples. We report on the surface effects of high aluminum concentrated AlGaAs to provide a high quantum efficiency for photons below 400 nm, providing information on reflectivity and charge collection.

9593-48, Session PWed

Gamma radiation sensor by using Si implanted SONOS device

Wen-Ching Hsieh, Minghsin Univ. of Science and Technology (Taiwan); Fuh-Cheng Jong, Southern Taiwan Univ. of Science & Technology (Taiwan); Shich-Chuan Wu, National Nano Device Labs. (Taiwan)

The Si implantation silicon -oxide-nitride-oxide-silicon (hereafter Si-SONOS) can be candidates for nonvolatile gamma radiation sensors. In the case of Si-SONOS gamma radiation sensors, the gamma radiation induces a significant decrease of threshold voltage VT. The change of threshold voltage for Si-SONOS after gamma irradiation has a strong correlation to the dose of gamma ray exposure as well. The Si-SONOS capacitor device in this study has demonstrated the better feasibility for non-volatile gamma radiation sensing in the future.

EXPERIMENTAL

In this paper, the changes of VT between SONOS & Si-SONOS after Gamma ray expose were compared. N-type SONOS capacitor structures were fabricated on p-type resistivity 15-25ohm-cm Si <100> substrate. We use thermal SiO2 for tunneling oxide, CVD Si3N4 or Si implanted CVD Si3N4 for trapping layer, CVD TEOS SiO2 for blocking oxide of ONO gate dielectric. The SiO2- Si3N4- SiO2 (hereafter ONO) gate stack consists of a 200 Å ~300 Å thick silicon nitride trapping layer and 50 Å ~100 Å bottom and top silicon oxides. To write data on these SONOS & Si-SONOS capacity devices, gamma radiation was exposed on these SONOS & Si-SONOS capacity devices. For the data read, the change of VT in this case can be correlated to the exposure dosage of gamma radiation as well. These trapped charges can be always accumulated in gate dielectric layer, so dose record can't be destroyed by data write and read.

RESULTS AND DISCUSSIONS

As illustrated in figure 3 it can be seen that the capacity to voltage curves (C-V curve) of Si-SONOS shifted far to the left after 10 Mrad of gamma irradiation. This implies that gamma radiation induces a significant decrease of VT for Si-SONOS. The amount of decrease of VT is about 2.5 volts. It is considered that the change is due to significant increase of net positive trapped charges in the Si implantation ONO (hereafter Si-ONO) gate dielectric layer after gamma irradiation. From figure 4, it also can be seen that C-V curve of SONOS shifted to the left after 10 Mrad of gamma irradiation. The amount of decrease of VT is up to about 2 volts. As shown in the experiment data, the change of VT for Si-SONOS is more than that for SONOS after 10Mrad TID of gamma irradiation. The dependence of VT shift on radiation dose for Si-SONOS is more than that for SONOS after gamma irradiation. It can be explained that the amount of net positive trapped charges in the Si-ONO gate dielectric is greater than that in the ONO gate dielectric after gamma irradiation. These radiation-induced shifts in the irradiated device are a combination of two effects; the first effect is a result from the loss of stored charge in the ONO trapping layer and the second effect is due to a build-up of positive charge resulted from asymmetric trapping of electrons and holes in the ONO trapping layer. These two combined effects cause a large threshold voltage shift in the Si-SONOS but create a smaller threshold voltage shift in the SONOS. In figure 5, it further shows the threshold voltage change as a function of TID of gamma radiation for Si-SONOS. The decrease of threshold voltage for Si-SONOS are plotted against the TID of gamma ray radiation received. The decrease of gate threshold voltage in this case can be correlated to the increase of positive trapped charges in the insulator and the increase of exposure dosage for gamma radiation as well. In figure 6, it further shows the VT change as a function of TID of gamma radiation for SONOS. The decrease of VT for SONOS are plotted against the TID of gamma ray radiation received. As shown in the experiment data, the effect of gamma ray dosage on the VT of the Si-SONOS device is more than that of SONOS device after 10 Mrad TID of gamma ray irradiation. This capacity device with Si-ONO gate dielectric in this study has demonstrated the better feasibility of using Si-SONOS capacity device for the application of gamma ray dosimeter.

Bismuth- and lithium-loaded plastic scintillators for gamma and neutron detection

H. Paul Martinez, Nerine J. Cherepy, Robert D. Sanner, Thomas T. Tillotson, Patrick R. Beck, Erik L. Swanberg,

Stephen A. Payne, Lawrence Livermore National Lab. (United States)

Plastic scintillators are widely deployed for ionizing radiation detection, as they can be fabricated in large sizes, for high detection efficiency, however commercial plastics are limited in use for gamma spectroscopy, since their photopeak is too weak, due to low Z, and neutron detection, since proton recoils are indistinguishable from other ionizing radiation absorption events in standard plastics. We are working on fabrication of transparent plastic scintillators based on polyvinyltoluene (PVT) with high loading of bismuth metallorganics for gamma spectroscopy, and with lithium metallorganics for neutron detection. When activated with Iridium complex fluors, PVT scintillators containing 22 wt% bismuth provide energy resolution of 10% at 662 keV. A PVT plastic formulation including 1.3 wt% lithium-6 provides a neutron capture peak at 525 keVee, with 11% resolution and 90% efficiency for thermal neutron capture in 2mm thickness.

9593-50, Session PWed

Comparative study of CdMnTe crystals grown by three different methods

Anwar Hossain, Aleksey Bolotnikov, Giuseppe Camarda, Yonggang Cui, Rubi Gul, Brookhaven National Lab. (United States); Kihyun Kim, Korea Univ. College of Health Sciences (Korea, Republic of); Utpal Roy, Ge Yang, Ralph James, Brookhaven National Lab. (United States)

CdMnTe has several potential advantages over CdZnTe as a room-temperature gamma-ray detector. However, there remain many shortcomings in the growth process of CdMnTe that limit the yield of large-volume single crystals with high resistivity and high electron-lifetimes. We recently characterized various bulk defects in the material, including Te inclusions, twins, and dislocations, as well as differences in the electrical properties of CdMnTe crystals grown by three different methods: The travelling heater method (THM), the modified floating zone (MFZ), and the Bridgman method (BM). In this presentation, we outline in detail our comparative findings and assessment of the three differently grown crystals.

Ionizing radiation detection by Yb-doped silica optical fibers

Cristina De Mattia, Ivan Veronese, Univ. degli Studi di Milano (Italy); Mauro Fasoli, Norberto Chiodini, Univ. degli Studi di Milano-Bicocca (Italy); Eleonora Mones, Azienda Ospedaliera Maggiore della Carità (Italy); Marie Claire Cantone, Simone Cialdi, Marco Gargano, Nicola Ludwig, Letizia Bonizzoni, Univ. degli Studi di Milano (Italy); Anna Vedda, Univ. degli Studi di Milano-Bicocca (Italy)

Rare earths-doped silica optical fibers have shown promising results for ionizing radiation monitoring, thanks to their radio-luminescence (RL) properties. However, the use of these systems for accurate and precise dosimetric measurements in radiation fields above the Cerenkov energy threshold, like those employed in radiation therapy, is still challenging, since a spurious luminescence, namely the “stem effect,” is also generated in the passive fiber portion exposed to radiation. The spurious signal mainly occurs in the UV-VIS region, therefore a dopant emitting in the near infrared may be suitable for an optical discrimination of the stem effect.

In this work, the RL and dosimetric properties of Yb-doped silica optical fibers, produced by sol-gel technique, are studied, together with the methods and instruments to achieve an efficient optical detection the Yb3+ emission, characterized by a sharp line at about 975 nm.

The results demonstrate that the RL of Yb3+ is free from any spectral superposition with the spurious luminescence. This aspect, in addition with the suitable linearity, reproducibility, and sensitivity properties of the Yb-doped fibers, paves the way to their use in applications where an efficient stem effect removal is required.

Isochronal annealing and passivation studies on 50 um 4H-SiC epitaxial layers

Mohammad A. Mannan, Khai V. Nguyen, Rahmi O. Pak, Cihan Oner, Krishna C. Mandal, Univ. of South Carolina (United States)

Schottky barrier radiation detectors were fabricated on the Si-face of 50 μm thick detector grade n-type 4H-SiC epitaxial layers. The junction properties of the fabricated detectors were investigated by current-voltage (I-V) and capacitance-voltage (C-V) measurements. The radiation detector performances were evaluated by alpha pulse height spectroscopy using a 0.1 μCi 241Am radiation source. Deep level transient spectroscopy (DLTS) measurements were carried out to identify and characterize the electrically active defect levels present in the epitaxial layers. The performance of the detector was found to be limited by the presence of electrically active defect centers in the epilayer. Deep level defects were reduced significantly by isochronal annealing and by using a new passivation method. Energy resolution of the detector was found to have improved following the reduction of the life time killing defects that were responsible for preventing full charge collection. Systematic and thorough C-DLTS studies were conducted prior and subsequent to isochronal annealing to observe evolution of the deep level defects.

Investigation of metal contacts on high-resistivity amorphous selenium alloy films

Krishna C. Mandal, Rahmi O. Pak, Mohammad A. Mannan, Khai V. Nguyen, Cihan Oner, Univ. of South Carolina (United States)

Amorphous selenium (a-Se) alloy materials with arsenic and chlorine doping were synthesized for room temperature nuclear radiation detection applications using an optimized alloy composition for enhanced charge transport properties. A two-step synthesis process has been implemented to first synthesize the a-Se (As) and a-Se (Cl) master alloys from zone-refined Se (~7N), and then synthesize the final mixed alloy used in thin-film deposition on oxidized aluminum and indium tin oxide (ITO) coated glass substrates. Material purity, morphology, and compositional characteristics of the a-Se alloy materials were confirmed using glow discharge mass spectroscopy (GDMS), x-ray diffraction (XRD), differential scanning calorimetry (DSC), and x-ray photoelectron spectroscopy (XPS). Eight metals of various work functions (Ni, W, Au, Pd, In, Cu, Sn, and Mo) were selected for Schottky detector performance studies. Current-voltage (I-V), capacitance voltage (C-V), and current transient measurements were performed at different temperatures to investigate the contact behavior and stability characteristics. Single and multi-element detectors with and without various blocking contacts (electron and holes) have been fabricated and tested and the results show promising characteristics for x-ray and high energy nuclear radiations with its high dark resistivity (1012 – 1013 ?-cm) and large area scalability.

9593-57, Session PWed

Defect characterization of nuclear detector grade Cd0.9Zn0.1Te crystals using electron beam induced current (EBIC) imaging, thermally stimulated current (TSC), and deep level transient spectroscopy (DLTS)

Rahmi O. Pak, Khai V. Nguyen, Cihan Oner, Mohammad A. Mannan, Krishna C. Mandal, Univ. of South Carolina (United States)

Semi-insulating Cd0.9Zn0.1Te nuclear detector grade crystals were grown by the tellurium solvent method from zone refined (7N) precursor materials. The processed crystals from the grown ingot were thoroughly characterized using electron beam induced current (EBIC) contrast imaging. The EBIC results were correlated with the infrared (IR) transmittance mapping, which confirms the variation of contrasts in EBIC is due to non-uniform distribution of tellurium precipitates in the grown CZT crystal. Electrical characteristics of defect regions in the fabricated detectors were further investigated using I-V measurements, spreading resistance microscopy (SSRM), deep level transient spectroscopy (DLTS), and thermally stimulated current (TSC) measurements. Finally, to demonstrate the high quality of the grown CZT crystals using the low temperature tellurium solvent method, pulse height spectra (PHS) measurements were carried out using gamma radiation sources of 241Am and 137Cs and the results will be presented.

Feasibility studies of icosahedral boron arsenide (B12As2) for thermal neutron detection

Yonggang Cui, Aleksey E. Bolotnikov, Giuseppe S. Camarda, Rubi Gul, Anwar Hossain, Utpal N. Roy, Ge Yang, Brookhaven National Lab. (United States); James H. Edgar, Ugochukwu Nwagwu, Kansas State Univ. (United States); Ralph B. James, Brookhaven National Lab. (United States)

The global shortage of 3He has motivated researchers to seek alternative materials for thermal neutron detection. Among them, solid-state detectors, which have potential advantages of compact size, light-weight, easy maintenance and low cost, are of special interest. Boron compound semiconductors are excellent candidates because the B-10 isotope has large thermal neutron capture cross-section (3840 barns) and is readily abundant (20% of natural boron). Currently we are investigating the feasibility of icosahedral boron arsenide (B12As2) materials as thermal neutron detectors. We studied both bulk materials grown from a metal flux solution and thin films produced by a chemical vapor deposition (CVD) process. In addition, we explored electron beam physical vapor deposition (EBPVD) process to produce B12As2 thin-film materials. For material characterization, we measured the photocurrent response of the materials with blue light and used Hall-effect measurements to determine the charge carrier type and its mobility. We also fabricated planar devices and conducted electrical characterization by measuring low- temperature, and above- room temperature I-V characteristic plots. In this presentation, we will discuss the characterization of the materials and devices and present our test results.

Interface modification of CdZnTe-based radiation detectors by glancing angle ion sputtering

Stephen Babalola, Jonathan Lassiter, David Brown, Charles Payton, Tsige Zergaw, Alabama A&M Univ. (United States); Anwar Hossain, Brookhaven National Lab. (United States)

CdZnTe has been well investigated as a top choice for room temperature radiation detectors due to its attractive physical and opto-electronic properties and room-temperature operation capabilities. The bulk of CdZnTe has been extensively studied, understoon and improved upon, hence the device fabrication factors are becoming more prominent and need to be addressed in order to obtain high performance detector devices. The main problem with current devices are charge trapping at surfaces and interfaces, which cause charge loss, distortion of near-surface electric field, high leakage current and deteriorates device performance. The surface and interfacial states of the metal-semiconductor interface formed affects the performance of CdZnTe nuclear detectors.. In this work we have modified CZT crystal surface, and hence the metal-semiconductor interface, by adding a surface preparation step of cleansing the surfaces of the CZT crystals with argon ion at a glancing angle in high vacuum, followed by gold contact sputtering using the Ion-Beam-Assisted Deposition (IBAD) technique. We went further to deposit a thin layer of nickel followed by sputtered gold and compared the interface properties. We characterized the ion-cleansed detectors and compared the interface properties with those of un-cleansed detectors. Results showing improvement of surface leakeage current and detector performance due to the additional step are presented.

Conference 9594: Medical Applications of Radiation Detectors V

SPIE. OPTICS+ PHOTONICS OPTICAL ENGINEERING+ APPLICATIONS

Thursday 13–13 August 2015

9594-1, Session 1

Dual-energy x-ray computed tomography system using a cadmium telluride detector and its application to gadolinium imaging

Yasuhiro Miura, Eiichi Sato, Yasuyuki Oda, Satoshi Yamaguchi, Iwate Medical Univ. (Japan); Osahiko Hagiwara, Hiroshi Matsukiyo, Manabu Watanabe, Shinya Kusachi, Toho Univ. (Japan)

To obtain two tomograms with two different-photon-energy ranges simultaneously, we performed dual-energy X-ray photon counting using a cadmium telluride (CdTe) detector, two comparators, two frequency-voltage converters (FVCs), and an analog digital converter (ADC). X-ray photons are detected using the CdTe detector with an energy resolution of 1% at 122 keV, and the event pulses from a shaping amplifier are sent to two comparators simultaneously to regulate two thresholds of photon energy. The logical pulses from a comparator are sent to an FVC to convert count rates into voltages. The smoothed outputs from the two FVCs are input to a personal computer through the ADC to carry out dual-energy imaging. The DE-CT was performed using gadolinium (Gd) contrast media with the Gd-K-edge energy of 50.2 keV. To observe contrast variations with changes in the energy range, we performed energy-dispersive computed tomography utilizing the dual-energy photon counting at a tube voltage of 80 kV. Two threshold energies were 30.0 and 50.2 keV, and two-different-energy tomograms were obtained simultaneously with two energy ranges of 30.0-50.2 keV and 50.2-80.0 keV. The maximum count rate was below 10 kilocounts per second with energies ranging from 30.0 to 80.0 keV, and the exposure time for tomography was 10 min.

9594-3, Session 1

X-ray imaging with scintillator-sensitized hybrid organic photodetectors

Patric Büchele, Siemens AG (Germany) and Karlsruhe Institute of Technology (Germany); Genesis N. Ankah, Leibniz-Institut für Neue Materialien GmbH (Germany); Moses Richter, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); Sandro F. Tedde, Rene Fischer, Barbara Wegler, Wilhelm Metzger, Markus Biele, Siemens AG (Germany); Gebhard J. Matt, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); Samuele Lilliu, Masdar Institute of Science & Technology (United Arab Emirates); Christoph J. Brabec, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); Tobias Kraus, Leibniz-Institut für Neue Materialien GmbH (Germany); Oliver Schmidt, Siemens AG (Germany)

Medical imaging requires large area X-ray detectors due to the limited ability to focus X-ray radiation. Most detectors today are realized by stacking a scintillating layer on top of an amorphous silicon (a-Si:H) photodetector array. These scintillators convert the incoming X-ray photons into visible light, which then can be detected by the photodiodes. Several concepts have been proposed recently to leverage the advantages of organic semiconductors in the field of flat panel X-ray detectors. The organic photodetector (OPD) technology is based on an interpenetrating donor-acceptor network of e.g. phenyl-C61-butyric acid methyl ester (PCBM) and poly(3-hexylthiophen-2,5-diyl) (P3HT), which is known as bulk heterojunction (BHJ). Solution-processed photodetectors provide exiting new opportunities for the realization of flat panel X-ray detectors as they can be processed from the solution phase on large areas at low cost. In combination with incorporated X-ray absorbing scintillators like terbium doped gadolinium oxysulfide (GOS:Tb) inside of the BHJ, a quasi-direct X-ray detection scheme has been realized. Significant advances towards cost-effective high resolution x-ray imaging are expected from this technology. These hybrid-organic photodiodes (HPDs) promise to achieve a modulation transfer function (MTF) that is as high as in direct converting materials such as amorphous selenium. Here we will demonstrate flat panel X-ray imaging detectors with a hybrid-organic photoactive layer, deposited by high throughput spraycoating. The a-Si:H TFT backplane has a pixel array of 256x256 pixels (pixel pitch of 98 μm). The emitted light from an X-ray excited GOS:Tb with a diameter of ~1.8 μm is absorbed within 300nm in the BHJ. This leads to an optical crosstalk, which is negligible compared to the pixel pitch. A comparison of HPDs with different thicknesses and GOS:Tb contents will be presented. Investigations include sample preparation and characterization by 3D profilometry and scanning electron microscopy (SEM) cross-sections, morphological data from grazing incidence wide angle X-ray scattering (GIWAXS) measurements. Optoelectronical data contains IV characteristics, X-ray conversion rates and mobility measurements from X-ray charge extraction by linearly increasing voltage (X-CELIV). X-ray images will demonstrate the feasibility on system level.

9594-4, Session 1

Monochromatic x-ray photon counting using a microcomputer and its application to iodine imaging

Yasuyuki Oda, Eiichi Sato, Satoshi Yamaguchi, Iwate Medical Univ. (Japan); Osahiko Hagiwara, Hiroshi Matsukiyo, Manabu Watanabe, Shinya Kusachi, Toho Univ. (Japan)

To perform quasi-monochromatic imaging, a photon-energy range should be selected by determining both the energy level and the width. Currently, the energy range for energy dispersive computed tomography (ED-CT) can be selected using a multichannel analyzer. However, the photon-count subtraction using a computer program is necessary using two comparators for determining two threshold energies for subtraction. Without the program, a microcomputer is useful for counting X-ray photons between two threshold energies. The monochromatic photon counting was performed using two comparators and a microcomputer. The low and high-threshold energies are determined using low and high-energy comparators, respectively. The microcomputer produces a single logical pulse when only a logical pulse from a low-energy comparator is input to the microcomputer. Next, the microcomputer does not produce the pulse when two pulses from low and high comparators are input to the microcomputer, simultaneously. The logical pulses from the microcomputer are input to a frequency-voltage converter (FVC) to convert count rates into voltages; the rate is proportion to the voltage. The output voltage from the FVC is sent to a personal computer through an analog-digital converter to reconstruct tomograms. The X-ray projection curves for tomography are obtained by repeated linear scans and rotations of the object, and the scanning is conducted in both directions of its movement. Iodine (I) K-edge CT was performed using I contrast media and X-ray photons with an energy range from 35 to 55 keV, since photons with energies just beyond I-K-edge energy 33.2 keV are absorbed effectively by I toms.

9594-5, Session 1

Si-strip photon counting detectors for contrast-enhanced spectral mammography *(Invited Paper)*

Buxin Chen, Ingrid Reiser, The Univ. of Chicago (United States); Jan C. Wessel, DxRay Inc. (United States) and Interon AS (Norway); Nail Malakhov, Gregor Wawrzyniak, Interon AS (Norway); Neal E. Hartsough, Thulasidharan Gandhi, DxRay Inc. (United States); Chin-Tu Chen, The Univ. of Chicago (United States); Einar Nygard, Interon AS (Norway); Jan S. Iwanczyk, DxRay, Inc. (United States); William C. Barber, DxRay, Inc. (United States) and Interon AS (Norway)

We report on the development of silicon (Si) strip detectors for energy-resolved clinical mammography. Typically, X-ray integrating detectors based on scintillating cesium iodide CsI(Tl) or amorphous selenium (a-Se) are used in most commercial systems. Recently, mammography instrumentation has been introduced based on photon counting Si strip detectors. The required performance for mammography in terms of the output count rate (OCR), spatial resolution, and dynamic range must be obtained with sufficient field of view (FOV) for the application, thus requiring the tiling of pixel arrays and particular scanning techniques. Room temperature Si strip detector, operating as direct conversion x-ray sensors, can provide the required speed when connected to application specific integrated circuits (ASICs) operating at fast peaking times with multiple fixed thresholds per pixel, provided that the sensors are designed for rapid signal formation across the X-ray energy ranges of the application. We present our methods and results from the optimization of Si-strip detectors for contrast enhanced spectral mammography. We describe the detector optimization methods that provide the required spatial resolution, low noise, high count rate capabilities, and minimal power consumption. We further describe the method being developed for quantifying iodine contrast using the energy-resolved detector with fixed thresholds. We demonstrate the feasibility of the method by scanning an iodine phantom with clinically relevant contrast levels.

9594-6, Session 2

Advances in molecular breast imaging *(Invited Paper)*

Haris Kudrolli, Timothy R. Garcia, Aleksandr Kivenson, Gamma Medica, Inc. (United States)

We will present the advances in Molecular Breast Imaging (MBI) instrumentation that allow for detection of breast cancer with high sensitivity, high specificity and low radiation exposure to the patient. In MBI, a patient is injected with Tc-99m labeled radiotracer that is preferential taken up by breast lesions and is detected using two planar arrays of cadmium zinc telluride (CZT) detectors in close proximity to the breast. Modifications to the collimator from a traditional hexagonal shaped collimator to tungsten collimator registered to the CZT pixels and optimized for breast imaging configuration has allowed the reduction of patient dose from 20 mCi to 8 mCi of Tc-99m-sestamibi. We will present our ongoing efforts to further reduce the injected dose by optimizations to the collimator and improvements to CZT detector performance. Development of the biopsy guidance capability with MBI will also be presented.

9594-7, Session 2

Integration of hardware and estimation methods in the design process for solid-state detectors

Esen Salcin, College of Optical Sciences, The Univ. of Arizona (United States); Lars R Furenlid, The Univ. of Arizona (United States)

In a traditional detector design process, questions about how the detector signals will be processed or what estimation algorithms will be used to extract imaged source attributes usually do not enter as part of the development stage. Generally the hardware and the estimation algorithms, which we will refer to as simply the “software” of the system, are developed separately by independent teams who have little visibility for each other’s process. The development is focused on designing the hardware first and the software is appended later that is made to work on the existing platform. For example, in an imaging semiconductor detector with pixel geometry, the simplest algorithm to estimate the x-ray/gamma-ray photon interaction location is to identify the pixel with the largest amplitude and assign the event to that pixel. In this case, the smallest resolution element becomes the pixel element itself and it is not possible to distinguish changes in the event locations smaller than the pixel size. It follows that, the decision of employing such an estimation algorithm drives the hardware design in a way to make pixels as small as possible.

In this work, we propose the idea of integrating the detector hardware and software design and development flows based on the expectation that the detector system can perform the best when the hardware is optimized for the algorithms that are running on it. Designing hardware for the estimators that take into account signal statistics can open a way to engineer detector signals, which are perhaps not intuitive and different from the current designs, but ultimately provide increased performance. We investigate this development methodology on an example system; a double-sided strip CdTe detector. We use Fisher Information as a “recipe’” on our understanding of how the detector signals should be shaped in order to obtain large signal separation for small differences in x-ray/gamma-ray event attributes we are interested in. By identifying the physical detector parameters that have influence on Fisher Information, we propose a list of detector parameters and their potential specifications based on this new methodology. We compare how the hardware design specifications change with the employment of different estimation algorithms.

Optimization of an adaptive SPECT system with the scanning linear estimator

Nasrin Ghanbari, Eric Clarkson, Matthew A. Kupinski, The Univ. of Arizona (United States)

Optimization of an Adaptive SPECT System with the Scanning Linear Estimator

The adaptive single-photon emission computed tomography (SPECT) system studied here acquires an initial scout image to obtain preliminary information about the object and then adjusts the configuration by selecting the size of the pinhole and the magnification that optimize system performance on an ensemble of virtual objects generated to be consistent with the scout data. In this study the object is a lumpy background that contains a Gaussian signal with a known width and amplitude. The virtual objects in the ensemble are imaged by all of the available configurations and the subsequent images are evaluated with the scanning linear estimator to obtain an estimate of the signal width and amplitude. The EMSE on the virtual ensemble between the estimated and the true parameters serves as the performance figure of merit for selecting the optimum configuration.

The results indicate that variability in the original object background and signal parameters leads to a specific optimum configuration in each case. A statistical study carried out for a number of objects show that the adaptive system on average performs better than its non-adaptive counterpart.

9594-10, Session 2

Fisher information analysis of digital pulse timing

Maria D. Ruiz-Gonzalez, Lars R. Furenlid, The Univ. of Arizona (United States)

In PET imaging with digital estimation of pulse timing, there is a trade-off between the sampling rate, the amount of data acquired, and the resulting timing resolution of a detector. In order to develop an efficient data acquisition system, the acquired data reported should be be the minimum number of digital samples that contains the information needed to achieve desired temporal resolution. We have written a simulation package that performs a Fisher Information analysis of simulated scintillation pulses with arbitrary decay times, shaper support, and A/D conversion rates. The results obtained in this work allow us to determine which parts of the digitized waveform are most needed for maximum likelihood timing analysis.

9594-11, Session 3

Properties of transparent (Gd,Lu)3(Al,Ga)5O12:Ce ceramic with Ca and Mg co-dopants *(Invited Paper)*

Yimin Wang, Gary Baldoni, William H. Rhodes, Urmila Shirwadkar, Charles Brecher, Chuncheng Ji, Jarek Glodo, Kanai S. Shah, Radiation Monitoring Devices, Inc. (United States)

Mixed lutetium/gadolinium and gallium/aluminum based garnets have a great potential as host structures for scintillation materials for medical imaging due to their cubic structure, high density, chemical radiation stability as well as high degree of transparency. The isotropic optical properties of garnets allow the fabrication of fully transparent, high-performance polycrystalline ceramic scintillator materials. Lutetium/Gadolinium aluminum/gallium garnets ((Gd,Lu)3(Al,Ga)5O12:Ce (GLuGAG:Ce, Gd3(Al,Ga)5O12:Ce (GGAG:Ce)) feature high effective atomic number and good light yield, which make them particularly attractive for Positron Emission Tomography (PET) and other ?-ray detection applications. The ceramic processing route offers an attractive alternative to single crystal growth for obtaining scintillator materials at relatively low temperature and reasonable cost with flexibility in dimension control as well as activator concentration adjustment.

For PET application, the decay and time resolution are critical for achieving the better resolution of the scan. The main decay component of most Ce-doped mixed garnet materials such as GLuGAG:Ce is about 80 ns. It has been reported co-doping GGAG:Ce (Gd3(Ga,Al)5O12:Ce) single crystal with different co-dopant such as Ca and B can effectively improve the decay of GGAG:Ce single crystal. In this study, Ce doped (Gd,Lu)3(Al,Ga)5O12 ceramic was co-doped with Ca, Mg and additional Ce to improve the scintillation properties. Transparent polycrystalline (Gd, Lu)3(Al,Ga)5O12:Ce ceramics with Ca, Mg co-dopant and additional Ce dopant were prepared by the sintering-HIP approach. The properties and microstructures of the ceramics were controlled by varying the processing parameters during sintering. The scintillation decay and light yield under gamma-ray excitation was investigated by using 137Cs excitation sources. The results shows the decay time of the sample with Ca co-dopant decreases from 80 ns to 39 ns with increasing Ca dopant level. Increasing Ce dopant level from 0.6 at% to 1.8 at% (with respect to (Gd+Lu)) slightly decreases the light yield of the ceramic without influence on decay. The transmission and excitation spectra were also measured and used to explain the results. The results shows the decay of the GLuGAG:Ce ceramic can be effectively tailored and improved by co-doping the ceramic for future PET applications.

9594-12, Session 3

Biomimetic-integrated surface nanostructures for medical imaging scintillation radiation

Ya Sha Yi, Univ. of Michigan (United States)

Inorganic scintillators are widely used in modern medical imaging modalities as converter for the x-rays and ?-radiation; they are also used to obtain information about the interior of the body, like x-ray, CT and PET scan. Most of the high-density scintillators have a high refractive index, so when the light travels from inside the crystal to the air, the total reflection critical angle is small, most of light is trapped in the crystal, only 10-30% of the light from the scintillator can enter into the photodetector, the majority of light couldn't be effectively extracted, which seriously affected the detection system's efficiency and detection sensitivity. The use of micro and nano photonics can help us to explore new structural flashing material, such as artificial micro-nano structures, photonic crystals, optical microcavity, and surface plasmon materials. Artificial micro-nano structure can improve the extraction efficiency of light-emitting materials (LED) and is becoming more mature. However, the idea to apply this novel photonic structure for scintillator has just started. In this work, we have investigated a novel class of nano scale devices based on photonic structures that function as efficient light extraction devices for scintillator detectors. We have studied the light output enhancement characteristics of Lu2SiO5:Ce thin film scintillator devices, similar mechanism can be extended to various types of scintillator detectors, such as ?-CuI single crystal and doped Tb3+ glass. We have designed light extraction structures based on their optical properties by using numerical simulation and optimized the sample preparation process, so that the overall efficiency of these scintillator detectors is increased significantly.

9594-14, Session 3

Development of an LSO-MPPC x-ray spectrometer and its application to high-count-rate energy-dispersive computed tomography using a high-speed linear scanner

Eiichi Sato, Yasuyuki Oda, Satoshi Yamaguchi, Iwate Medical Univ. (Japan); Osahiko Hagiwara, Hiroshi Matsukiyo, Toho Univ. (Japan); Manabu Watanabe, Iwate Medical Univ. (Japan) and Toho Univ. (Japan); Shinya Kusachi, Toho Univ. (Japan)

To measure X-ray and gamma-ray spectra with high count rates, we developed an LSO-MPPC spectrometer. Photocurrents flowing through an MPPC are converted into voltages and amplified using a high-speed current-voltage (I-V) amplifier. Event pulses from the amplifier are sent to a multichannel analyzer (MCA) to measure spectra. The maximum energy

increased with increasing tube voltage. In contrast, the bremsstrahlung peak energy increased with the increase in the tube voltage and the insertion of a 5.0-mm-thick aluminum filter. The energy-dispersive computed tomography (ED-CT) system consists of following main components: an X-ray generator, a turn table, a high-speed linear X-ray scanner, comparators, frequency voltage converters, an analog-digital converter (ADC), and a personal computer (PC). The X-ray projection curves for tomography are obtained by repeated linear scans and rotations of the object, and the scanning is conducted in both directions of its movement. The event pulses from the spectrometer are input to comparators, and the count rates are converted into voltages and sent to the PC through the ADC. The maximum count rate was approximately 1 Mcps, and the scan velocity was beyond 100 mm/s.

9594-15, Session 4

GPU programming for biomedical imaging *(Invited Paper)*

Luca Caucci, Lars R. Furenlid, The Univ. of Arizona (United States)

Driven by the insatiable demand for real-time high-definition 3D graphics, programmable graphics processing units (or GPUs) have evolved into highly parallel, multithreaded, manycore processors with tremendous computational horsepower. No longer confined to the entertainment industry, GPU technology has found applications in many scientific fields, ranging from signal processing to medical imaging, and from life sciences to fluid dynamics. This paper summarized the basic concepts of GPU programming and provides introductory details about the CUDA computing platform. CUDA is a minimal extension to the C/C++ programming language that allows the development of parallel algorithms that can run on modern GPUs. We consider two concrete examples of GPU programming related to the field of medical imaging. In the first example, we discuss a real-time maximum-likelihood algorithm for the estimation of gamma-ray photon parameters from photomultiplier (PMT) tube data. In the second example, we examine a possible GPU implementation of the maximum-likelihood expectation-maximization (MLEM) algorithm. These examples have the dual intent of 1) showing how highly parallelizable algorithms can be implemented in CUDA; and 2) illustrating the unique capabilities (such as texture and constant memory spaces) of today's GPU devices. We conclude this paper by arguing that GPU technology will enable the development of new detector concepts---such as photon-processing detectors---capable of performing maximum-likelihood estimation of parameters (such as position, energy, time of arrival, direction of propagation, etc.) on a photon-by-photon basis.

9594-16, Session 4

Design of photonic-channeled x-ray detector array for single-grating x-ray differential phase contrast imaging system

Yuzuru Takashima, Young-Sik Kim, Chris Summitt, Sunglin Wang, The Univ. of Arizona (United States)

Grating based X-ray differential phase contrast (DPC) imaging systems employing an incoherent X-ray source are widely adopted for medical imaging applications. Thanks to the grating-based source, the overall length of the system is on the order of meters, which is substantially shorter compared to other system employing sources such as synchrotron radiation light sources or propagation based detection methods which typically requires more than tens of meters of propagation distance. On the other hand, the limited absorption of the source and detector gratings impose a trade-off between the signal contrast and field-of-view. Thus grating less source and detectors are highly desirable to overcome the limitations. We propose a grating less detector, Photonic-channeled X-ray Detector Array (PcXDA). The PcXDA is an X-ray and visible hybrid detector concept which eliminates high aspect ratio gratings. X-ray fringe pattern is converted to photon fringe pattern by a scintillator and is forming a three dimensional and incoherent volumetric secondary light sources. The volumetric light pattern is detected by micro optics array which operates in a similar manner to confocal microscopy. As a key optical device, phase plate is incorporated to increase the depth of field of the micro optics based confocal detection so that the three dimensional light sources effectively creates signal contrast. Complete ray trace model of PcXDA along with physical optics based X-ray DPC imaging system provides an enhanced performance for X-ray DPC imaging system which enables high contrast and wide field of view detection.

Portable LED-induced autofluorescence imager with a probe of L shape for oral cancer diagnosis

Ting-Wei Huang, Nai-Lun Cheng, Yung-Jhe Yan, Hou-Chi Chiang, Jin-Chern Chiou, Ou-Yang Mang, National Chiao Tung Univ. (Taiwan)

Many researches utilize the autofluorescence of cells and tissue to diagnose oral cancer. The difference of spectral distribution between lesions of epithelial cells and normal cells after excited fluorescence is one of methods for the cancer diagnosis. We developed the hyperspectral and multispectral techniques for oral cancer diagnosis in three generations. In our previous work of the third generation, we proposed a portable LED Induced autofluorescence imager that can acquire the image of specific spectrum in vivo for oral cancer diagnosis. Our portable system for detection of oral cancer has a probe in front of the lens for fixing the object distance. The shape of the probe is cone, and it is not convenient for doctor to capture the oral image. Therefore, a probe of L shape containing a mirror is proposed in this paper, it is easy for doctors to capture the images from different angles. Besides, a glass plate is placed in front of LED to prevent the liquid entering in the body. The radiance intensity of LED is enhanced. Therefore, we can capture clearer oral images of the specific wavelength via fluorescence reaction. The recent experiments show that the specificity and sensitivity of the system are better than previous results.

9594-19, Session 4

Natural radioactivity in scintillators

H. Bradford Barber, The Univ. of Arizona (United States)

Recently, many new scintillators have been developed with novel properties relevant to PET or SPECT imaging. Examples include: LSO:Ce, LYSO:Ce, Cs2LiLaBr6:Ce and LaBr3:Ce. Some of these scintillators include elements with naturally-occurring radionuclides (e.g. Lu-176 in LYSO:Ce). We review these materials and discuss the implications of radioactive decay for gamma-ray spectroscopy and imaging.

Maximum likelihood source localization using elpasolite crystals as a dual gamma neutron directional detector

Paul P. Guss, Thomas G. Stampahar, Sanjoy Mukhopadhyay, National Security Technologies, LLC (United States); Alexander Barzilov, Amber Guckes, Univ. of Nevada, Las Vegas (United States)

The problem of accurately detecting extremely low levels of nuclear radiation is rapidly increasing in importance in nuclear counter-proliferation, verification, and environmental and waste management. Because the 239Pu gamma signature may be weak, for instance, even when compared to the natural terrestrial background, coincidence counting with the 239Pu neutron signature may improve overall 239Pu detection sensitivity. However, systems with sufficient multiple-particle detectors require demonstration that the increased sensitivity be sufficiently high to overcome added cost and weight. We report the results of measurements and calculations to determine sensitivity that can be gained in detecting low levels of nuclear radiation from use of a relatively new detector technology based on elpasolite crystals. We have performed investigations exploring cerium (Ce3+)-doped elpasolites Cs2LiYCl6:Ce3+0.5% (CLYC) and Cs2LiLa(Br6) 90%(Cl6)10%:Ce3+0.5% (CLLBC:Ce). These materials can provide energy resolution (r(E) = 2.35?(E)/E) as good as 2.9% at 662 keV (FWHM). The crystals show an excellent neutron and gamma radiation response. The goals of the investigation were to set up the neutron/gamma pulse shape discrimination electronics for elpasolite detectors; perform limited static source benchmarking, testing and evaluation to validate system performance; and explore application of a maximum likelihood algorithm for source location. Data were measured and processed through a maximum likelihood estimation algorithm providing a direction to the radioactive source for each individual position. The estimated directions were good representations for the actual directions to the radioactive source. This paper summarizes the maximum likelihood results for our elpasolite system.

9595-2, Session 1

Imaging system for dynamic x-ray diffraction and radiographic diagnostics from 17 to 25 keV

Dane V. Morgan, National Security Technologies, LLC (United States)

X-ray imaging systems in the energy range of 17–25 keV are commonly used with short-pulse radiographic and x-ray diffraction (XRD) diagnostics for dynamic materials experiments. For the x-ray imaging system described, scintillators were directly coupled to a fiber-optic taper, and the image was transmitted to a CCD camera via coherent fiber-optic bundle. We have characterized the resolution and signal-to-noise ratio of P-43, P-47, and LSO scintillators in this configuration, using a 35-stage Marx bank to generate a 400 kV, 30 ns x-ray pulse from a molybdenum anode. Design considerations for the x-ray imaging system also include the spectral response, x-ray shielding, and blast protection. This imaging system is an integral part of a novel single-pulse XRD diagnostic developed for nanosecond studies of shocked polycrystalline materials. The diagnostic has been used to observe phase transformations, grain size distribution, texture, and the presence of inelastic behavior in single crystals. We describe a series of high explosives–driven zirconium shock experiments at 5.6–5.8 GPa uniaxial interface stress, with a thin, vitreous carbon window for sample shock loading. The experiments consistently have shown the presence of a broad diffraction peak, which is indicative of an amorphous structure within the shocked material.

9595-3, Session 1

Microsystem for remote sensing of high-energy radiation with associated extremely-low photon flux densities

Vijay K. Jain, Alex Otten, Univ. of South Florida (United States)

This paper presents a microsystem for remote sensing of high energy radiation in extremely low flux density conditions. With wide deployment in mind, potential applications range from nuclear non-proliferation, to hospital radiation-safety. At smaller scales, on the other hand, potential applications include bio-sensing at small-sample and even single-cell levels. The daunting challenge is the low level of photon flux densities – emerging from a Scintillation Crystal (SC) on to a ~1 mm-square detector, which are a factor of 10000 or so lower than those acceptable to recently reported photonic chips (including 'single-photon detection' chips), due to a combination of low LUX, small detector size, and the short SC output pulse widths – on the order of 1 micro-s each. These challenges are overcome by effective coupling from the SC to the photodetector at each stage through: SC geometry, multiple layers of PTFE wrapping, efficient optical coupling, and most of all high detector sensitivity achieved in a microchip.

Basic overview of system: The system consists of a CsI(Tl) SC and an application specific IC (ASIC), which houses a 0.6mm?1.2mm, n+ diff p-epi photodiode (PD), as well as the associated analog amplification circuitry fabricated in 0.5micron, 3-metal 2-poly CMOS technology. The amplification, together with pulse-shaping of the photocurrent-induced voltage signal, is achieved through a tandem of two capacitively coupled, double-cascode amplifiers, with an observed overall-small-signal gain of up to 13,000.

9595-4, Session 1

Measuring x-ray spectra of flash radiographic sources

Amanda E. Gehring, Michelle A. Espy, Todd J. Haines, Robert Sedillo, Los Alamos National Lab. (United States)

A Compton spectrometer has been re-commissioned for measurements of flash radiographic sources. The determination of the energy spectrum of these sources is difficult due to the high count rates and short nature of the pulses (~50 ns). The spectrometer is a 300 kg neodymium-iron magnet which measures spectra in the <1 MeV to 20 MeV energy range. Incoming x-rays are collimated into a narrow beam incident on a converter foil. The ejected Compton electrons are collimated so that the forward-directed electrons enter the magnetic field region of the spectrometer. The position of the electrons at the magnet's focal plane is a function of their momentum, allowing the x-ray spectrum to be reconstructed. Recent measurements of flash sources and continuous sources will be presented.

9595-5, Session 1

Auger compositional depth profiling of the metal contact-TlBr interface

Art J. Nelson, Erik L. Swanberg, Lars F. Voss, Robert T. Graff, Adam M. Conway, Stephen A. Payne, Lawrence Livermore National Lab. (United States); Hadong Kim, Leonard J. Cirignano, Kanai S. Shah, Radiation Monitoring Devices, Inc. (United States)

Degradation of room temperature operation of TlBr radiation detectors

with time is thought to be due to electromigration of Tl and Br vacancies within the crystal as well as the metal contacts migrating into the TlBr crystal itself due to electrochemical reactions at the metal/TlBr interface. Scanning Auger electron spectroscopy (AES) in combination with sputter depth profiling was used to investigate the metal contact surface/interfacial structure on TlBr devices. Device-grade TlBr was polished and subjected to a 32% HCl etch to remove surface damage and create a TlBr1-xClx surface layer prior to Pt contact deposition. Auger compositional depth profiling results reveal non-equilibrium interfacial diffusion before and after device operation in both air and N2 at ambient temperature. These results improve our understanding of contact/device degradation versus operating environment for further enhancing radiation detector performance.

9595-6, Session 1

Design and optimization of a radiation detector for ground- and spaced-based exposure

Dileon Saint-Jean, Louisiana Tech Univ. (United States); Kazim R. Abbot, Darnel D. Williams, Grambling State Univ. (United States); Pedro Derosa, Lee Sawyer, Dilip K. Jana, Louisiana Tech Univ. (United States)

This project aims to construct a detector capable of analyzing the effects of radiation on different biological samples for ground and space-based expeditions. The device will measure the amount of radiation that reaches DNA, a result that if correlated with the observed damage will help in assessing human survival under those radiation conditions. In order to optimize the design of the detector, simulations were run using the Monte Carlo technique as implemented in GEANT4; a toolkit for the simulation of particles through matter.

The detection system design places the sample between glasses and a series of scintillator fiber arrays above and below to track radiation before and after hitting the sample. Two designs, one with 3 fiber layers above and below and a second model with 4 fiber layers were tested. A proton beam was fired with energies between 5 MeV and 200MeV.

Simulation results show that below 40MeV, protons are absorbed before reaching the last fiber layers and thus outgoing direction cannot be determined, protons of even lower energy are fully absorbed in the top fiber not reaching the sample. It is observed that the energy deposited in the sample peaks for protons between 40-50 MeV.

9595-7, Session 2

Detector blur associated with MeV radiographic imaging systems *(Invited Paper)*

Stuart A. Baker, Kristina K. Brown, Duane D Smalley, Russell A. Howe, Stephen E. Mitchell, National Security Technologies, LLC (United States); Stephen S. Lutz, Keystone International, Inc. (United States); Rachel M Posner, National Security Technologies, LLC (United States); Timothy J. Webb, Sandia National Labs. (United States); Jeremy Danielson, Todd J. Haines, Los Alamos National Lab. (United States)

We are investigating scintillator performance in radiographic imaging systems at x-ray energies from 2.3 to 8 MeV in single-pulse x-ray machines. The trade-offs for brightness versus resolution in monolithic scintillators thickness is being examined. A custom large-format lens relays the scintillator image to be recorded on an integrating high-resolution CCD camera. Previous discussion1 has reviewed energy absorption and efficiency of various imaging scintillators with the 2.3 MeV Cygnus source. The 2.3 MeV data is supplemented with some higher-energy x-ray efficiency data. The focal point of our study is how scintillator blur contribution affects overall image quality. Monolithic LYSO:Ce (cerium-doped lutetium yttrium orthosilicate) is being studied to understand brightness and resolution trade-offs to a range of micro-columnar CsI:Tl (thallium-doped cesium iodide) scintillator screens. The micro-columnar scintillator structure exhibits an optical gain mechanism that results in brighter signals from thinner samples. For higher-energy x-rays, thicker materials generally produce brighter signal due to greater x-ray absorption and the optical emission properties of the material. However with the scintillator image produced throughout its thickness, blur begins to dominate imaging quality due to the volume image generated in the scintillator depth. We investigate imaging LYSO:Ce at thickness from 3 mm to 10 mm. Results are compared with micro-columnar CsI:Tl screens less than 1 mm thick.

9595-8, Session 2

Quantitative criteria for assessment of gamma-ray imager performance

Hans Malik, Stephen R. Gottesman, Kristi Keller, Northrop Grumman Electronic Systems (United States)

In recent years gamma ray imagers such as the GammaCam™ and Polaris have demonstrated good imaging performance in the field. Imager performance is often summarized as “resolution”, either angular, or spatial at some distance from the imager, however the definition of resolution is not always related to the ability to image an object. It is difficult to quantitatively compare imagers without a common definition of image quality. This paper examines three categories of definition: point source; line source; and area source. It discusses the details of those definitions and which ones are more relevant for different situations. Metrics such as Full Width Half Maximum (FWHM), variations on the Rayleigh criterion, and some analogous to National Imagery Interpretability Rating Scale (NIIRS) are discussed. The performance against these metrics is evaluated for a high resolution coded aperture imager modeled using Monte Carlo N-Particle (MCNP), and for a medium resolution imager measured in the lab.

9595-9, Session 2

Physical basis for signal separation for remote sensing of multiple high-energy radiation sources

Vijay K. Jain, John Richards, Univ. of South Florida (United States)

In ‘radiation remote sensing’ multiple unknown high energy sources are generally involved. The detectors, upon sensing the corresponding mixed signals, must separate their contributions blindly for further analysis. With wide deployment in mind, potential applications range from nuclear non-proliferation, to hospital radiation-safety. An effective way to perform this separation is through Independent Component Analysis algorithm. However, the challenges faced are the low level of photon flux densities emerging from a Scintillation Crystal (SC) on to a ~1 mm-square detector, and the fact that theoretically there is no correlation among events, even those arising from the same source. We overcome the latter by use of a thin barrier and by taking into account the detector pulse shape. The radiation events that interact with the barrier take a longer time to reach the detector due to their increased path length. They also lose energy, which makes them increasingly prone to capture in the barrier once they have scattered. These observations are confirmed through Monte-Carlo simulations upon Gamma-radiation sources. This includes modeling of isotropic sources of 662 keV radiation impinging upon a thin tungsten barrier (0 to 0.5mm to 5mm), while using the Klein-Nishina formula to precisely follow the track of each Gamma-ray from each source. Normalized cross-covariance ranging from 0.02 to 0.22 was found, and conveniently controllable by the duration of the detector shaping-pulse. Finally, the application of the ICA approach is demonstrated to demix, or separate, the individual contributions of the sources to the observed detector signals.

9595-10, Session 2

Design of x-ray differential phase contrast imaging system for high energy and incoherent x-ray sources

Yuzuru Takashima, Young-Sik Kim, Jihun Kim, The Univ. of Arizona (United States)

A grating based Talbot-Lau interferometer, differential phase contrast (DPC) imaging employing a low brilliance X-ray source is actively researched in medical imaging community. A grating in front of the incoherent source (G0) produces an array of partially coherent line sources. Each line sources forms a Talbot image by the second grating (G2). Deformation of a wave front induced by an object distorts the Talbot image. The distortion is detected by the third grating (G2) placed in front of detector array. Recently the X-ray DPC imaging for aviation security purpose becomes of interest because it provides richer information enabling detection of potentially hazardous materials. For the purpose, a higher X-ray photon energy is needed so that X-ray can penetrate deeply into the object. For the higher X-ray energy applications, more careful understanding of the signal formation mechanism is required since the X-ray DPC optics is not achromatized, but the source spectrum becomes wider.

We optimized X-ray DPC imaging system based on a physical optics modeling while taking into account source and absorption spectrum of X-ray optical components. The optimum design energy maximizing signal contrast is independent to X-ray photon spectrum, and is about 40KeV. The smaller absorption of the G0 and G2 is one of the limiting factors to apply the X-ray DPC system for the higher energy applications. The result suggests a grating-less sources and detectors are highly preferable to utilize higher X-ray photon while increasing the field of view of the system.

9595-11, Session 3

Co-linear neutron and x-ray imaging at the National Ignition Facility *(Invited Paper)*

Frank E. Merrill, Los Alamos National Lab. (United States); Kim Christensen, Lawrence Livermore National Lab. (United States); Christopher R. Danly, Valerie Fatherley, Los Alamos National Lab. (United States); David N. Fittinghoff, Lawrence Livermore National Lab. (United States); Jeffrey R. Griego, Los Alamos National Lab. (United States); Gary P. Grim, Nobuhiko Izumi, Lawrence Livermore National Lab. (United States); Donald R. Jedlovec, Lawrence Livermore National Lab. (United States) and Los Alamos National Lab. (United States); Raspberry Simpson, Los Alamos National Lab. (United States); Kenneth M. Skulina, Lawrence Livermore National Lab. (United States); Petr L. Volegov, Carl H. Wilde, Los Alamos National Lab. (United States)

Neutron and x-ray imagers are standard diagnostics for Inertial Containment Fusion (ICF) experiments at the National Ignition Facility (NIF). Since neutrons are produced by deuterium-tritium fusion, neutron images show burning regions of the deuterium-tritium plasma, and since any sufficiently hot regions of the plasma produce x-rays, x-ray images are sensitive to the electron temperature, density and atomic composition of plasma. While neutron and x-ray images from imploding fusion capsules may appear to be similar in many 2D calculations and in some experiments, recent 3D simulations and some experiments at the NIF indicate that asymmetric or 3D behavior of the implosion may produce neutron and x-ray images that are significantly different. Since the current neutron imager and x-ray imagers at NIF are located at different polar or azimuthal angles around target chamber, we are developing the ability to obtain a time-integrated x-ray image on the same line of sight as the current neutron imager to allow us to look for asymmetry effects in the imploding capsules. In this paper, we will discuss the current designs, including the resolution, field of view and potential co-registration of the neutron and x-ray images.

9595-12, Session 3

Testing of the gamma-ray imaging system with a mono-energetic gamma source at HIGS

Daniel A Lemieux, College of Optical Sciences, The Univ. of Arizona (United States)

A gamma ray imaging system was designed for use at the National Ignition Facility. Previous testing of this system used a broad spectrum of 50-300 keV X-rays but not the 4.44 MeV gammas the system is designed to image. Consequently the system was taken to Duke University where the High Intensity Gamma Source (HIGS) was used as a 4.44 MeV monoenergetic source to radiograph tungsten targets. These targets consisted of simple shapes and coded aperture images that were simulated to represent 180-micron shells similar to those used at the National Ignition Facility. These coded images were reconstructed using a Maximum Likelihood Estimation method and characterized using Legendre Polynomials.

9595-13, Session 4

The challenge of building large-area high-precision tracking detectors for upgrading the ATLAS Muon Spectrometer for the LHC high-luminosity phase *(Invited Paper)*

Oliver Stelzer-Chilton, TRIUMF (Canada)

The current innermost stations of the Atlas endcap muon tracking system must be upgraded in 2018 and 2019 to retain the good precision tracking and trigger capabilities in the high background environment expected with the upcoming luminosity increase of the LHC. The upgraded detector will consist of 2 detectors technologies, Micromegas (MICRO-MEsh-GAseous Structure) and sTGC (small-strip Thin Gap Chamber) modules, 2 to 3m2 in size, and totalling an active area each of 1200 m2. In order to achieve a 15% transverse momentum resolution for 1TeV muons, and take benefit of the very good position resolution of the detectors, the position of each strip must be known with an accuracy of 30 μm along the precision coordinate and 80 μm along the beam. On such large area detectors, the mechanical precision is a key point and then must be controlled and monitored all along the process of construction and integration. Design and construction methods of large area Micromegas and sTGC modules will be presented together with studies of thermo-mechanical deformations. The methods for quality control of modules and the system for strip alignment in the detection layers will be also reported, together with prototype results from test beam measurements.

9595-14, Session 4

Spatial response characterization of He-4 scintillation detectors

Ryan P. Kelley, Noah Steinberg, Univ. of Florida (United States); David Murer, Arktis Radiation Detectors Ltd. (Switzerland); Heather Ray, Kelly A. Jordan, Univ. of Florida (United States)

Helium-4 detectors are a new technological development with demonstrated energy discrimination and gamma rejection capabilities. These detectors take advantage of the high He-4 cross section for elastic scattering at fast neutron energies. A neutron elastically scattering in the detector volume results in the production of helium scintillation light, which is counted by photomultiplier tubes (PMTs) at either end of the detector. The amount of light detected by the PMTs for a given event is proportional to the neutron energy.

For this work a collimator was designed and built using polyethylene and lead to confine the flux from an isotropic Cf-252 spontaneous fission source

into a narrow beam. Measurements were conducted with this beam focused at various points along the axis of the He-4 detector's active volume, and the resulting light responses were compared. The results show that the position of particle interaction along the axis of the active volume has a measurable effect on the scintillation light response of the detector, and therefore this characterization is directly applicable to efforts to unfold the neutron energy spectrum from the detector light output distribution. Additionally, the count rate at each beam position was also measured and compared in order to assess the detection sensitivity along the tube axis.

By analyzing each PMT trace independently of the other, the two-sided PMT readout allowed for the calculation of the "centroid" of each event by computing the ratio of light measured between the two PMTs. This metric provided the relative position of particle interaction along the detector axis.

An algorithm was developed using the distribution of these centroid measurements to estimate the direction to the neutron source with respect to the detector. A Cf-252 source was moved through a 180-degree arc around the detector while being kept at a fixed distance. Obviously, measurements with the source position closer to one PMT resulted in a higher fraction of centroid measurements near that PMT, but it was also demonstrated that a reverse application of this principle could be used to predict the direction to the source based on the distribution of centroids detected by the He-4 system. In a cargo-scanning scenario, this principle could be applied to reduce uncertainty regarding the position of special nuclear material (SNM) within a sealed container prior to opening it for search.

All measurements described above were further supported by MCNPX-PoliMi simulations modeling the neutron transport characteristics between the source and detector. In summary, these simulations and measurements were used to characterize the spatial sensitivity of the He-4 fast neutron scintillation detector, the spatial response with respect to the scintillation light output, and to develop a new method of source localization. Combined with their demonstrated neutron energy sensitivity and gamma rejection abilities, these results expand the potential for these new He-4 detectors to be implemented as powerful instruments for the detection of hidden shielded nuclear material.

9595-15, Session 4

ENGA: a novel large area neutron detector

Marian Jandel, Gencho Y. Rusev, Terry N. Taddeucci, Los Alamos National Lab. (United States)

A large area neutron detector prototype was developed and tested at Los Alamos National Laboratory [1]. The detector consists of two walls of five plastic scintillation detectors, each with the dimensions 10 cm x10 cm x1m, and Cadmium (Cd) foils placed around it and in between.

Fission neutrons from special nuclear material (SNM) slow down in plastic material until they are absorbed in Cd material via the neutron capture reaction. After neutron capture, a cascade of energetic gamma rays is emitted and detected in the detector system within 20-40 ns narrow coincidence windows. The neutron capture event is then determined from the two dimensional multiplicity and total deposited energy information. The detector sensitivity to fission neutrons was determined to be superior to existing technology with a high signal-to-background (STB) ratio of 5-to-1 and confirmed by series of benchmark measurements. The STB ratio was determined for the neutrons detected from Cf-252 (1uCi) source at 20 cm from the ENGA detector to a number of cosmic neutrons at Los Alamos altitude of 7300 feet above the sea level.

The detection sensitivity in terms of amounts of SNM and the interrogation time length were determined. A significant advantage of this detector system is its scalability to larger areas at low costs. The internal efficiency to detect one fission neutron is as high as 15% for the smaller prototype, which was confirmed experimentally. With the different materials that would provide better efficiency and resolution for the detecting gamma-rays, highly efficient detectors can be developed, superseding the He-3 based systems, and providing both gamma-ray and neutron detection capabilities in one box.

9595-16, Session 4

Operational performance of a high-speed neutron detector using CLYC

Erik B. Johnson, Chad M. Whitney, Sam Vogel, Radiation Monitoring Devices, Inc. (United States); Keith E. Holbert, Premkumar Chandhran, Arizona State Univ. (United States); Joshua P. Tower, Patrick J. O'Dougherty, Craig Hines, James F. Christian, Radiation Monitoring Devices, Inc. (United States)

A replacement for He-3 neutron measurement is CLYC (Cs2LiYCl6), a scintillation material that has a pulse shape that depends on the linear energy transfer producing the event, e.g., electrons from gamma rays versus charged ions from neutrons. Pulse shape discrimination of neutrons and gamma rays with CLYC has shown an eight FWHM separation. The drawback to CLYC is the long emission time, where using traditional charge comparison methods (i.e., integration of a fast component compared to the integration of a slow component) will fail beyond event rates exceeding 100 kHz. We have developed algorithms that handle the pulse pileup and provide both gamma-neutron discrimination and gamma energy, where one of these algorithms has demonstrated discrimination greater than two FWHM beyond an event rate of 1 MHz. A prototype detector system was built using a 250 MSPS, 12-bit ADC and read out with a Zynq system-on-a-chip (SOC), which was mounted on a development board (microZed). The prototype consisted of a 1-cm cube of CLYC coupled to a photomultiplier tube, and the system operated from +5 V. The detector was tested at RMD using an AmBe source and was tested at Idaho National Laboratories with reactor grade Pu. This paper provides a review of the operational performance of the prototype CLYC detector.

9595-17, Session 4

Time-gating for energy selection and scatter rejection: high-energy pulsed neutron imaging at LANSCE

Alicia L. Swift, Los Alamos National Lab. (United States) and The Univ. of Tennessee (United States); Richard C. Schirato, Edward A. McKigney, James F. Hunter, Brian Temple, Los Alamos National Lab. (United States)

The Los Alamos Neutron Science Center (LANSCE) is a linear accelerator in Los Alamos, New Mexico that accelerates a proton beam to 800 MeV, which then produces spallation neutron beams. Flight path FP15R uses a tungsten target to generate neutrons of energy ranging from several hundred keV to ~600 MeV. The beam structure has micropulses of sub-ns width and period of 1.784 ns, and macropulses of 625 ?s width and frequency of either 50 Hz or 100 Hz. This corresponds to 347 micropulses per macropulse, or 1.74 x 104 micropulses per second when operating at 50 Hz. Using a very fast, cooled ICCD camera (Princeton Instruments PI-Max 4), gated images of various objects were obtained on FP15R in January 2015. Objects imaged included blocks of lead and borated polyethylene; a tungsten sphere; and a tungsten, polyethylene, and steel cylinder. Images were obtained in 36 min or less, with some in as little as 6 min. This is novel because the gate widths (some as narrow as 10 ns) were selected to reject scatter and other signal not of interest (e.g. the gamma flash that precedes the neutron pulse), which has not been demonstrated at energies above 14 MeV. This proof-of-principle experiment shows that time gating is possible above 14MeV and is useful for selecting neutron energy and reducing scatter, thus forming clearer images. Future work (simulation and experimental) is being undertaken to improve camera shielding and system design and to precisely determine optical properties of the imaging system.

9595-18, Session PWed

Evaluation of a gamma camera system for the RITS-6 accelerator using the self-magnetic pinch diode

Timothy J. Webb, Mark L. Kiefer, Sandia National Labs. (United States); Raymond Gignac, Stuart A. Baker, National Security Technologies, LLC (United States)

The self-magnetic pinch (SMP) diode1 is an intense radiographic source fielded on the Radiographic Integrated Test Stand (RITS-6) accelerator at Sandia National Laboratories in Albuquerque, NM. The accelerator is an inductive voltage adder (IVA) that can operate from 2-10 MV with currents up to 160 kA (at 7 MV). The SMP diode consists of an annular cathode separated from a flat anode, holding the bremsstrahlung conversion target, by a vacuum gap. The resulting spot size or x-ray source distribution is characterized by the analysis of the radiograph of a thick "L" rolled edge with both time-resolved and time-integrated diagnostics. It has been found that the spot size and dose varies according to the diode geometry (cathode size and A-K gap) and diode materials but similar minimum spot sizes are achievable independent of voltage.

* Sandia National Laboratories is a multi-program laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000.

9595-19, Session PWed

Influence of tailed-current on UXO prospecting

Linlin Zhang, Shuang Zhang, Shudong Chen, Haoyang Fu, Jilin Univ. (China)

Time-domain electromagnetic method used in unexploded ordnance detection has always faced the problem of losing early-time response due to tailed-current. In this article, the response of UXO like targets with different tailed-current is calculated and measured, and the influence of tailed-current on UXO prospecting is talked. The targets include a sphere, an iron pipe and a shell, and the tailed-current is set with cut-off time varies from 0μs to 250μs. According to magnetic surface modes(MSM), the step response of a compact steel target exhibits an early algebraic regime wherein the response transitions from t-1/2 to t-3/2 decay, followed by a late regime characterized by an exponentially decay. In fact, the transmitting current cannot be turned off immediately, especially for system with multi-turn coil and large current. The cut-off process is decided by system parameters such as coil induction, resister and maximum voltage across the coil.

The target response of tailed-current is calculated through a convolution algorithm and measured with a specially designed system. The result shows that the response of UXO like targets is influenced by the tailed-current in two ways. Firstly, the primary response of the tailed-current will lead to signal saturation in the early times. Secondly, the off-time response of UXO like targets is distorted by the tailed-current. All the influences will affect the system ability on detecting and discriminating the UXO like targets. An extra-fast switch-off system and deconvolution strategies are good advices to solve the problems of the response.

9595-20, Session PWed

An improved RF circuit for overhauser magnetometer excitation

Di Zheng, Shuang Zhang, Xin Guo, Haoyang Fu, Jilin Univ. (China)

Overhauser magnetometer is a high-precision device for magnetostatic field measurement, which can be used in a wide variety of purposes: UXO detection, pipeline mapping and other engineering and environmental applications. Traditional proton magnetometer adopts DC polarization, suffering from low polarization efficiency, high power consumption and low signal noise ratio (SNR). Compared with the traditional proton magnetometer, nitroxide free radicals are used for dynamic nuclear polarization (DNP) to enhance nuclear magnetic resonance (NMR). RF excitation is very important for electron resonance in nitrogen oxygen free radical solution, and it is primarily significant for the obtention of high SNR signal and high sensitive field observation. Therefore, RF excitation source plays a crucial role in the development of Overhauser magnetometer.

In this paper, an improved design of a RF circuit is discussed. The new RF excitation circuit consists of two parts: Quartz crystal oscillator circuit and RF power amplifier circuit. Simulation and optimization designs for power amplifier circuit based on software ADS are presented. Finally we achieve a continuous and stable sine wave of 60MHz with 1- 2.5 W output power, and the second harmonic suppression is close to -20dBc. The improved RF circuit has many merits such as small size, low-power consumption and high efficiency, and it can be applied to Overhauser magnetometer to obtain high sensitive field observation.

9595-21, Session PWed

Stacked filtered multi-channel x-ray diode array

Lawrence P. MacNeil, Eric C. Dutra, National Security Technologies, LLC (United States); Steven M. Compton, Barry A. Jacoby, Lawrence Livermore National Lab. (United States); Mark L. Raphaelian, National Security Technologies, LLC (United States)

There are many types of X-ray diodes that are used for X-ray flux or spectroscopic measurements and estimating the spectral shape of the VUV to soft X-ray spectrum. However, a need arose for a low cost, robust X-ray diode to use for experiments in hostile environments on multiple platforms, and for explosively driven experiments that may potentially destroy the diode(s). Since the typical use required a small size with a minimal single line-of-sight, a parallel array could not be used. So, a stacked, filtered multi-channel X-ray diode array was developed, called the MiniXRD. To achieve significant cost savings while maintaining robustness and ease of field setup, repair, and replacement, we designed the system to be modular. The filters were manufactured in-house and cover the range from 900 eV to 5000 eV. To achieve the line-of-sight accuracy needed, we developed mounts and laser alignment techniques. We modeled and tested elements of the diode design at NSTec Livermore Operations to determine temporal response and dynamic range, leading to diode shape and circuitry changes to optimize impedance and charge storage. We deployed individual and stacked systems at several national facilities to test and improve the design usability. We present results on MiniXRD sensitivity, individual diode comparisons and multiple-system correlations. The system performance supports consideration of the MiniXRD as a viable low-cost alternative for multiple-channel low-energy X-ray measurements.

This work was done by National Security Technologies, LLC, under Contract No. DE-AC52-06NA25946 with the U.S. Department of Energy and supported by the Site-Directed Research and Development Program.

9595-22, Session PWed

The short line of sight neutron imaging diagnostic at the National Ignition Facility

Raspberry Simpson, Frank E. Merrill, Christopher R. Danly, Petr L. Volegov, Carl H. Wilde, Los Alamos National Lab. (United States); David N. Fittinghoff, Nobuhiko Izumi, Kim Christensen, Kenneth M. Skulina, Donald R. Jedlovec, Lawrence Livermore National Lab. (United States)

The Neutron Imaging System (NIS) at NIF is an important diagnostic tool for understanding characteristics of DT implosions at ignition. The NIS is positioned 28m from the NIF target chamber center to produce

the appropriate imaging magnification and resolution. However, recent testing of a short line of sight neutron imaging system has proven to be a promising technique to preserve the source reconstruction capabilities of the existing NIS at 10 m. Therefore, multiple neutron imaging diagnostics can be positioned at a shorter detector distance providing additional views of the target and improved diagnostics of implosion asymmetries and failures. The system is primarily composed of stacks of 2mm thick high-density polyethylene converter material followed by a phosphorous image plate. Neutrons generated from the DT reaction pass through a pinhole aperture array located 32.5 cm from TCC, enter the converter material, interacts with a proton, which recoils and deposits its energy on the image plate. We present details of the measurement scheme for this novel technique to produce energy-integrated neutron images as well as its source reconstruction results.

Conference 9596: Signal and Data Processing of Small Targets 2015

Infrared moving target detection algorithm based on improved multiscale codebook model

Lei Liu, Yayun Zhou, Nanjing Univ. of Science and Technology (China)

With the continuous development of science and technology, infrared sensor technology has played an important role in national defense, medical, transportation and other areas. The tracking technology of small infrared target is an important branch of infrared imaging technology, which has not only very important scientific research value, but also has broad application prospect in the military and civil area.

Nowadays, different algorithms have been proposed for infrared target tracking. However, under complex backgrounds, such as clutter, varying illumination, and occlusion, the traditional tracking method often loses the real infrared small target.

To cope with these problems, in this paper we have present a novel infrared moving target detection algorithm based on multiscale codebook model according to the characteristics of small target in infrared images. The basic principles and the implementing procedure of these algorithms for target tracking are described. Firstly, the infrared video is stratified by Gauss Pyramid. Secondly, codebook model is built for each layer image and the moving target in infrared video is detected according to model. Finally, each layer results are combined and the final detection result is get. The experimental results show that, compared with traditional detection algorithms, the result of multiscale codebook model has better detection effects, richer target information and lower false detection rate. This algorithm can not only be used in the field of image fusion, in order to improve the fusion effect, but also be used in security surveillance, night vision surveillance and other civil and military fields.

9596-2, Session 1

Enhanced accuracy of heart-rate measurement using the green light diode laser and infrared reflection model from Taipei, Taiwan

Yen-Hsing Lin, National Taipei Univ. of Technology (Taiwan); Guan-Jhong Lin, National Taiwan Univ. (Taiwan); Chung-Ping Chen, National Taipei Univ. of Technology (Taiwan)

In order to improve the accuracy of the heart rate measurement, the system combining a green light diode laser with an infrared reflection model is developed. With this configuration, the R-wave detection accuracy is significantly enhanced around 99%, and the analysis of heart rate variability to get the user's fatigue level and the degree of pressure is also implemented. In addition, the measurement error occurring between the stable state and the motion state is also investigated. This system not only builds an interface for user to monitor body status, but also constructs a backend platform with a data base for a long time monitoring.

9596-3, Session 1

Small and dim target detection by background modeling

Jing Hu, Yi Yu, Fan Liu, Huazhong Univ. of Science and Technology (China)

For images with complicated background and low signal-to-noise ratio, it's a challenge to detect small and dim moving point target. In the paper an effective method for small and dim target detection in complicated background is proposed. It takes advantage of the Non-local means filter, and applies a novel weight calculation model based on circular mask to the original background modeling method. We name it R-NLM algorithm.

By associating similarity of grayscale distribution of the images with temporal information, the extended method estimates the complicated background precisely and extracts point target successfully. It's robust to low and fast target velocities, moreover, it need neither prior knowledge nor learning and training procedure. Owing to its effectiveness and implementability, the proposed method is well adapted to target detection system, where it outperforms significantly conventional spatio-temporal filters. Furthermore, by applying this new weight model within single frame, the method can be robust to large background motions and work well even without images accumulation.

More than 1000 frames of images with different complicated backgrounds and different intensity of targets are used in the experiment. To compare existing target detection methods with the proposed one, signal-to-clutter ratio gain (SCRG) and background suppression factor (BSF) are employed for spatial performance comparison, and receiver operating characteristics (ROC) is used for detection-performance comparison of the target trajectory. Experimental results demonstrate good performance of the proposed method for images in complicated scene, especially for low signal-to-noise ratio images. This work was supported by the fund of CAST under Grant 2014A06.

9596-4, Session 1

Raman laser spectrometer adaptive processing for Mars exploration

Carlos Diaz Cano, Andoni G. Moral Inza, Carlos Pérez Canora, INTA Instituto Nacional de Técnica Aeroespacial (Spain); Guillermo López Reyes, Univ. de Valladolid (Spain); Eva Díaz Catalá, INTA Instituto Nacional de Técnica Aeroespacial (Spain) and INTA (Spain); Fernando Rull, Universidad de Valladolid (Spain); Gonzalo Ramos Zapata, INTA Instituto Nacional de Técnica Aeroespacial (Spain); Maria Colombo, INTA (Spain); Jose Antonio Rodriguez, ISDEFE, S.A. (Spain)

The Raman Laser Spectrometer (RLS) is one of the Pasteur Payload instruments, within the ESA's Aurora Exploration Programme, ExoMars mission. Particularly, the RLS scientific objectives are as follows: identify organic compound and search for life; identify the mineral products and indicators of biologic activities; characterize mineral phases produced by water-related processes; characterize igneous minerals and their alteration products; characterise water/geochemical environment as a function of depth in the shallow subsurface A flexible operational concept has been designed to accomodate scientific return to the sample nature and available resources (energy, time and data bandwidth).

The nature of the materials being analysed makes the measurement differ one to the other, based on the fluorescence, background and Raman efficiency. The acquisition of the spectra from different materials shall be, therefore, adaptative and dynamic to the sample. This, plus the restricted and changing communication bandwidth, makes mandatory the development of means to perform on-board: estimation of acquisition parameters, dynamic time-distribution, adaptative size of images and number of spots within the sample to be analysed. Currently, development of Phase C is on going and it is expected to deliver a functional model end 2015. RLS will perform Raman spectroscopy on crushed powdered samples inside the Rover's Analytical Laboratory Drawer.

Conclusions: RLS complete and flexible operation concept is neccesary to make benefit of the full potential of the instrument.

9596-5, Session 1

Numerical study of the statistical characteristics of range-resolved sea clutter

Jianing Wang, Xiaojian Xu, BeiHang Univ. (China)

Knowledge of sea clutter is of great significance in marine target detection and discrimination, especially for small targets where false alarms caused by sea spikes easily happen. To assist with the target detection algorithm test and the marine surveillance radar system design, the simulation of range-resolved sea clutter data and the analysis of its statistical characteristics have been performed by Toporkov et al. based on 1-D sea surfaces. In this paper, the range-resolved sea clutter data of 2-D sea surfaces are numerically simulated and studied. The linear sea surfaces, the Creamer (2) sea surfaces and the choppy wave model (CWM) sea surfaces are used. The wideband backscattering fields of the sea surfaces are calculated employing the weighted curvature approximation (WCA) method. A large number of Monte Carlo trials are performed under different range-resolutions, grazing angles, beam widths, and azimuth angles to investigate the influences of radar parameters on amplitude statistics of the range-resolved sea clutter. It is found from our studies that the sea clutter tends to be spikier with finer radar resolution, lower grazing angle, and narrower beam width. Sea spikes are also more likely to appear when the radar sight is parallel with the wind direction. Meanwhile, different distribution models are adopted to fit with the sea clutter distribution and the Pareto distribution is found to describe the amplitude statistics of sea clutter better. In addition, comparison between sea clutter data from different sea surface models suggests that the nonlinear effect between sea waves is one factor causing the sea spikes.

9596-6, Session 1

Research on the algorithm of infrared target detection based on the frame difference and background subtraction method

Yun Liu, Yuejin Zhao, Ming Liu, Liquan Dong, Mei Hui, Xiaohua Liu, Beijing Institute of Technology (China)

As an important branch of infrared imaging technology, infrared target tracking and detection has a very important scientific value and a wide range of applications in both military and civilian areas. For the infrared image which is characterized by low SNR and serious disturbance of background noise,an innovative and effective target detection algorithm is proposed in this paper, according to the correlation of moving target frame-to-frame and the irrelevance of noise in sequential images based on OpenCV. Firstly, since the temporal differencing and background subtraction are very complementary, we use a combined detection method of three frame difference and background subtraction which is based on adaptive background updating. Results indicate that it is simple and can extract the foreground moving target from the video sequencestably. For the background updating mechanism continuously updating each pixel, we can detect the infrared moving target more accurately. It paves the way for eventually realizing real-time infrared target detection and tracking, when transplanting the algorithms on OpenCV to the DSP platform. Afterwards,the adaptive threshold method of image segmentation is adopted. It transforms the gray images to black-white images in order to provide a better condition for the image sequences detection. In this way, it can adapt to the changes in various scenes better. Finally,according to the relevance of moving objects between different frames and mathematical morphology processing, we can eliminate noise, decreasethe area, and smooth region boundaries.Experimental results provesthat our algorithm precisely achieve the purpose of rapid detection of small infrared target.

Detection of bone fragment embedded in de-boned chicken meat using near-infrared hyperspectral reflectance imaging technique

Jongguk Lim, Giyoung Kim, Changyeun Mo, Rural Development Administration (Korea, Republic of)

White meat such as chicken meat is considered a healthy and beneficial food because of low contents of fat and cholesterol, and abundant proteins, mineral salt, and vitamins compared to red meat. The safety and quality of chicken meat is related to physical, chemical, and biological conditions. The presence of foreign materials in agricultural products and food should be removed because they are food hazards to consumers. If someone inadvertently eats bone fragments contained in boneless chicken meat, it will cause serious damage to the teeth and mouth. In recent years, hyperspectral imaging technique has been regarded as an emerging spectroscopy technology attainable a large amount of imaging and continuous spectrum information for agricultural products and food. In this study, near-infrared (NIR) hyperspectral reflectance imaging technique was investigated whether it can discriminate the embedded bone fragment in chicken meat. The boneless and skinless breast chicken breast of 1 ? thick and 5 bone fragments of 2 ? long were used for this experiment. The reflectance spectra of 5 bone fragments under the chicken breast in the wavelength range from 1,000 nm to 1,700 nm are collected from hyperspectral reflectance images obtained using quartz-tungsten halogen illumination. The discrimination result was able to detect 100% of bone fragments in chicken breast especially with a ratio image of 1061/1480 nm. Thus, NIR hyperspectral reflectance imaging technique showed considerable potential for the discrimination of bone fragments in chicken meat.

A survey of maneuvering target tracking: Part VId: sampling-based nonlinear filters

Xiao-Rong Li, Vesselin P. Jilkov, Univ. of New Orleans (United States)

This paper is Part VId of a comprehensive survey of maneuvering target tracking without addressing the so-called measurement-origin uncertainty. It provides an in-depth coverage of various sampling-based nonlinear filters, commonly referred to as particle filters, developed particularly for handling the uncertainties induced by potential target maneuvers as well as nonlinearities in the dynamical systems commonly encountered in target

tracking. Various implementations and tracking applications are reviewed. Some computational issues, such as different resampling schemes and parallel processing are addressed.

9596-22, Session PWed

Detecting ground moving objects using panoramic system

Fu-yuan Xu, Guohua Gu, Nanjing Univ of Science and Technology (China); Jing Wang, LiShui MinFeng Town Bank (China)

The moving objects detection is an essential issue in many computer vision and video processing tasks. In this paper, a detecting moving objects method using a panoramic system is proposed. It can detect ground moving objects when the camera is rotated, so it is called the moving objects detection in rotation (MODIR). The detection area and flexible of the panoramic system are be enhanced by MODIR. The background and moving objects are moving in image when the camera is rotated. Compare with the traditional methods, the aim of MODIR is to segment the isolated entities out according to the motions in the video whether imaging platform is moving or not. Firstly, the corresponding relations between the images captured from two different views is deduced from the multi-view geometric. The moving objects and stationary background in the images are distinguished by this corresponding relations. Secondly, the moving object detection framework base on multi-frame is established. This detection framework can reduce the impacts of the image matching error and cumulative error on the moving objects detection. In the experiment, an evaluation metrics method is used to compare the performance of MODIR with the traditional methods. And a lot of videos captured by the panoramic system are processed by MODIR to demonstrate its good performance in practice.

A new geometric constraint method of moving object detection using moving camera

Wei Yang, Nanjing Univ of Science and Technology (China); Guohua Gu, Nanjing Univ. of Science and Technology (China); Wenjuan Wang, Nanjing Panda Handa Technology Company Limited (China)

The ground motion object detection is an essential issue in many computer vision and video processing tasks, such as vision-based motion analysis, intelligent surveillance and regional defense. The epipolar constraint is a commonly method for the motion object detection using a moving camera. Indeed, there is a special plane where the epipolar constraint cannot detect the motion object which moves on. This phenomenon is called “surface degradation”. In order to overcome the surface degradation of the epipolar constraint, a new three-view constraint for the motion object detection using a moving camera is proposed. The feature points in the video sequence can distinguished into background and motion object by applying the epipolar constraint and the new three-view constraint which called the “Three-view Distance Constraint”. The three-view distance constraint, being the main contribution of this paper, is derived from the relative camera poses in three different views and implemented within the detection framework. Unlike the epipolar constraint, the three-view distance constraint modifies the surface degradation to the line degradation. The three-view distance constraint is capable of detecting the motion object followed by a moving camera in the same direction. We evaluate the proposed method with several video sequences to demonstrate the effectiveness and robustness of the three-view distance constraint

9596-24, Session PWed

Motion object tracking algorithm using multi-cameras

Xiao-fang Kong, Qian Chen, Nanjing University of Science and Technology (China); Guohua Gu, Nanjing Univ. of Science and Technology (China)

Motion object tracking is one of the most important research directions in the field of computer vision. Challenges in designing a robust tracking method are usually caused by partial or complete occlusions on targets. However, motion object tracking algorithm based on multiple cameras according to the homography relation in three views can deal with this issue more effectively since the information combining from multiple cameras in different views can make the target more complete and accurate. In this paper, a robust visual tracking algorithm based on the homography relations of three cameras in different views is presented to cope with the occlusion. First of all, being the main contribution of this paper, the motion object tracking algorithm based on the low-rank matrix representation under the framework of the particle filter is applied to track the same target in the public region respectively in different views. The target model and the occlusion model are established and an alternating optimization algorithm is utilized to solve the proposed optimization formulation while tracking. Then, we confirm the plane in which the target has the largest occlusion weight to be the principal plane and calculate the homography to find out the mapping relations between different views. Finally, the images of the other two views are projected into the main plane. By making use of the homography relation between different views, the information of the occluded target can be obtained completely. The proposed algorithm has been examined throughout several challenging image sequences, and experiments show that it overcomes the failure of the motion tracking especially under the situation of the occlusion. Besides, the proposed algorithm improves the accuracy of the motion tracking comparing with other state-of-the-art algorithms.

9596-8, Session 2

Track-to-track association for object matching in an inter-vehicle communication system

Ting Yuan, Tobias Roth, Qi Chen, Mercedes-Benz Research & Development North America, Inc. (United States); Jacob Breu, Miro Bogdanovic, Christian Weiss, Mercedes-Benz Research & Development North America, Inc. (Germany)

Dedicated Short Range Communication (DSRC), serving as an inter-vehicle communication systems, can provide information processing center (on host vehicle) the information of surrounding remote vehicles. The transmitted data, including real-time kinematic observations, current driving status and past trajectory histories, are containing beneficial information for advanced driver assistant systems. However, in a heavy vehicle traffic, there is a matching uncertainty issue (object identity problem), i.e., which DSRC sender is identical with which Radar observed object. If the DSRC data are associated with the corresponding host vehicle Radar observations, the useful remote vehicle information can be used to enhance host vehicle environment perceiving capability.

This paper presents a track-to-track association approach for associating the DSRC information with the corresponding Radar information. In this study, only GPS position data from remote vehicle are used in host vehicle information processing center for object matching purpose. The association between remote vehicle GPS position information via DSRC and the host vehicle locally perceived Radar information is examined, with the help of statistical tools. The challenge lies in high uncertainties of the heterogeneous-source data that belong to a same remote vehicle (i.e., the target) in complicated driving scenarios. The uncertainties lead to significant difficulties in matching decision if one uses directly the raw observations. Based on Kalman filtering techniques, we present a track-to-track association (T2TA) approach and build a real-time driving

system for on-road scenario object matching. The matching results show a promising potential for DSRC systems as an important/reliable enhancement component in advanced driver assistant systems.

9596-9, Session 2

Relationship between fractional calculus and fractional Fourier transform

Yan-Shan Zhang, Feng Zhang, Mingfeng Lu, Beijing Institute of Technology (China)

The Fractional calculus (FC) deals with integrals and derivatives of arbitrary (i.e., non-integer) order, and shares its origins with classical integral and differential calculus. The fractional Fourier transform (FRFT), which has been found having many applications in optics and other areas, is a generalization of the usual Fourier transform. The FC and the FRFT are two of the most interesting and useful fractional areas. In recent years, it appears many papers on the FC and FRFT, however, few of them discuss the connection of the two fractional areas. We study the relationship between the FC and the FRFT. The relational expression between them is deduced. It is a very nice result. The expectation of interdisciplinary cross fertilization is our motivation. For example, we can use the properties of the FC (non-locality, etc.) to solve the problem which is difficult to be solved by the FRFT in optical engineering; we can also through the physical meaning of the FRFT optical implementation to explain the physical meaning of the FC. Therefore, the FC and FRFT approaches can be transposed each other in the two fractional areas. It makes that the success of the fractional methodology is unquestionable with a lot of applications, namely in nonlinear and complex system dynamics and image processing.

9596-14, Session 2

Implementation and performance comparison of FPGA-accelerated particle flow and particle filters

Jiande Wu, Vesselin P. Jilkov, Dimitrios Charalampidis, Univ. of New Orleans (United States)

The Particle filter (PF) and particle flow filter (PFF) are powerful methods for nonlinear filtering but their computation is intense and may be prohibitive for real-time applications. This paper proposes design and program implementation of a parallel PF and a PFF using a field-programmable gate array (FPGA) as a parallel environment to speedup the computation. Simulation results from a nonlinear filtering problem for performance evaluation and comparison are presented. It is demonstrated that using FPGA can dramatically accelerate both particle filters and particle flow filters through parallelization at the expense of a tolerable loss in accuracy as compared to nonparallel implementation.

9596-16, Session 3

Dim target trajectory-associated detection in bright earth limb background

Penghui Chen, Xiaojian Xu, Xiaoyu He, Yuesong Jiang, BeiHang Univ. (China)

The intensive emission of earth limb in the field of view of sensors contributes much to the observation images. Due to the low signal-to-clutter ratio, it is a challenge to detect small targets in earth limb background, especially for the detection of point-like targets from a single frame. To improve the target detection, track before detection based on the frame sequence is performed.

In this paper, a new technique is proposed to determine target trajectories, which jointly deploys background removing, maximum value projection (MVP) and modified Hough transform (HT). First, the background of earth and its limb are estimated and eliminated based on the contour. Second, MVP is carried out to generate a synthetic image from the residual images. Thus, the pixels indicating targets are collected into one image. Third, if targets' motion can be considered to be linear in a short time interval, HT is implemented for the residual image to find target trajectories from location-associated pixels. Therefore, line segments are extracted including the target trajectory and some texture of clutter and noise. Finally, to discriminate true trajectories, extra information from MVP recording the frame serial number for each pixel in the synthetic image is employed. For a moving target, the corresponding pixels in the MVP image are shifting approximately regularly in time sequence. And the target trajectory is determined according to the pixel characteristics of the target and the clutter and noise.

Comparing with traditional frame-by-frame methods, determining associated trajectories from MVP reduces the computation load. Meanwhile, the modified HT method has a better performance to overcome the target pixel shift. Numerical simulations are presented to demonstrate the effectiveness and efficiency of the approach proposed in this paper.

9596-17, Session 4

Action windows with resource limits

David D Sworder, Univ of California San Diego (United States); John Boyd, Cubic Defense Applications, Inc. (United States)

An assurance region at level p, Ap, is an area in motion space that contains the target with assigned probability p. It is on the basis of Ap that an action is taken or a decision made. Common model-based trackers generate a notional distribution function for the kinematic state of the target. Unfortunately, this distribution is very coarse, and the resulting Ap lack credibility.

Let us consider an engagement in which a target of uncertain intent is detected. The defender must illuminate the target to infer its purpose. The defender will focus on a small area to increase the interrogation accuracy. In another engagement, the defender recognizes a target with hostile intent and must neutralize the target. In the latter case, the defender may use a directed energy weapon (DEW) focused at the current position. Or the weapon may use ballistic particles focused on a future location of the target.

In what follows we will investigate the ability of a defender to place an action window about a target, either concurrently or predictively. If the target is within the action window, it is counted as a hit. If the target is outside the action window, it is counted as a miss. In either of the above engagements, proper defense requires that we hit the target a specified fraction of the time.

It is shown that a map-enhanced, multiple model algorithm reduces the tracking error and leads to a compact assurance region. The algorithm minimizes the expenditure of defensive assets.

9596-18, Session 4

Implementation and evaluation of a detector of clutter embedded resolved targets in optical and infrared maritime video

Martin Jaszewski, Eric Hallenborg, Space and Naval Warfare Systems Ctr. Pacific (United States)

We implement the method proposed in 2014 by Stotts and Hoff (SH14) [1] to automatically detect resolved targets embedded in background clutter. The SH14 method provides a test statistic which emphasizes comparing apparent contrast rather than signal to noise ratio. The SH14 authors demonstrated through analysis and simulations that their method can detect low or even zero contrast targets in clutter if the background variance is greater than the common system noise variance.

We apply this detector to the maritime domain in which marine vessels are typically found amid clutter such as waves, glint, whitecaps, wakes, port

and harbor infrastructure, etc. Our implementation provides an estimate of the common system noise variance whereas SH14 uses a fixed value in their theoretical validation. We estimate the system noise from the video directly without any prior knowledge of the imaging sensor parameters. After considering several noise models with different assumptions about the spatiotemporal variance of system noise we will compare the results to justify our model selection. Further, we provide a means to compute the background statistics needed by the SH14 detector, following the approach in [2] by using a sliding annulus with a guard band and distinct background mean and variance estimation bands.

Finally, we will evaluate the detection accuracy of our implementation of the SH14 detector using a video dataset depicting marine vessels in real world maritime environments using the PASCAL VOC Challenge evaluation framework. We will analyze the computational performance of our detector as a function of various input parameters.

Off-the-grid recovery of piecewise constant MR images

Mathews Jacob, The Univ. of Iowa (United States)

We introduce a novel piecewise polynomial continuous model, whose discontinuities are localized to the zero level-sets of band-limited curves, to represent MR images. We show that such images can be perfectly recovered from their very few Fourier coefficients. Unlike current compressed sensing recovery schemes, the proposed approach is completely off-the-grid; this approach generalizes Prony-like methods that are widely used in signal processing. We also introduce efficient algorithms and demonstrate their application to recovery of MR images from Fourier samples.

9597-2, Session 1

Learning sparsifying filter banks

Luke Pfister, Yoram Bresler, Univ. of Illinois at Urbana-Champaign (United States)

Recent years have numerous algorithms to learn a sparse synthesis or analysis model from data. Recently, a generalized analysis model called the 'transform model' has been proposed. Data following the transform model is approximately sparsified when acted on by a linear operator called a sparsifying transform.

While existing transform learning algorithms can learn a transform for any vectorized data, they are most often used to learn a model for overlapping image patches. However, these approaches do not exploit the redundant nature of this data and scale poorly with the dimensionality of the data and size of patches.

We propose a new sparsifying transform learning framework where the transform acts on entire images rather than on patches. We illustrate the connection between existing patch-based transform learning approaches and the theory of block transforms, then develop a new transform learning framework where the transforms have the structure of an undecimated filter bank with short filters.

Unlike previous work on transform learning, the filter length can be chosen independently of the number of filter bank channels.

Learning is accelerated using Forward-Backward Splitting and convolution is implemented using the overlap-add algorithm. The resulting algorithm scales gracefully to high dimensional data and long filters.

Numerical results show our new model sparsifies images better than earlier patch-based transforms.

Image denoising experiments show our method to be competitive with state-of-the-art analysis operator learning methods. While our experiments utilize a set of training images, our framework can also learn a model from a single noisy image.

A fast algorithm for reconstruction of spectrally sparse signals in super-resolution

Jian-Feng Cai, Suhui Liu, Weiyu Xu, The Univ. of Iowa (United States)

We propose a fast algorithm to reconstruct a spectrally sparse signal from a small number of randomly observed time domain samples. In conventional compressed sensing setting, the frequencies are ususally discretized, and it suffers from basis-mismatch caused by the resolution of the discretization. In this talk, we consider the super-resolution case where the frequencies can be any values in the nomalized continous frequency domain [0,1]. Under this setting, the problem of reconstruct a specatrally sparse signal can be solved by convex optimizations such as atomic norm minimization and enhanced matrix completion. However, in these methods, the optimization is performed in an N^2-dimensional space for signals of size N. Thus, large scale problems are prohibited. To relieve this, we propose an efficient algorithm for large-scale super-resolution of spectrally sparse signals. The signal recovery problem is first converted into a low rank Hankel matrix completion problem. Then, we employ an efficient feasible point algorithm named projected gradient algorithm(PGA). Since each iteration is either a Hankel or a low-rank matrix, our proposed algorithm can handel large-scale problems. By using the Kurdyka-Lojasiewicz property, we give the convergence analysis of the algorithm. The algorithm can be significantly accelerated by the FISTA-like technique. Numerical experiments are provided to illustrate the effectiveness of our proposed algorithm.

Algebraic and geometric spread in finite frames

Emily J. King, Univ. Bremen (Germany)

When searching for finite unit norm tight frames (FUNTFs) of M vectors in $mathbb{F}^N$ which yield robust representations, one is concerned with finding frames consisting of frame vectors which are in some sense as spread apart as possible. Algebraic spread and geometric spread are the two most commonly used measures of spread. A frame with optimal algebraic spread is called full spark and is such that any subcollection of N frame vectors is a basis for $mathbb{F}^N$. A Grassmannian frame is a FUNTF which satisfies the Grassmannian packing problem; that is, the frame vectors are optimally geometrically spread given fixed M and N. A particular example of a Grassmannian frame is an equiangular frame, which is such that the absolute value of all inner products of distinct vectors is equal. The relationship between these two types of optimal spread is complicated. The folk knowledge for many years was that equiangular frames were full spark; however, this is now known not to hold for an infinite class of equiangular frames. The exact relationship between these types of spread will be further explored in this talk, as well as Pl"ucker coordinates and mutual coherence, which are measures of how much a frame misses being optimally algebraically or geometrically spread.

Sparse frame representation in DOA estimations under severe noise

Cao Zeng, Xidian Univ. (China); Shidong Li, San Francisco State Univ. (United States); Guisheng Liao, Xidian Univ. (China)

Direction of arrival (DOA) estimation has been one of the main topics of array signal processing, which is widely encountered in application platforms such as radar, communication, navigation and sonar et al [1]. Subspace-based methods such as multiple signal classifications (MUSIC) [2] and estimations of signal parameters via rotation invariance techniques (ESPRIT) [3] can achieve relatively high resolution with enough snapshots under moderately high signal-to-noise ratio (SNR). These methods also require that the source number is precisely known and the sources are not strongly correlated.

Among new techniques, sparse-representation-based (SR) methods perform relatively well when observations carry high signal-to-noise ratio (SNR). Typical techniques in these new methods are, e.g., ?1-norm based convex optimization (?1-min) [4], orthogonal matching pursuit (OMP) [5], and various variations. However, performances of these methods degrade substantially under typically very noisy observations in DOA application platforms. The method of ?1-based singular value decomposition (?1-SVD) [6] can improve the performance of SR-based methods in low SNR circumstances. The cost, however, is its rather time-consuming computational complexities.

In this report, a fast and super-resolution DOA estimation approach based on a crucial correlation operation and sparse-representations is proposed. Typical DOA formulations by a sparse frame representations or compressed sensing with frames suffer seriously under severe noisy measurement which is common in the platform of DOA applications. To mitigate low SNR issue in typical DOA application, a crucial and effective correlation operation is proposed from the sparse frame representation point of view. The proposed DOA recovery technique is based on a new iterative null space tuning method with feedbacks (NST+FB) [7]. An improvement to the adaptive scheme of the NST+FB is also proposed to estimate the source number dynamically, by a technique of thresholding differences. Simulation results demonstrate apparent advantages of the proposed technique over known approaches. The proposed method has the characteristics of simultaneous high resolution, robustness to noise, and effectiveness at estimating the number of sources. The algorithm is also computationally efficient.

Shearlets-based regularization in fan-beam ROI-CT problems

Tatiana A. Bubba, Univ. of Ferrara (Italy); Silvia Bonettini, Univ. degli Studi di Ferrara (Italy); Demetrio Labate, Univ. of Houston (United States); Gaetano Zanghirati, Univ. degli Studi di Ferrara (Italy)

This talk is invited by special session organizer prof. D. Labate.

Region-of-interest Computed Tomography (ROI CT) is a challenging problem, currently receiving increasing attention due to a wide range of applications, especially in biomedical imaging. It has the potential to significantly reduce the X-ray radiation dose and shorten the scanning time. However, due to the truncation of projection images, the ROI reconstruction problem is severely ill-posed in general and naive local reconstruction algorithms may be very unstable. In order to obtain a stable reconstruction, the ROI CT can be modelled as a convex optimization problem with a regularized functional and solved using an iterative algorithm. In this study, we consider different regularization approaches, based on wavelets or shearlets, and possibly coupled with a Total Variation (TV) regularization term. For our numerical solution, we propose and analyse an iterative approach based on the scaled gradient projection method (SGP). We compare the reconstruction performance of our algorithm under different regularization conditions in the case of fan-beam CT using both simulated and real data. One major advantage of our approach is that - in contrast to many existing methods - no assumptions are made either on the size or on the location of the ROI.

Investigating the impact of blood pressure increase to the brain using high resolution serial histology and image processing

Frédéric Lesage, Baoqiang Li, Alexandre Castonguay, Pramod Avti, Joel Lefebvre, Ecole Polytechnique de Montréal (Canada)

We recently developed a combined serial OCT/confocal scanner to image large sections of biological tissues at microscopic resolution. Embedding organs in agarose blocks and cutting through tissue using a vibratome enabled serial high resolution imaging. The vibratome is integrated in the microscopic platform to sequentially cuts slices in order to reveal new tissue to image, overcoming limited light penetration encountered in microscopy. In this work, the mechanisms of white matter properties change by inducing transverse, between carotids, aortic constriction (TAC) in healthy WT mice are investigated in relation with microvasculature properties. At sacrifice, mice were transcardially perfused with a FITC containing gel. The dual imaging capability of the system allowed to reveal different contrast information: OCT imaging reveals changes in refractive indices giving contrast between white and grey matter in the mouse brain, while transcardial perfusion of a FITC shows microsvasculature in the brain with confocal imaging. We then describe a method to enhance microvessels from confocal images using curvelets and compare to Frangi's vesselness filter. These are then used to correlate white matter and microvasculature changes.

Estimating brain's functional graph from the structural graph's Laplacian

Farras Abdelnour, Michael Dayan, Weill Cornell Medical College (United States); Orrin Devinsky, Thomas Thesen, New York Univ. Langone Medical Ctr. (United States); Ashish Raj, Weill Cornell Medical College (United States)

The relationship between anatomic connectivity of large-scale brain networks and their functional connectivity is of immense importance and an area of ongoing research. Previous attempts have required complex simulations which model the dynamic of each cortical region, and explore the coupling between regions as derived by anatomic connections. While much insight is gained from these nonlinear simulations, they can be computationally taxing tools for predicting functional from anatomic conductivities. We show that a simple linear model based on the Laplacian of the structural graph adjacency matrix can predict the brain's functional network.

9597-22, Session 5

Phase retrieval by projections

Peter G. Casazza, Univ. of Missouri-Columbia (United States)

Over the 100 year history of phase retrieval, it

has had broad application to x-ray crystallography, electron microscopy, diffractive imaging, DNA, x-ray tomography and much more. Phase retrieval will even be needed to align the mirrors of the new James Webb Space Telescope scheduled for launch in 2018. Recently, in crystal twinning and related areas, a variation of standard phase

retrieval called phase retrieval by projections has arisen. We will look at recent advances in the mathematics of phase retrieval by projections, including the surprising result that in the real case, phase retrieval can be done with 2n-1 arbitrary rank projections in an n-dimensional Hilbert space.

Self-calibration and biconvex compressive sensing

Thomas Strohmer, Shuyang Ling, Univ. of California, Davis (United States)

The design of high-precision sensing devises becomes ever more difficult and expensive.

At the same time, the need for precise calibration of these devices (ranging from tiny sensors to space telescopes) manifests itself as a major roadblock in many scientific and technological endeavors.

To achieve optimal performance of advanced high-performance sensors one must carefully calibrate them, which is often difficult or even impossible to do in practice. In this work we bring together three seemingly unrelated concepts, namely Self-Calibration, Compressive Sensing, and Biconvex Optimization.

The idea behind self-calibration is to equip a hardware device with a smart algorithm that can compensate automatically for the lack of calibration.

We show how several self-calibration problems can be treated efficiently within the framework of biconvex compressive sensing via a new method called SparseLift. More specifically, we consider a linear system of equations y = DAx, where both x and the diagonal matrix D (which models the calibration error) are unknown. By ``lifting'' this biconvex inverse problem we arrive at a convex optimization problem. By exploiting sparsity in the signal model, we derive explicit theoretical guarantees under which both x and D can be recovered exactly, robustly, and numerically efficiently via linear programming.

Applications in array calibration and wireless communications are discussed and numerical simulations are presented, confirming and complementing our theoretical analysis. This talk is invited by special session organizers Radu Balan, Bernhard Bodmann, and Gitta Kutyniok.

Fast live cell imaging at nanometer scale using spare recovery

Junhong Min, KAIST (Korea, Republic of); Michael Unser, Suliana Manley, Ecole Polytechnique Fédérale de Lausanne (Switzerland); Jong Chul Ye, KAIST (Korea, Republic of)

Super resolution microscopy such as STORM/PALM can achieves nanoscale spatial resolution by iterative localization of sparse subset of fluorescence molecules. However, this basic scheme generally leads to a long acquisition time which is critical limitation for investigating live cell dynamics. Imaging of densely activated molecules can accelerate temporal resolution by incorporating advanced localization algorithms to deal with overlapping point spread functions (PSFs). Recently, we introduced localization algorithm called FALCON using continuous localization model to deal with this issue. Specifically, it combines a sparsity-promoting deconvolution formulation with Taylor approximation of PSF for refining positions of localization on a continuous space. Our localization model is not only accurate, showing minimum localization bias, but also computationally advantageous. In addition, it can be implemented in a computationally efficient way by utilizing fast sparse recovery algorithms such as ADMM. Furthermore, we extended our approach to fast 3D super-resolution imaging which is more challenging than 2D case since PSFs are often far more similar along the axial dimension than the lateral dimensions. Therefore, we considered the hybrid system that is implemented by combining astigmatic and biplane imaging. Using mutual coherence analysis of model PSFs, we validated that the hybrid system is more suitable than astigmatic or biplane imaging alone for 3D localization of high-density data. We also successfully demonstrated fluorescent-protein-based 3D live cell imaging with a temporal resolution of just 3 seconds which is, to our best knowledge, currently the fastest 3D localization microscopy.

PSF super-resolution using sparsity and low rank matrices constraint

Fred Ngole, Jean-Luc Starck, Commissariat à l'Énergie Atomique (France)

In large scale spatial surveys such as the forthcoming ESA Euclid mission, images may be undersampled due to the optical sensors sizes. Therefore, one may consider using a super-resolution (SR) method to recover aliased frequencies, prior to further analysis. This is particularly relevant for point source images which provide direct measurements of the instrument point spread function (PSF). We propose a sparsity-based SR approach. Assuming that different shifted low resolution (LR) versions of the same PSF are available, we show that our method provides significant improvements over existing SR methods.

In practice, even if the PSF varies slowly across the instrument field of view, strictly speaking, one only has a single LR observation of the PSF at a given position in the field. Therefore we propose to jointly super-resolve a PSF field, exploiting the fact that the PSFs are randomly shifted on the sensor grid, and are similar to each other. This global prior translates into a low rank matrix constraint on the whole set of super-resolved PSFs.

Higher-order graph wavelets and sparsity on circulant graphs

Madeleine S. Kotzagiannidis, Pier Luigi Dragotti, Imperial College London (United Kingdom)

The notion of a graph wavelet gives rise to a more advanced processing of data on graphs due to its ability to operate in a localized manner, across newly arising data-dependency structures, with respect to the graph signal and underlying graph structure, thereby taking into consideration the inherent geometry of the data. In this work, we tackle the problem of creating graph wavelet filterbanks on circulant graphs for a sparse representation of certain classes of graph signals, lying on the vertices of such graphs, in the graph wavelet domain. Hereby, we consider scenarios in which the underlying graph is data-driven as well as fixed, for applications including image processing and social network theory, whereby clusters can be modelled as circulant graphs, respectively. We present a set of novel graph wavelet filterbank constructions, which annihilate higher-order polynomial graph signals defined on the vertices of undirected, circulant graphs and are localized in the vertex domain. Their design is based on a generalization of the annihilation property of the corresponding graph Laplacian matrix, which is shown to have two vanishing moments for a sufficiently small bandwidth. The derivation is conducted through spectral factorization, using similar methods as in the traditional domain; we additionally present constructions using matrix theory. We give preliminary results on their performance for non-linear approximation. Furthermore, we provide extensions to our previously developed segmentation-inspired graph wavelet framework for non-linear image approximation, by incorporating notions of smoothness and vanishing moments, which further improve performance compared to traditional methods.

Applied and computational harmonic analysis on graphs and networks *(Keynote Presentation)*

Naoki Saito, Univ. of California, Davis (United States)

In recent years, the advent of new sensor technologies and social network infrastructure has provided huge opportunities and challenges for analyzing data recorded on such networks. For analyzing data recorded on regular lattices, computational harmonic analysis tools such as the Fourier and wavelet transforms have well-developed theories and proven track records of success. It is therefore quite important to extend such tools from the classical setting of regular lattices to the more general setting of graphs and networks.

In this talk, I will first review basics of Laplacian matrices of a graph whose eigenpairs are often interpreted as the frequencies and the Fourier basis vectors on a given graph. I will point out, however, that such an interpretation is misleading unless the underlying graph is unweighted path or cycle. I will then discuss our recent effort of constructing multiscale basis dictionaries on a graph including the Hierarchical Graph Laplacian Eigenbasis Dictionary and the Generalized Haar-Walsh Wavelet Packet Dictionary, which are viewed as the generalization of the classical hierarchical block DCTs and the Haar-Walsh wavelet packets for the graph setting. If time permits, I will also discuss how to generalize those constructions for directed graphs.

Directed brain graphs from autoregressive models

Fabrizio De Vico Fallani, Institut National de Recherche en Informatique et en Automatique (France) and L'Institut du Cerveau et de la Moelle épinière (France)

In the last decade, the sparse representation of the brain as a graph, consisting of nodes and links, has allowed to visualize functional brain networks and describe their non-trivial topological properties in a compact and objective way.

Nowadays, the use of graph analysis in neuroscience has become essential to quantify the physiological brain organization and pathological dysfunctions in terms of aberrant reconfiguration of functional brain

networks. After defining the brain nodes, which usually correspond to different brain regions, assigning the inks between them is the subsequent crucial modeling step.

In functional neuroimaging the links of a brain graph are given by evaluating the similarity between the activities of the two brain regions, through functional connectivity (FC) measures. FC methods fall into two broad categories: those measuring symmetric mutual interaction (undirected weighted links) and those measuring asymmetric information propagation (directed weighted links).

In the present talk, I will focus on the construction of directed brain graphs from a given set of signals representing the activities recorded in different brain regions. Specifically, I will introduce the use of autoregressive models to build directed graph links that code Granger-causality between different brain areas. Also, I will present some applications to real data ranging from electroencephalography (EEG) in healthy and diseased subjects to calcium imaging signals optically recorded from the spinal cord of the zebrafish.

Finally, I will conclude by highlighting current limitations and open issues related to the construction, analysis and interpretation of directed brain graphs.

3D imaging of amplitude objects embedded in phase objects using transport of intensity

Mahmudunnabi Basunia, Univ. of Dayton (United States); Partha Banerjee, University of Dayton (United States)

The amplitude and phase of the complex optical field in the Helmholtz equation obey a pair of coupled equations, arising from equating the real and imaginary parts. The imaginary part yields the transport of intensity equation (TIE), which can be used to derive the phase distribution at the observation plane. If a phase object is approximately imaged on the recording plane(s), TIE yields the phase without the need for phase unwrapping. In our experiment, we recover the 3D image of an amplitude object embedded in a phase object. The phase object is created by heating a liquid, comprising a solution of red dye in alcohol, using a focused 514 nm laser beam to the point where self-phase modulation of the beam is observed. The optical intensities are recorded are various planes during propagation of a low power 633 nm laser beam through the liquid. In the process of applying TIE to derive the phase at the observation plane, the real part of the complex equation is also examined as a cross-check of our calculations. Our work can find applications in, for instance, referenceless 3D imaging of debris in a fireball, and is well suited for moving objects.

9598-2, Session 1

Linear fitting interpolation based on FOV division for correcting wide angle fish-eye lens distortion

An Li, Yisi Wu, Chi Chen, Zhenrong Zheng, Zhejiang Univ. (China)

The wide angle lens, like fish eye lens, suffers great optical distortion that causes severe deformation of the real world. A method to correct the strong distortion was presented in this work. Due to the nonlinear distribution of the distortion, linear algorithms are generally not under consideration to establish the math model of distorted-to-ideal images. However, this method employed the calibration pattern that comprised of regular array of dots to divides the full field of view (FOV) to subsections, each subsection is a small FOV, the mapping parameters between the distorted image and ideal image in each small FOV can be calculated by employing the very simple linear polynomial. Thus, applying the determined parameters to their corresponding sub-FOVs, respectively, all the ideal pixel coordinates of the distorted image can be obtained. The method employed linear polynomial characterizes the geometric deformation between the distorted and ideal images directly. Therefore, it contains both of radial distortion and tangential distortion and there is no need of concerning any intrinsic or extrinsic parameters of the optical systems. So, this algorithm reliefs the computational work that employed by conventional radial models and other mathematical models. Experiments performed on off-axis optical systems which exist complicated distortion, such as the head mounted displays (HMDs), had already yielded accurate correcting results. Likewise, in this paper, the experiments refer to the fish-eye lens also verified the effectiveness and flexibility of this method.

9598-3, Session 1

Real-time sine transform of images based on volume holographic optical correlator

Fanglin Liu, Liangcai Cao, Dezhao Kong, Guofan Jin, Tsinghua Univ. (China)

Volume holographic correlator (VHC) is a multi-channel optical correlator with the merits of high speed, high storage density and parallel computing [1]. It presents the potential in areas where fast computing and massive capacity are acquired [2, 3]. In this work, the two-dimensional discrete sine transform based on this optical method is proposed. More than two thousand data pages standing for the orthogonal sine transform functions are recorded in a photorefractive crystal by angle multiplexing [4]. During the transform process, an input image is uploaded to the optical path through a spatial light modulator. VHC calculates the inner products between the input image and all the pre-recorded data pages in parallel. All the angle-multiplexed reference beams are simultaneously reconstructed and the intensities of correlation spots are detected by a CCD. The transform coefficient of each transform function can be retrieved according to the intensities in the center of each correlation spot. These transform coefficients can also be used to reconstruct the original input image. Because the transform time for optical method is only the light propagation time and the computing is finished in parallel, the VHC has a great advantage over the purely electronic method. The real-time sine transform using an automatic optical correlator is demonstrated.

Modeling for space-based visible imaging characteristics of space object

Cheng-Ming Sun, Academy of Opto-Electronics (China); Yan Yuan, BeiHang Univ. (China); Zhiliang Zhou, Academy of Opto-Electronics (China)

With the development of space technology, the number of space objects dramatically increases in recent years. The miniaturization, diversification and complication of space objects pose new challenges for their detection. Space-based visible imaging detection, which is flexible and intuitive, gradually becomes an important means for space object detection. As the theoretical foundation and technical support for the schematic design and performance analysis of imaging detection systems, an imaging detection model should synthetically involve the physical parameters of the object, the performance parameters of the detector, and the orbit parameters of the sun, object and detector.

In order to enhance the capability of space-based surveillance, the detailed modeling for visible imaging characteristics of space object is described in this paper. Firstly, a space-based imaging detection model is built based on the scattering visible radiation from space object. The model consists of radiation transmission based on the bidirectional reflectance distribution function (BRDF) and grayscale transformation. Then, according to the position of the sun, object and detector, the imaging conditions such as imaging angle and size are analyzed. Finally, the grayscale images of the HuanJing-1 satellite are simulated. It shows the grayscales for the different regions of the object appear great difference, indicating that the space-

based detector needs a larger dynamic range. The simulation results can provide reference basis for space object detection.

The fast Fresnel diffraction algorithm: from the ray matrix approach to experimental virtual propagation systems *(Invited Paper)*

Jeffrey A Davis, Don M. Cottrell, Cassidy A. Berg, Christopher Li Freeman, Adriana Carmona, William Debenham, San Diego State Univ. (United States); Ignacio Moreno, Univ. Miguel Hernández de Elche (Spain)

In this paper the fast Fresnel diffracion algorithm is reviewed from different non-standard points of view and applied to some novel applications. The algorithm (also named the angular spectrum method) is a very powerful numerical technique that has been employed for years in the calculation of diffraction patterns. It utilizes two Fourier transform operations, thus becoming computationally much faster than the conventional approach. We analyze the practical implementation with spatial light modulators (SLM).

First, the ray matrix approach is applied to derive and reexamine the technique. This approach permits to easily find explicit expressions for the distances over which the algorithm is accurate. Then, we describe its practical implementation to encode Fresnel propagated masks onto a SLM. We discuss the limitations caused by the Nyquist limit.

Finally, we apply the technique to create an experimental virtual optical beam propagator system. This system uses one SLM and allows the experimental study of beam propagation without physically moving any element. This laboratory propagator system can be extremely useful to build compact optical architectures or to emulate beam propagation without misalignments caused by moving elements.

As examples, we design holograms producing different patterns at different distances, and we can change the effective plane of observation by changing the encoded propagation. Other multiplexed patterns are designed to create azimuthal multiple beam interference effects by applying different propagation distances to different vortex generating maks. The technique can find applications in many different contexts, including the analysis of propagation dynamics of nondiffracting beams, and Airy beams.

9598-5, Session 2

Image quality improvement of digital holography by use of various rectangle apertures

Takanori Nomura, Takahiko Fukuoka, Yutaka Mori, Wakayama Univ. (Japan)

Digital holography is a useful technique for recording the fully complex field of a wavefront. In line with advances in imaging devices such as charge coupled devices, digital holography is available. Digital holography has been used for lots of applications including display, encryption and three-dimensional object recognition. However, the quality of a reconstructed image of a digital hologram is not good, because it is suffering from speckles. Compared with a conventional film hologram, the extent of a digital hologram is small. This is why the reconstructed image has noticeable speckles, because, the speckle size of reconstructed image is in inverse proportion to the image sensor size. Therefore, the synthetic aperture digital holography was proposed to decrease the size of speckles. If a huge size image sensor is used, the size of speckles is enough small to ignore. However, it is not practical.

Then we propose a speckle reduction method in digital holography using various rectangular apertures. In the proposed method, different-sized rectangular apertures are applied for the hologram. Furthermore, the position of the aperture is arbitrary. Owing to the various size and position, the generated speckles have the various sizes and patterns. By averaging the speckle, the speckle noise can be reduced.

Some reconstructed images based on the experimental results are shown to confirm the proposed method. For quantitative evaluation, the speckle contrast is also shown.

9598-6, Session 2

Static and dynamic effects of flicker in phase multilevel elements on LCoS devices

Andrés Márquez, Francisco J. Martínez-Gaurdioloa, Sergi Gallego, Manuel Ortuño, Jorge Francés, Augusto Beléndez, Inmaculada Pascual, Univ. de Alicante (Spain)

Phase-only modulation is necessary in a great number of modern spatial light modulation applications, and the spatial light modulator (SLM) technology of choice is usually the parallel-aligned liquid crystal on silicon (PA-LCoS) microdisplay. Various degradation effects have been analyzed in the literature which may be introduced by SLMs and whose quantitative knowledge enables to select the best working conditions and/or to design specific compensation strategies to diminish negative effects. In this paper we concentrate on the phase flicker typically produced by PA-LCoS devices. The availability of a recent polarimetric-based method, the average Stokes polarimetric technique, to measure the linear retardance and its flicker amplitude eases the capability to simulate the performance of spatially varying phase multilevel elements typically addressed onto PA-LCoS. A representative element is the blazed grating. We analyse both their average diffraction efficiency, “static” analysis, and its associated time fluctuation, “dynamic” analysis, under a wide set of conditions. We obtain a good agreement between simulation and experiment, thus further demonstrating the predictive capability of the calibration provided by the average Stokes polarimetric technique. An interesting result is that, in general, the influence of flicker greatly diminishes when the number of quantization levels in the optical element increases, thus limiting to acceptable levels the effects introduced by the phase flicker.

9598-7, Session 2

Incoherent holography to obtain depth information by a rotational shearing interferometer

Kaho Watanabe, Takanori Nomura, Wakayama Univ. (Japan)

The possibility of incoherent holography has been widely studied. It enables us to record hologram without coherent illumination such as a laser. We have proposed the system to record incoherent Fourier hologram of an object (incoherently illuminated or self-luminous object) using a rotational shearing interferometer. The system can record incoherent hologram by self-interference of the two coherent object points created by the beam splitter from one object point. The Fourier hologram has the advantage of increasing space-bandwidth product performance. However, no depth information is obtained. In general, rotational shearing interferometer cannot reproduce any depth information. The reason is indicated that the shear by rotational shearing interferometer is a purely lateral shear orthogonal to the optical axis by Bryngdahl and Lohmann. In this paper, we propose the system of incoherent holography which can record depth information using a rotational shearing interferometer. The system has a lens for the shear which is parallel to the optical axis. This is because we can obtain depth information by a rotational shearing interferometer. A preliminary experiment was performed to confirm our method. A liquid crystal display with a LED backlight was used as an incoherent object. The Fresnel zone-like intensity was recorded from a circular object pattern. We reconstructed recorded incoherent hologram by a Fresnel diffraction integral at some reconstruction distances. We obtained reconstructed images which defocus and focus on the incoherent object. These experimental results confirm the proposed system of incoherent holography to obtain depth information using a rotational shearing interferometer.

Spectral characterization and tuning with liquid-crystal retarders

María del Mar Sánchez-López, Ignacio Moreno, Univ. Miguel Hernández de Elche (Spain); Asticio V. Vargas, Univ. de la Frontera (Chile); Pascuala García-Martínez, Univ. de València (Spain)

We present an accurate and simple technique to characterize the spectral retardance of a liquid-crystal retarder (LCR), including multiple-beam Fabry-Perot (FP) interferences. Interference effects occur in LCR devices devoid of an antireflective coating and must be considered in applications that require a fine control of the phase or the polarization.

The proposed technique is based on a simple physical model with few parameters, namely: absorption losses, the complex transmission coefficients in the extraordinary and ordinary axes accounting for the FP interference in the liquid crystal layer, and the phase shifts introduced by the compensator layer present in most devices. Considering that the retarder is illuminated under normal incidence, the wavelength dependence of the model parameters is first retrieved by characterizing the LCR in the off-state. Then, we apply a voltage transfer fuction valid in the spectral range of characterization. As a result of this procedure, a full description of the LCR spectral modulation properties is obtained.

By tilting the LCR we extend the former analysis to illumination under non-normal angles of incidence. This situation is relevant for liquid crystal on silicon (LCoS) displays, which are often illuminated under oblique incidence to avoid the use of beam splitters. With this technique we can retrieve the ordinary and extraordinary spectral phase delays and distinguish between fast and slow axis. This allows us to use the stationary phase-time approach and discuss the arising of superluminal and slow-light group delay regimes for the LCR inserted between linear polarizers. It is also useful to design optical architectures to achieve full spectral control.

9598-9, Session 2

Z-domain modeling and analysis of vertically coupled triple asymmetrical optical micro ring resonator (VCTAOMRR)

Sanjoy Mandal, Suchita Lakra, Indian School of Mines (India)

Theoretical modeling of a carefully designed vertically coupled triple asymmetrical optical micro ring resonator(VCTAOMRR) is developed using delay line signal processing approach. Overall transfer function of the proposed VCTAOMRR is determined in Z-domain using signal flow graph and Mason's rule. Vertically coupled triple micro ring resonator(VCTMRR) of two symmetrical ring was successfully modeled in Z-domain by S Mandal et.al.[1] where its performance in terms of free spectral range (FSR) and crosstalk of the VCTMRR with two symmetric rings is compared with previously published results, and found to be in very close agreement.

Frequency response , group delay and dispersion characteristics of the proposed VCTAOMRR are evaluated in MATLAB environment. Performance in terms of free spectral range (FSR) and crosstalk of the VCTAOMRR is determined from the frequency response characteristics. The Vernier principle is used to expand the FSR when optical triple micro ring resonators with unequal radii are combined so that the passbands overlap only once in several periods.The proposed VCTAOMRR can produce very wide FSR around 80 nm. The design provides frequency response characteristics where crosstalk at the interstitial frequencies that lie between the extended FSR is adequately suppressed.Dispersion causes broadening of signal pulses around the resonant peaks.Dispersion characteristics is evaluated from group delay characteristics of the proposed VCTAOMRR.

9598-10, Session 3

Measurement of repetitive surface displacement modulation induced by illuminating femto-second laser pulses

Ryoma Tozawa, Daisuke Barada, Shigeo Kawata, Utsunomiya Univ. (Japan)

When an opaque object is illuminated by femto-second laser pulses, an acoustic wave is generated. The fundamental frequency of the acoustic wave seems depend on the repetition frequency of the laser pulse. It is considered that the acoustic wave is generated by repetitive surface displacement modulation. In this study, momentary optical phase modulation of another continuous wave laser beam was investigated and the repetitive phase modulation was measured by interferometry. In experiments, Ti: Sapphire laser pulses with a central wavelength of 780 nm were illuminated onto a mirror used as a sample from the back. The pulse width and repetition frequency was set to tens femtoseconds and 1 kHz, respectively. In order to confirm the spatial effect, the femto-second laser pulse was spatially modulated by a liquid crystal spatial light modulator. A He-Ne laser beam was used as a probe beam. The He-Ne laser beam was split to two beams by a beam splitter and illuminated onto the sample mirror and the reference mirror. The two reflected beams were superposed onto a CMOS image sensor and the interference fringe was obtained with a frame rate of 100,000 fps. In order to block the femto-second pulses, a low pass filter was put on a front of CMOS image sensor. Then, it was observed that the interference fringe is periodically changed with a frequency of 1kHz by temporal Fourier transform pattern at each pixel. By extracting the 1kHz signal from all pixels, the phase modulation distribution was visualized.

9598-11, Session 3

Phase correction method for least-squares wavefront calculation in statistical generalized phase-shifting digital holography

Nobukazu Yoshikawa, Kazuki Kajihara, Saitama Univ. (Japan)

The continuous fringe scanning scheme offers some advantages such as short measurement time, high phase stability and high noise tolerance. However, it may be difficult to generate a constant phase-shift using a low-cost system because it requires accurate synchronization between an image sensor and phase-shifter. On the other hand, the generalized phase-shifting method does not require a specific phase-shift value such as the integral multiples of $\varpi/2$ phase shift. Therefore, there is no difficulty in implementation of the continuous fringe scanning scheme.

In this study, we propose statistical generalized phase-shifting digital holography using continuous fringe scanning scheme and the phase-shift estimation method using a least-squares algorithm. The phase-shifts are generated by a continuous fringe scanning technique, and time-varying interference fringes are detected sequentially by an image sensor without synchronizing a phase-shifter. Integrations of the time-varying intensity in the interference fringe produce an arbitrary phase-shifted digital hologram. Since there is no wait time for phase stabilization unlike the step fringe scanning technique, many phase-shifted interference fringes can be obtained in a short time. Signed phase-shift values are estimated by the statistical approach and then the object wave is obtained by the least-squares algorithm. The proposed method does not require precise control and calibration of the phase shifter and synchronization between the image sensor and phase shifter. Experiments demonstrate the validity of the proposed method. The practical digital holography system with high accuracy can be implemented at low cost.

9598-12, Session 3

A hybrid MEMS-planar waveguide optical signal processor

Dwayne Macik, Russell J. Howe, Christi K. Madsen, Texas A&M Univ. (United States)

An optical signal processor is proposed that performs a direct signal-filter convolution without the use of Fourier Transformed filter multiplication. The convolution operation is carried out utilizing electro-optical components to generate and steer an optical beam to a digital micro-mirror device. Input signal in the form of a collimated optical beam is scanned through an imaging optic across a micro-mirror array that presents a 1-D spatial filter function. The filter function is shifted spatially with changing row or column to carry out a convolution operation. Filter "bit depth" is determined by the mirror pattern in the local spot zone giving a ratio of 'on' state to 'off' state area. The reflected signal returns along the original path through the imaging lens and is read by a receiver following a beam splitter. Design feasibility is presented along with laboratory setup results. Functionality limits based on component selection are considered.

9598-13, Session 3

The solution spectroellipsometry objectives for environmental monitoring

Ferdenant A. Mkrtchyan, Institute of Radio Engineering and Electronics (Russian Federation)

Ellipsometry is an optical technique that uses the change in the state of polarization of light upon reflection and refraction for the in-situ and real-time characterization of surfaces, interfaces, thin films in the physics, and liquid solutions in the hydrochemical investigations. Spectroellipsometry methods are used for the undestroying investigation of chemical and physical characteristics of solid materials and liquid solutions. These methods are based on the registration of optical polarization effects appearing under reflection or deformation of the light wave as a result of its interaction with studied object. In the solid physics, spectroellipsometry gives possibility to measure simultaneously amplitude and phase characteristics of studied object and allows the precise definition of the film thickness and optical constants for film material. The diagnostics of liquids gives possibility to assess the concentration of chemicals dissolved and weighed in the liquid as well as to determine the spots of pollutants on the water surface.

In this paper the task of liquid solutions identification is considered basing on the measurement data of optical characteristics delivered by the multi-channel spectroellipsometer. Learning decision making system is proposed. Four algorithms are proposed and analyzed for this task solution. These algorithms are based on different procedures for the spectral image recognition. Comparative empirical assessments are given for precision of these algorithms and dependence of index for identification reliability on the solution concentration is shown. Efficiency of proposed algorithms is shown by means of the examples of diagnostics of water systems located in South Vietnam.

The reported study was partially supported by RFBR, research project No. 13-07-00146.

9598-15, Session 4

Measuring refractive index of glass by using two captures under speckle field illumination

Changliang Guo, Univ. College Dublin (Ireland); Dayan Li, Institut Langevin (France) and Ecole Supérieure de Physique et de Chimie Industrielles de la Ville de Paris (France); Damien P. Kelly, Technische Univ. Ilmenau (Germany); John T. Sheridan, Univ. College Dublin (Ireland)

Measurement of the refractive index of regular shaped glass by speckle correlation is reported. One intensity image in the diffraction field of a speckle-illuminated sample is captured by a CCD before the presence of glass sample and another intensity image is captured after the presence of glass sample. As the position of peak correlation coefficient is quantitatively related to the change in optical path length arising due to the presence of glass, the refractive index of the glass can be evaluated by the correlation of the intensity images before and after the glass insertion. The theoretical correlation function is first derived that describes the relationship between optical path length change and speckle decorrelation. In experiment, various regular shaped glasses are measured to demonstrate the accuracy and robustness of the proposed technique.

9598-16, Session 4

Compressive sensing based ptychography image encryption

Nitin Rawat, Gwangju Institute of Science and Technology (Korea, Republic of) and Analog and Mixed Signal Integrated Circuit Design Lab. (Korea, Republic of)

A compressive sensing (CS) based ptychography combined with an optical image encryption is proposed. The diffraction pattern is recorded through ptychography technique further compressed by non-uniform sampling via CS framework. The system requires much less encrypted data and provides high security. The diffraction pattern as well as the lesser measurements of the encrypted samples serves as a secret key which make the intruder attacks more difficult. Furthermore, CS shows that the linearly projected few random samples have adequate information for decryption with a dramatic volume reduction. Experimental results validate the feasibility and effectiveness of our proposed technique compared with the existing techniques. The retrieved images do not reveal any information with the original information. In addition, the proposed system can be robust even with partial encryption and under brute-force attacks. To the best of our knowledge, this is the first report on an optical encryption ptychography integrating with CS.

9598-17, Session 4

Research on signal-to-noise ratio characteristics and image restoration for wavefront coding

Yijian Wu, Yuejin Zhao, Liquan Dong, Xiaohu Guo, Wei Jia, Ji Zhao, Beijing Institute of Technology (China)

Wavefront coding, a technique of optical-digital hybrid image, can be used to extend the depth of the field. However, it sacrifices the signal-to-noise ratio (SNR) of system at a certain degree, especially on focus situation. The on-focus modulation transfer function (MTF) of wavefront coding system is much lower than that of generally traditional optical system. And the noise will be amplified in the digital image processing. This paper analyzes characteristics of the SNR of the wavefront coding system in the frequency domain and calculates the rate of noise amplification in the digital processing. It also explains the influence of the image detector noise severely reducing the restored quality of images. In order to reduce noise amplification in the process of image restoration, we propose a modified wiener filter which is more suitable for restoration in consideration of noise suppression. The simulation experiment demonstrates that the modified wiener filter, compared with traditional wiener filter, has much better performance for wavefront coding system and the restored images having much higher SNR in the whole depth of the field.

9598-18, Session 4

Fractional Fourier transform of non-integer vortex beams

Yaqin Zhao, Xin Zhong, Guanghui Ren, Zhilu Wu, Harbin Institute of Technology (China)

In these two decades, optical vortices with orbital angular momentum have gained a lot of attention in physics, information science and so on. Most of the researches focus on the beams with integer topological charges, because these beams are spatially orthogonal with each other. Nevertheless, some researches have shown that vortex beams with fractional topological charges also have great potential in the areas of particle manipulation, communications and so on. Fractional Fourier transform (FrFT) is a powerful tool to analyze and process both electric and optical signals and it has the potential to process non-integer vortex beams.

The properties of vortex beams with fractional topological charges when propagating through fractional Fourier planes are analyzed. Based on the FrFT, the theoretical formula is derived to analyze the effects of the parameters of non-integer vortex beams. Numerical results of the evolution of non-integer vortex beams through different fractional Fourier planes are illustrated. The results show that the fractional order of the FrFT has great influence on the normalized intensity distribution properties of non-integer vortex beams. The beams show the same evolution trend, but different shapes.

9598-19, Session 5

Characterization of dynamic speckle sequences using principal component analysis and image descriptors

José Manuel López-Alonso, Univ. Complutense de Madrid (Spain); Eduardo Grumel, Ctr. de Investigaciones Ópticas (Argentina); Nelly L. Cap, Centro de Investigaciones Opticas (Argentina); Hector J. Rabal, Marcelo Trivi, Ctr. de Investigaciones Ópticas (Argentina); Javier Alda, Univ. Complutense de Madrid (Spain)

Speckle is being used as a characterization tool for the analysis of the dynamic of slow varying phenomena ocurring in biological and industrial samples. The retrieved data takes the form of a sequence of speckle images. The analysis of these images should reveal the inner dynamic of the biological or physical proccess taking place in the sample. Very recently, it has been shown that principal component analysis is able to split the original data set in a collection of clasess. These classes can be related with the dynamic of the observed phenomena. At the same time, statistical descriptors of biospeckle images have been used to retrieve information on the characteristics of the sample. These statistical descriptors can be calculated in real time and provides a fast monitoring of the sample. On the other hand, principal component analysis requires longer computation time but the results contain more information related with spatial-temporal pattern that can be identified with physical proccess. This contribution merges both descriptions and uses principal component analysis as a pre-processing tool to obtain a collection of filtered images where a simpler statistical descriptor can be calculated. The method has been applied to slow-varying biological processes

9598-20, Session 5

Edge extraction of optical subaperture based on fractal dimension method

Yunqi Wang, Mei Hui, Ming Liu, Liquan Dong, Xiaohua Liu, Yuejin Zhao, Beijing Institute of Technology (China)

The main problem of optical synthetic aperture imaging system is to achieve cophasing between each subaperture, it is necessary to detect edge phase of subaperture. The edge of optical synthetic aperture imaging system is more complex than that of traditional optical imaging system. For large-aperture optical component, the steep-slope in edge region leads to quite dense interference fringe. So it is significant to extract edge phase of subaperture to avoid the loss of effective frequency.

The anti-jamming capability is weak for traditional edge extraction algorithm, such as Sobel, Roberts, Prewitt, LOG, Canny and Laplacian. They may mistakenly identify noise as edge phase, resulting in the loss of effective frequency.

Fractal dimension as a measure method of image surface irregularities can not only statistically evaluate the complexity but also carry the invariant properties of multi-scale and multi-resolution. It is consistent with human visual image perception of rough surface texture. Fractal theory is based on self-similarity of image, and has a certain suppression effect on noise. Therefore, fractal dimension provides a powerful tool to describe surface characteristics of image.

For edge detection, the box-counting dimension was used to calculate fractal dimension of the whole image. Then the calculated fractal dimension is mapped to grayscale image. The region with large fractal dimension represents a sharper change of the gray scale in original image, which was accurately extracted as the edge region of optical subaperture.

9598-21, Session 5

Low crosstalk optical hierarchical authentication with a fixed random phase lock based on two beams interference

Dajiang Lu, Wenqi He, Xiang Peng, Shenzhen Univ. (China)

We propose a novel method to achieve the purpose of hierarchical authentication based on two beams interference. In this method, different target images indicating different authentication levels are analytically encoded into corresponding phase-only masks (phase keys) and amplitude-only masks (amplitude keys) with the help of a random phase mask, which is created in advance and acts as the fixed lock of this authentication system. For the authentication process, a legal user can obtain a specified target image at the output plane if his/her phase key, and amplitude key, which should be settled close against the fixed internal phase lock, are respectively illuminated by two coherent beams. By comparing the target image with all the standard certification images in the database, the system can thus verify the user's identity. In simple terms, this system can not only confirm the legality of a user but also distinguish his/her identity level. Moreover, in despite of the internal phase lock of this system being fixed, the crosstalk between different target images is low. Theoretical analysis and numerical simulation are both provided to demonstrate the validity of this method.

9598-22, Session 5

Variants of light modulation for MINACE filter implementation in 4-F correlators

Dmitry V. Shaulskiy, Nikolay N. Evtikhiev, Evgenie Y. Zlokazov, Sergey N. Starikov, Rostislav S. Starikov, Elizaveta K. Petrova, National Research Nuclear Univ. MEPhI (Russian Federation)

We address the recognition problem of grayscale images of object subjected to out-of-plane rotation distortion. We compare filter realization as computer generated hologram and filter projection on modulator domain. Our study results of filter discriminating characteristic analysis are shown. The results of filter implementation modeling in 4-f correlator and initial experimental resuls are represented.

9598-23, Session 5

A fast decoding of Reed-Solomon code with p-polynomial and look-up table method

Yan-Haw Chen, Chong-Dao Lee, Trieu-Kien Truong, I-Shou Univ. (Taiwan); Ching-Fu Huang, I-Shou University (Taiwan)

An efficient lookup table method for evaluating syndrome needed in the RS decoder is presented in this paper. It can also be applied to data storage of RAID, 2D bar code, DVD, and CD decoder, which are based on p-polynomial and lookup table method. The method can evaluate the 2t syndromes that can be simplified by the iteration method of P-polynomial and lookup table method. It can reduce the decoding time by fifty-percent only using the p-polynomial method, and thus the speed is much faster than Horner's rule. Finally, the proposed syndrome evaluation method for RS codes is suitable to software implementations on DSP systems.

Summary

In this paper, the decoding of RS codes has been performed by pre-computing lookup table method and efficiently evaluating p-polynomial method. Regarding the complexity of the developed method, table lookup time for evaluating syndromes are only O(2t(n-2)/n). Whereas, the computational complexity of the Horner rule with the same table can provide more efficient scheme for speeding up the decoding syndrome evaluation in RS codes. Furthermore, the experimental results show that the proposed method for decoding of RS codes is more effective than the previous methods, such as traditional p-polynomial and Horner's rule.

9598-56, Session 5

Novel cellular recurrent deep network for image registration

Mahbubul Alam, L. Vidyaratne, Khan M. Iftekharuddin, Old Dominion Univ. (United States)

Image registration is a geometric transformation process where two images (source image and target image) of the same scene with different viewpoints are overlaid to match the alignment. In a rigid registration, the source image is translated, rotated or scaled to spatially align its coordinate locations to those of a target image. Biological evidence suggests that registration is an integral part of human visual system. However, image registration utilizing Artificial Neural Network (ANN) remains a challenging learning task. Registration can be posed as a two-step problem: parameter estimation and actual alignment/transformation. To date ANN based image registration techniques only perform the parameter estimation, while the actual transformation is done using affine equations. In this paper, we propose a novel deep ANN based image rigid registration technique that combines parameter estimation and transformation as a simultaneous learning task. Image transformation represents complex topological mappings. Our previous work shows that a complex universal approximator known as Cellular Simultaneous Recurrent Network (CSRN) can successfully approximate affine transformations with known transformation parameters. This study introduces a deep ANN that combines a feed forward network with a CSRN to perform full rigid registration. A layer wise training approach is followed to pretrain the feed forward network for parameter estimation and the CSRN for transformation. The deep network is then fine-tuned to perform the final registration task. The novel deep ANN based architecture is inspired by deep neural network based classification where the feature extraction step is replaced by parameter estimation and the classification step is replaced by transformation. Our result shows that the deep ANN architecture achieves comparable registration accuracy to that of a usual image affine transformation using CSRN where the parameters are known. We also demonstrate the efficacy of our novel deep architecture by a performance comparison with a deep clustered MLP.

9598-24, Session 6

Video annotations of Mexican nature in a collaborative environment

Lester Arturo Oropesa Morales, Abraham Montoya Obeso, Ctr. de Investigación y Desarrollo de Tecnología Digital (Mexico); Rosaura Hernández García, Escuela Superior en Cómputo (Mexico); Sara Ivonne Cocolán Almeda, MIRAL R&D&I (United States); Mireya Saraí García Vázquez, Ctr. de Investigación y Desarrollo de Tecnología Digital (Mexico); Jenny Benois-Pineau, Bordeaux Univ. (France); Luis Miguel Zamudio Fuentes, Ctr. de Investigación y Desarrollo de Tecnología Digital (Mexico); Jesús A. Martinez Nuño, Escuela Superior de Cómputo (Mexico); Alejandro Alvaro Ramírez Acosta, MIRAL R&D&I (United States)

Multimedia content production and storage in repositories are now an increasingly widespread practice. The index concepts for search in multimedia libraries are very useful for users at the repositories. However the search tools of content based on automatic video tagging, still do not have great consistency. Regardless of how these systems are implemented, it is vital importance possess lots of videos that have concepts tagged with ground truth (training and testing sets). This paper describes a novel methodology to make complex annotation on video resources through ELAN software. These concepts are annotated and related to Mexican nature in a High Level Features (HLF) from development set of TRECVID 2014 on a collaborative environment. Base on this set, each nature concept observed is tagged on each video shots using concepts of the TRECVid 2014 set also we propose new concepts, like tropical settings, urban scenes, actions, events, weather, places for name a few and propose specific concepts that best describe video content of Mexican culture. We have been careful to get the database tagged with concept of nature and ground truth. It is clear evident that a collaborative environment is more suitable for annotated concepts related to ground truth and nature. As a result a Mexican nature database was built also is the basis for test and train sets to classify automatically new multimedia contents of Mexican nature.

9598-25, Session 6

Detecting fiducials affected by Trombone delay in ARC and the main laser alignment at the National Ignition Facility

Abdul A. S. Awwal, Richard R. Leach Jr., Randy S. Roberts, Karl Wilhelmsen, Victoria J. Miller-Kamm, Roger R. Lowe-Webb, Lawrence Livermore National Lab. (United States)

Four of the 192 beams of the National Ignition Facility (NIF) are diverted for use in the Advanced Radiographic Capability (ARC) system to generate a sequence of short (1-50 picoseconds) laser pulses. These beams generate pulses of high energy x-rays that illuminate and penetrate the imploding fuel plasma during ignition scale experiments. The transmitted x-rays imaged with x-ray diagnostics will create a movie of radiographs that is expected to provide unprecedented insight into the implosion dynamics and serve as a diagnostic for tuning the experimental parameters for successful fusion reaction. Beam delay is introduced into the ARC beamlets via independent, free-space optical trombones to stagger these eight pulses responsible for creating the x-ray movie. However, this beam delay causes optical distortion of various beam alignment fiducials used in both in the main laser and the ARC system. This work describes how these alignment fiducials are detected and position estimated in the presence of distortion.

9598-26, Session 6

Robust estimators for speech enhancement in real environments

Yuma Sandoval Ibarra, Víctor H. Díaz-Ramírez, Ctr. de Investigación y Desarrollo de Tecnología Digital (Mexico); Vitaly Kober, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico)

Common statistical estimators for speech enhancement rely on several assumptions about stationary of speech signals and noise. For instance, it is assumed that the Fourier coefficients (real and imaginary parts) of speech and noise processes are zero-mean independent Gaussian random variables; the variance of the Fourier coefficients is time-variant; and the speech is quasi-stationary within a short time interval. In real-life applications, these assumptions may not always valid. In this work, we propose new estimators based on existing estimators such as maximum likelihood (ML) and minimum mean-squared-error (MMSE) by incorporation of rank-order statistics. It is known that rank-order statistics-based filters are robust and able to preserve high frequency details of the processed signals. In speech enhancement, this feature helps to suppress additive noise while preserving speech intelligibility. The estimators proposed in the present work are better adapted to non-stationary characteristics of speech signals and noise. Through computer simulations we show that the proposed estimators yield a better performance than known estimators in terms of objective metrics of intelligibility when speech signals are contaminated with babble and street noise. The proposed estimators are implemented in FPGA.

9598-27, Session 6

Automatic alignment of the Advanced Radiographic Capability at the National Ignition Facility

Randy S. Roberts, Abdul A. S. Awwal, Erlan S. Bliss, Richard R. Leach Jr., Charles D. Orth, Michael C. Rushford, Roger R. Lowe-Webb, Karl Wilhelmsen, Lawrence Livermore National Lab. (United States)

The Advanced Radiographic Capability (ARC) at the National Ignition Facility (NIF) is a pettawatt-class, short-pulse laser system designed to provide x-ray backlighting of NIF targets. ARC uses four NIF beamlines to produce eight beamlets to create a sequence of eight images of imploding fuel capsules using backlighting targets and diagnostic instrumentation. ARC employs a specially designed master oscillator which produces two pulses, disperses the pulses in wavelength, and then injects the pulses into two halves of each of four NIF beamlines. These pulses are amplified by NIF pre- and main amplifiers and transported to compressor vessels located in the NIF target area. The pulses are then compressed and pointed into the NIF target chamber where they impinge upon an array of backlighters. The interaction of the ARC laser pulses and the backlighting material produces bursts of high-energy x-rays that illuminate an imploding fuel capsule. The transmitted x-rays are imaged by diagnostic instrumentation to produce a sequence of images. A key component of the success of ARC is the automatic alignment system that accomplishes the precise alignment of the beamlets to avoid damaging equipment and to ensure that the beamlets are directed onto the tens-of-microns scale backlighters. In this paper, we describe the ARC automatic alignment system, with emphasis on control loops used to align the beampaths. We also provide a detailed discussion of the alignment image processing, because it plays a critical role in providing beam centering and pointing information for the control loops.

9598-28, Session 6

Annotations of Mexican bullfighting videos for semantic index

Abraham Montoya Obeso, Lester Arturo Oropesa Morales, Ctr. de Investigación y Desarrollo de Tecnología Digital (Mexico); Luis Fernando Vazquez, Instituto Politécnico Nacional (Mexico); Sara Ivonne Cocolán Almeda, MIRAL R&D&I (United States); Andrei Stoian, Conservatoire National des Arts et Metiers (France); Mireya Saraí García Vázquez, Luis Miguel Zamudio Fuentes, Ctr. de Investigación y Desarrollo de Tecnología Digital (Mexico); Jesús Yaljá Montiel Pérez, Saúl A. de La O Torres, Instituto Politécnico Nacional (Mexico) and Escuela Superior en Cómputo (Mexico); Alejandro Álvaro Ramírez Acosta, MIRAL R&D&I (United States)

The video annotation is extremely important. Due this, it allows to obtain a content descriptors that permit an automatic index and classification from the same kind of files. Therefore, it is necessary generate a database with semantic index that represents the digital content of the Mexican bullfighting atmosphere. This paper proposes a scheme to make complex annotations in a video. Each video is partitioned using our segmentation algorithm that creates shots of different length and different number of frames. In order to make complex annotations about the video we are using the ELAN software. These annotations are done in two steps: First, we took note about the whole content in each shot. Second, we wrote down the actions with parameters regarding to the camera like direction, position and deepness, as a consequence we obtained a more complete descriptor of every action. In both cases we used the concepts of the TRECVid 2014 set also we propose new concepts. This methodology generated a database with the information necessary to create descriptors and algorithms capable of detect actions in order to automatically index and classify new bullfighting multimedia content. It is important to have a database of concise annotations that represents the “ground truth” about the videos already annotated, the quality of the descriptors and algorithms based on that information increase, therefore the entire system improves too.

9598-500, Session Plen

Visual Signal Analysis: Focus on Texture Similarity

Thrasyvoulos N. Pappas, Northwestern Univ. (United States)

Texture is an important visual attribute both for human perception and image analysis systems. We present new structural texture similarity metrics and applications that critically depend on such metrics, with emphasis on image compression and content-based retrieval. The new metrics account for human visual perception and the stochastic nature of textures. They rely entirely on local image statistics and allow substantial point-by-point deviations between textures that according to human judgment are similar or essentially identical.

We also present new testing procedures for objective texture similarity metrics. We identify three operating domains for evaluating the performance of such similarity metrics: the top of the similarity scale, where a monotonic relationship between metric values and subjective scores is desired; the ability to distinguish between perceptually similar and dissimilar textures; and the ability to retrieve “identical” textures. Each domain has different performance goals and requires different testing procedures. Experimental results demonstrate both the performance of the proposed metrics and the effectiveness of the proposed subjective testing procedures.

9598-29, Session 7

Mathematical model for classification of EEG signals

Victor Hugo Ortiz Flores, Instituto Politécnico Nacional (Mexico) and Ctr. de Investigación y Desarrollo de Tecnología Digital (Mexico); Juan Jose Tapia Armenta,

Ctr. de Investigación y Desarrollo de Tecnología Digital (Mexico) and Instituto Politécnico Nacional (Mexico)

A mathematical model to filter and classify brain signals from a brain machine interface is developed. The mathematical model classifies the signals from the different lobes of the brain to differentiate the signals: alpha, beta, gamma and theta, besides the signals from vision, speech, and orientation. The model to develop further eliminates noise signals that occur in the process of signal acquisition. This mathematical model can be used on different platforms interfaces for rehabilitation of physically handicapped persons.

9598-30, Session 7

Luminance and contrast ideal balancing based tone mapping algorithm

Amine Besrour, SUP'COM (Tunisia) and Univ. de Technologie Troyes (France); Mohamed Siala, Fatma Abdelkefi, SUP'COM (Tunisia); Hichem Snoussi, Univ. de Technologie Troyes (France)

Despite the recentness of the tone mapping researches, a number of surveys summarizing the current solutions have been published. In general, the tone mapping can be considered as a technique depending on time and it is dedicated to process time independent sequences. It is especially developed to handle static images. Also, there are different algorithms attempting to model certain characteristics of the human visual system and others representing pure image processing transforming an image into another.

On the other hand, a final classification takes into account the fact that the same mapping function is used for all the pixels (global operators), or if the mapping function deals with random variables given in a vicinity of the pixel that is often dependent on modeling the spatial adaptation (local operators). In this paper, we are concerned by the local ones. Indeed, the local tone mapping methods are more efficient in terms of the compression for high dynamic range images. In fact, they perceive the neighborhood of the given pixel and assign the suitable function of local compression. This paper proposes a design of a recent tone mapping operator used in a high dynamic range imaging system. The proposed operator represents a local method which uses an adaptable factor combining the average neighboring contrast and the brightness difference. Thanks to that, this solution provides good results with better brightness, contrast, and visibility without producing undesired artifacts neither halo effects.

9598-31, Session 7

A 3D approach for object recognition in illuminated scenes with adaptive correlation filters

Kenia Picos, Víctor H. Díaz-Ramírez, Ctr. de Investigación y Desarrollo de Tecnología Digital (Mexico)

Object recognition is a computer vision task that is needed in several applications to improve human activities, such as surveillance, automotive navigation, medical image processing, among others. However, to obtain an accurate object recognition system is very challenging, due to several factors that compromise its performance. In a real-life images, the presence of noise, geometrical distortions of objects, occlusion, and the influence of several light sources are some issues that make object recognition a complex task. These issues modify the appearance of an object of interest with respect an observation point. Due to this problem, we analyze the physical phenomena implied in the visualization of the geometrical distortions and the interaction of light of 3D objects. To solve target recognition of an object in a scene we use a correlation filtering method. Correlation filtering possesses an accurate performance, however for a 3D object recognition approach becomes expensive to compute. The current proposal focuses on improving the algorithm execution using a combination of data parallelism and task parallelism taking advantage of a CPU/GPU architecture. Computer simulations results are obtained in order to evaluate the performance of the proposed system in terms on recognition accuracy, computational efficiency and tolerance to illumination.

Robust modulation formats recognition technique using wavelet transform for high speed optical networks

Latifa Guesmi, Abir Hraghi, Mourad Menif, SUP'COM (Tunisia)

The rapid growth of capacity demand on wavelength division multiplexing (WDM) system and orthogonal frequency division multiplexing (OFDM) has caused considerable interest in alternative multi-carrier modulation format that can increase the capacity of communication system. Moreover, high speed optical networks are nowadays becoming more heterogeneous, supporting a plethora of services with different modulation formats. Therefore, in recent years, to enable a real-time information about the signal modulation format and discuss the pattern recognition approach, much interest by academic and military research institutes has focused around the research and development of modulation format recognition (MFR) algorithms.

In this paper, we present a new achievement of MFR technique, where we propose the use of wavelet transform and statistical parameters of the detected signal in conjunction with the artificial neural network (ANN) algorithm at high bit rates using direct detection and coherent detection.

In order to investigate the validity of the proposed technique for a no prior knowledge of the transmitted signal, numerical simulation have been performed for four optical modulation schemes namely NRZ-OOK as a single-carrier format, DC-PDM-QPSK, OFDM DP-16QAM, and WDM Nyquist NRZ-DP-QPSK as a multi-carrier formats at high data rate.

The proposed technique is shown to be capable of recognizing the modulation scheme with high accuracy under different transmission impairments such as chromatic dispersion (CD), differential group delay (DGD) and accumulated Amplified Spontaneous Emission (ASE). This technique allows us the estimation of the optical signal to-noise ratio (OSNR) in the range of 10-30 dB, chromatic dispersion (CD) in the range of -500 to 500 ps/nm and differential group delay (DGD) in the range of 0-15 ps.

The results of numerical simulation demonstrate successful recognition of all modulation formats from a known bit rates with a higher estimation accuracy.

Real-time image dehazing using local adaptive neighborhoods and dark-channel-prior

Jesus A. Valderrama, Víctor H. Díaz-Ramírez, Ctr. de Investigación y Desarrollo de Tecnología Digital (Mexico); Enrique Hernandez, Ctr. de Investigación Científica y de Educación Superior de Ensenada (Mexico); Vitaly Kober, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico)

A real-time algorithm for single image dehazing is presented. The algorithm is based on calculation of local neighborhoods of a hazed image inside a moving window. Next the dark-channel-prior is applied to local neighborhoods to estimate the scene

transmission without any refining algorithm. To achieve high-rate signal processing the algorithm is implemented in parallel on a graphics processing unit (GPU). Computer simulation results are carried out to test the performance of the algorithm in terms of dehazing e?ciency and speed of processing. These results are analyzed and compared with those obtained with existing dehazing algorithms.

9598-34, Session 7

Development of a polarimetric experimental setup for surface profiling based on a microscopy application

Alejandra Serrano Trujillo, Univ Autónoma de Baja California (Mexico); Adriana Nava, Univ. Autónoma de Baja California (Mexico); Victor Ruiz-Cortes, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico)

The experimental setups for recovering an object's surface according to the polarimetric and fringe projection approaches are implemented. Both experiments are carried under the use of coherent light and over a reference testing piece. Fringe projection images are processed using standard phase wrapping and unwrapping routines, while an algorithm for analysis of the Stokes parameters is implemented for the polarization images. An analysis of the resulting 3D surface from both techniques is done, comparing the features that each method was able to detect, relating them to the properties of the projected light. In this contribution we deduce the characteristics required by an algorithm to deliver a detailed surface reconstruction, based on the two tested methods.

9598-35, Session PWed

High dynamic range imaging for shiny surface with single-shot raw data of the color camera

Yongkai Yin, Shandong Univ. (China) and Univ. of Wollongong (Australia); Jiangtao Xi, Univ. of Wollongong (Australia); Zewei Cai, Shenzhen Univ. (China); Yanguang Yu, Univ. of Wollongong (Australia); Xiang Peng, Shenzhen Univ. (China)

Fringe projection profilometry (FPP) has been widely applied in many industrial sectors in recent years, such as reverse engineering, product design and garment industry and so on so forth. Although traditional FPP performs well to ordinary diffuse surface of objects, it still remains a challenging issue to get satisfied results in terms of 3D imaging for shiny surface, e.g. the surface of metal and porcelain. The difficulty mainly arises from the wide variation of surface reflectivity, which results in the high dynamic range of the deformed fringe image reflected form the surface. Therefore, FPP for shiny surfaces usually needs high dynamic range imaging (HDRI) technique. Existing HDRI for shiny surface focuses on the approach of multiple exposures, leading to an unavoidable extra time expense. To overcome this disadvantage, HDRI with single-shot raw data of the color camera is presented in this paper. A fringe pattern is projected based on monochromatic illumination and the deformed fringe image is captured in single-shot fashion using a color camera. From the single-shot raw data, three monochrome images corresponding to R, G and B channels can be separated respectively. The three images have different intensity attenuation because the quantum efficiency of R, G and B channels are quite different for specific wavelength. After the attenuation ratios corresponding to R, G and B channels are calibrated, a higher dynamic range image can be synthesized with the three images. Experiments demonstrate the validity of proposed method for shiny surface.

Automated counting of morphologically normal red blood cells by using digital holographic microscopy and statistical methods

Inkyu Moon, Faliu Yi, Chosun Univ. (Korea, Republic of)

The fully automated morphologically normal red blood cells (RBCs) counting method can be helpful in computer-aided-diagnosis and beneficial to the medical doctor for effectively analyzing the RBCs relevant disease. In this paper we overview an automated approach to count morphologically normal RBCs with the three-dimensional morphological and biophysical parameters of mature RBCs such as projected surface area, average phase value, mean corpuscular hemoglobin (MCH), perimeter, MCH surface density (MCHSD), circularity, mean phase of center part, sphericity coefficient, elongation, and pallor. The fully automated RBCs counting method is based on the integration of digital holographic microscopic imaging system and multivariate statistical method. This technique can be easily extended to the classification of different kinds of cells representing a promising diagnosis tool.

3D face recognition based on matching of facial surfaces

Beatriz A. Echeagaray Patrón, Vitaly Kober, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico)

Face Recognition is a problem that has remained relevant in pattern recognition and computer vision in recent years due to its wide range of applications such as access control, surveillance, human-computer interaction and biometric identification systems. Despite the variety of techniques that have been developed, the problem remains open: accurate and robust face recognition still offers a number of challenges, especially under unconstrained environments. This work introduces a method for 3D face recognition in presence of facial expression, pose and illumination variations. The proposed approach uses 3D shape data without color or texture information. Before face recognition techniques are applied, the surfaces are standardized and aligned. Next step is extraction from face regions which are almost expression-invariant. Finally, a new matching algorithm based on conformal and isometric mapping of original facial surfaces onto a Riemannian manifold followed by a comparison of conformal and isometric invariants computed in the manifold is proposed. This approach preserves angles and geodesic distances in the original face surface while simplifies the correspondence problem in 3D. Experimental results are presented using common 3D face databases that contain significant amount of expression and pose variations.

Illumination-invariant hand gesture recognition

América I. Mendoza-Morales, CICESE (Mexico); Daniel Miramontes-Jaramillo, Vitaly Kober, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico)

In recent years, human-computer interaction (HCI) has received increased interest in industry and science because it provides new ways to interact with a wide variety of devices through voice, body, and facial/hand gestures. Applications range from accessibility to entertainment. Hand gesture recognition is a particularly interesting problem because the shape and dynamic of hands are complex and flexible to codify many different signs. In this work we propose a three step algorithm: first, detection of hands in the current frame is carried out; second, hand tracking across the video sequence is performed; finally, robust recognition of gestures across subsequent frames is made. Recognition rate highly depends on nonuniform illumination of the scene and occlusion of hands. In order to overcome these issues we use two Microsoft Kinect devices utilizing combined information from RGB and infrared sensors. The algorithm performance is tested in terms of recognition rate and processing time. Finally, our algorithm is compared with other state-of-the-art hand gesture recognition algorithms.

Research on the high-precision non-contact optical detection technology for banknotes

Xiaofeng Jin, Shanghai Institute of Optics and Fine Mechanics (China); Tiancai Liang, Pengfeng Luo, GRG Banking Equipment Co., Ltd. (China); Jianfeng Sun, Shanghai Institute of Optics and Fine Mechanics (China)

The technology of high-precision laser interferometry was introduced for optical measurement of the banknotes in this paper. Taking advantage of laser short wavelength and high sensitivity, information of adhesive tape and cavity about the banknotes could be checked efficiently. Compared with current measurement devices, including mechanical wheel measurement device, Infrared measurement device, ultrasonic measurement device, the laser interferometry measurement has higher precision and reliability. This will improve the ability of banknotes feature information in financial electronic equipment.

9598-40, Session PWed

The research of measurements mode of optical spectra by spectral device based on acousto-optic tunable filter

Georgy Korol, Saint- Petersburg State Univ. of Aerospace Instrumentation (Russian Federation)

Optical spectral device, based on acousto-optic tunable filter (AOTF), is very promising to spectral analysis problems solving, where analyzed optical radiation is very narrow-band emission approximate to monochromatic. Spectral analysis problem is the optical harmonics resolution and their levels measuring. With particular interest is spectrum spread function width of the spectral device, which determines its resolution. The formula, describing the spectrum spread function of the spectral device based AOTF, was obtained previously (Proc. of SPIE Vol. 9216 92161F-1-11). This spectrum spread function is expressed in terms of Fresnel integrals and contains complex depending on the following parameters: average frequency and rate of change of frequency control of electrical oscillations, the deviation of frequency of the optical radiation from the average mean of band of analyzed frequencies. These parameters determine the form of spectrum spread function depending on the mode analysis of the optical spectrums. The purpose of this paper is broad mathematical modeling of the spectrum spread function of spectral device on the basis of AOTF in various modes of analysis to solve the problem of optimizing the process of spectral measurements.

Objects tracking with adaptive correlation filters and Kalman filtering

Sergio E. Ontiveros Gallardo, Vitaly Kober, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico)

Object tracking is commonly used for applications such as video surveillance, motion based recognition, and vehicle navigation. In this work, a tracking system using adaptive correlation filters and robust Kalman's prediction of target locations is proposed. Tracking is performed by means of multiple object detections in reduced frame areas. A bank of filters is designed from multiple views of a target using synthetic discriminant functions. An adaptive algorithm is used to improve discrimination capability of the synthesized filters. The bank of filters allows adapting the filters to multiple types of backgrounds. The number of filters in the bank can be controlled to guarantee a prescribed tracking accuracy. With the help of computer simulation the performance of the proposed algorithm is evaluated and compared with that of state-of-art algorithms in terms of detection efficiency and accuracy of object tracking.

Optical image encryption based on phase-truncated Fresnel diffraction

Chenggong Zhang, Wenqi He, Xiang Peng, Dajiang Lu, Shenzhen Univ. (China)

A novel optical cryptosystem based on phase-truncated Fresnel diffraction (PTFD) and transport of intensity equation (TIE) is proposed. By using of the phase truncation technique, a phase-encoded plaintext could be encrypted into a real-valued noise-like intensity distribution by employing a random amplitude mask (RAM) and a random phase mask (RPM), which are regarded as two secret keys. For decryption, a generalized amplitude-phase retrieval (GAPR) algorithm combined with the TIE method are adopted to obtain the plaintext with the help of two keys. Different from the current phase-truncated-based optical cryptosystems which need record the truncated phase as decryption keys, our scheme have no need of the truncated phase because of the introducing of the TIE method. Moreover, the proposed scheme is expected to against existing attacks. A set of numerical simulation results show the feasibility and security of the proposed method.

Optical hierarchical identity authentication based on hash function and moiré effect of nonlinear gratings

Meihua Liao, Wenqi He, Dajiang Lu, Jiachen Wu, Xiang Peng, Shenzhen Univ. (China)

A new optical identity authentication scheme based on the phase modulation of moiré effect in the phase-space optics is proposed. The information of standard authentication image can be hidden into the phase function of two gratings by using of the phase modulation of optical moiré effect. One of the gratings settled into the authentication system is designed as the "Authentication lock", and the other will be held by a legal user. The authentication procedure is performed by optical setup. The evaluation of the identity authentication relies on the correlation coefficient between moiré pattern of the two designed gratings superposition and the standard authentication image. Theoretical analysis and simulation experiments are both provided to verify the feasibility and effectiveness of the proposed scheme.

Evolution of optical pulses in the optical fiber as basis of spectral devices

Ilya ?. Osmakov, Oleg D. Moskaletz, Saint- Petersburg State Univ. of Aerospace Instrumentation (Russian Federation)

Optical pulse evolution in the form cutting monochromatic optical radiation at it's propagation in optical fiber as dispersive system is considered. Ratio between the duration of the input pulse, and differential group delay in a dispersive system which provides that distorted form of the input pulse which is proportional to its spectrum is determined. This result defines a complex spectrum spread function of the optical device. That complex spectrum spread function is its exhaustive characteristic of spectral device. Complex spectrum spread function is the kernel of the integral operator witch sets the ratio of the input-output spectral device for complex spectra. In the process of researching the evolution the deviation of pulse distortion of the spread function from the ideal spectral device performing the Fourier transform of the segment monochromatic oscillations is investigated.

Analysis method using a single segment of optical fiber provides a spectrum non-real-time, which leads to loss of information about the analyzed optical radiation. For this loss information excluding the question of multi-channel fiber-optic system to measure the optical spectrum for a long period of time by forming a sequence of short optical pulses is considered. The optical fiber must have a different length.

Result of the measurement in the optical range is power spectrum of optical radiation. To obtain an estimate of the power spectrum of optical radiation in each optical fiber channel, which is part of the spectral device, photodetection is applied. After then the total sum from photodections results is preformed.

Influence of lens system aperture on optical information processing

Sergey N. Mosentsov, Vasily Kazakov, Oleg D. Moskaletz, Saint- Petersburg State Univ. of Aerospace Instrumentation (Russian Federation)

Any optical information system is characterized by sizes of input aperture, lengths of free space layers and the lens system apertures.

In terms of constructions, an important issue is relationship between the sizes of input aperture and the lens system aperture.

Simple optical system is considered, which including:

- input aperture of finite size, on which supplied optical signal;

- free space layer, described by Fresnel's diffraction;

- lens system with own finite aperture, larger than the size of input aperture.

This simple optical system is considered as element of more complex optical information systems.

Known mathematical analysis of optical systems suggests that the lenses system has infinite size. But, the real construction of any optical system suggests the presence of a lens system with finite size aperture. This results to occurrence of errors, affecting on further processing diffractive optical field. Assessment of error based on the analysis of piece of optical radiation, which partially extends beyond the lens system.

Transmission of optical radiation through finite aperture of the lens systems expressed in form the Fresnel's integrals. Mathematical modeling of such a system is based on the Fresnel integrals expansion in asymptotic series with large values of the argument. Results of the calculation are to definition the minimum size of the lens aperture, considering the allowable loss of optical radiation due to the finite size of the aperture.

Correlation measurements in optical range

Aleksey Orlov, Oleg D. Moskaletz, Saint-Petersburg State Univ. of Aerospace Instrumentation (Russian Federation); Dmitry O. Moskaletz, Saint Petersburg Electrotechnical Univ. "LETI" (Russian Federation)

Three variants of the possible implementation of the measurement time correlation functions of optical radiation:

- multichannel correlation measurements of optical radiation with delay lines in the optical fiber cuts form (optical correlator analogue RF) ;

- refined consideration of correlator of optical radiation in the form of a Michelson's interferometer;

- correlation measurement of optical radiation on the basis of the analysis of instantaneous complex spectra.

Mathematical basis for calculating of correlation functions of pulsed optical radiation on the basis of an analysis of its instantaneous complex spectrum is given. The proposed mathematical apparatus is based on the theorem of Wiener - Paley and the theory of integral operators with reproducing kernels.

Algorithm for computing of correlation functions of pulsed optical radiation is based on the basis of calculating the instantaneous complex spectrum of optical radiation. These instantaneous spectra can be obtained using diffractive optical spectral devices. New definition of the instantaneous spectrum is given into account the specifics of measuring diffraction spectral devices.

This algorithm is implemented in the system including two complex spectrum analyzers, the adder, the squaring unit, the spatial integrator.

The estimation of advantages and disadvantages for each option of possible implementation of measurements time correlation functions of optical radiation is discussed. Method of calculating the correlation function on the basis of analysis of instantaneous spectra is especially important in the context of intense development of physics and technology of femtosecond pulses.

Power spectrum estimation of optical radiation by multichannel resonant spectral device

Artur Paraskun, Oleg D. Moskaletz, Saint-Petersburg State Univ. of Aerospace Instrumentation (Russian Federation)

The estimating problem of power spectrum in optical range via new type of optical spectral device constructed on the basis of resonance phenomenon in narrow-band interference filters which performs parallel analysis of the optical spectrum is solved.

Such device is based on phenomenon resonance in narrowband interference filters.

Spectral decomposition of the optical radiation is performed by multichannel resonant optical system. That device includes forming optics, fiber-optic beam; optical system of narrowband interference filters, each filter is connected in series with the photodetector.

One of main aspects from statistical measurement is power spectrum assessment of stationary random processes. Optical radiation is the one such process. Therefore, main attention is given to photodetection and properties of power spectrum resulting estimates.

However, since all channels spectral device are identical, the process for estimation of power spectrum is considered in one channel. Two detection modes of photodetection operations are considered.

The equivalent circuit of the first mode includes a quadratic photodetector and integrator completed by system of integration result reset. It has been established that the thus obtained evaluation is good. In the case of the second mode equivalent circuit includes quadratic photodetector and low-pass filter. Thus, this system operates in continuously mode evaluating of power spectrum.

The comparison of photodetection on two modes is completed.

The conception and implementation of a local HDR fusion algorithm depending on contrast and luminosity parameters

Amine Besrour, SUP'COM (Tunisia) and Univ. de Technologie Troyes (France); Fatma Abdelkefi, Mohamed Siala, SUP'COM (Tunisia); Hichem Snoussi, Univ. de Technologie Troyes (France)

Nowadays, the high dynamic range (HDR) imaging represents the subject of the most researches. The major problem lies in the implementation of the best algorithm to acquire the best video quality. In fact, the major constraint is manifested in the need to implement a fusion algorithm fast enough to meet the rapid movement of video frames. The implemented merging algorithms were not quick enough to reconstitute the HDR video. In this paper, we detail each of the previous existed works before detailing

our algorithm and presenting results from the acquired HDR images, tone mapped with various techniques. This algorithm represents a more enhanced and faster solution than the existing ones. In fact, it has the ability to calculate the saturation matrix representing the saturation rate of the neighboring pixels. The computed coefficients are affected respectively to each picture from the tested ones. This analyze provides faster and more efficient results in terms of quality and brightness. The originality of our work remains on its processing method including the pixels saturation in the totality of the captured pictures and their combination in order to obtain the best pictures illustrating all the possible details. These parameters are computed for each zone depending on the contrast and the luminosity of the current pixel and its neighboring. The final HDR image's coefficients are calculated dynamically ensuring the best image quality equilibrating the brightness and contrast values and making the perfect final image.

Correlations filters used for object recognition and tracking in UAV's applications

Francisco Javier Ramirez-Arias, Univ. Autónoma de Baja California (Mexico); Víctor H. Díaz-Ramírez, Ctr. de Investigación y Desarrollo de Tecnología Digital (Mexico); Antonio Gomez Roa, Univ. Autónoma de Baja California (Mexico)

One of the most attended problems within unmanned aerial vehicles is the optimization of the control system module to operate under different environments. Coupled with this human perception and the operator skills play an important role to perform tasks of specific purpose those are assigned to these vehicles. The trend in these applications is the recognition and tracking objects are offline due to computational cost off this algorithms and the limited resources in these vehicles, therefore develop algorithms that are optimal from a computational point of view is important. The correlation filters are considered a viable option for use in unmanned aerial vehicles for their results presented in applications for recognition and tracking of objects when the opto-electronic sensor is fixed and the computational cost is optimal, because these algorithms are based on the fast Fourier transform. In this work the opto-electronic sensor is in the unmanned aerial vehicle therefore it is considered dynamic. Evaluate the performance of correlation filters for tracking and object recognition becomes important due to applications that can be derived from the used of these filters. Besides the recognition and tracking of objects is desirable to develop efficient algorithms for implementing these with good response time to be implemented on computers that are on board of the unmanned aerial vehicles. Basically, we are interested in developing new techniques for digital image processing, while performing practical implementations of these techniques.

Numerical analysis of holographic tomography with different reconstruction algorithms in the presence of noise

Andrey V. Belashov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation) and Ioffe Physical-Technical Institute (Russian Federation); Nikolay V. Petrov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Irina V. Semenova, Ioffe Physical-Technical Institute (Russian Federation); Igor A. Shevkunov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

Due to the rapid progress in computer technologies and development of digital cameras digital methods of hologram processing become an important instrument for investigations of physical objects and phenomena. Digital holography allows one to reconstruct a wave front of a light beam interacted with an object under study. If the object is transparent one can detect an integral phase shift gained by the light passed through it. An interpretation of the acquired information in the case of complex objects, such as for instance biological tissues, can be difficult, since it is hard to understand to what extent each domain inside the object shifts the phase of the wave front. One can however extract the necessary data from a set of phase images recorded at various angles to the object. We analyze the performance of holographic tomography technique depending upon the number of digital holograms and sampling degree. The procedure is as follows. First we simulated a process of hologram recording from different positions in a presence of noise. Then a set of integral phase shift images were obtained from these holograms using different reconstruction algorithms. Afterwards a spatial distribution of refractive index variations has been obtained using the inverse radon transformation.

Alignment mask design and image processing for the Advanced Radiographic Capability (ARC) at the National Ignition Facility

Richard R. Leach Jr., Abdul A. S. Awwal, Simon J. Cohen, Roger R. Lowe-Webb, Randy S. Roberts, Joseph T. Salmon, David A. Smauley, Karl Wilhelmsen, Lawrence Livermore National Lab. (United States)

The Advance Radiographic Capability (ARC) at the National Ignition Facility (NIF) is a laser system that employs up to four petawatt (PW) lasers to produce a sequence of short pulses that generate X-rays which backlight high-density inertial confinement fusion (ICF) targets. ARC is designed to produce multiple, sequential X-ray images by using up to eight backlighters. The images will be used to examine the compression and ignition of a cryogenic deuterium-tritium target with tens-of-picosecond temporal resolution during the critical phases of an ICF shot. Multi-frame, hard-X-ray radiography of imploding NIF capsules is a capability which is critical to the success of NIF's missions. As in the NIF system, ARC requires an optical alignment mask that can be inserted and removed as needed for precise positioning of the beam. Due to ARC's split beam design, inserting the nominal NIF main laser alignment mask in ARC produced a partial blockage of the mask pattern. Requirements for a new mask design were needed. In this paper we describe the ARC mask requirements, the resulting mask design pattern, and the image analysis algorithms used to detect and identify the beam and reference centers required for ARC alignment.

High-speed and large accepted incidence area for a self-pumped phase conjugate mirror

Che-Chu Lin, Yeh-Wei Yu, Ching-Cherng Sun, National Central Univ. (Taiwan)

In this Letter, a study for the incidence geometry to extend the accepted incidence position is presented and demonstrated. High-quality self-pumped phase conjugate mirror (SPPCM) can be formed with a counter-direction incidence with respect to the master light for the Cat-SPPCM. The study starts from changing the incidence position from the other in-plane three faces. The incident direction along the c axis or in the reverse direction cannot form the Kitty-SPPCM effectively. The situation depends on the coupling strength of the grating for the four-wave mixing across the fanning loops. When the incident light is sent into the crystal in the counter direction of the master light, effective Kitty-SPPCM can be observed. According to the forming of the Kitty-SPPCM, the position acceptance can be divided into three regions. In such a matter, we can find that the incidence on the other face rather than the usual Kitty-SPPCM can generate three different SPPCMs, where the first is a counter-direction Kitty-SPPCM, the second is the high-pass Kitty-SPPCM and the third is similar to Bridge-SPPCM. The discovery of these three SPPCMs is helpful to apply the SPPCM in various applications.

Simultaneous transmission of accurate time and stable frequency through bidirectional channel over telecommunication infrastructure with excessive spans

Josef Vojtěch, Vladimir Smotlacha, CESNET z.s.p.o. (Czech Republic)

Very accurate time or timing is essential for broad range of fields, e.g. sensing, metrology, navigation, geodesy, radio-astronomy, seismology, fundamental physics, etc. The optical time transfer undergoes increased interest in recent years. It eliminates usage of antennas in case of global navigation satellite systems (e.g. GPS). Furthermore, it delivers accuracy in the order of tens of picosecond compared with both IEEE 1588 and satellite systems. Typical challenge of long haul accurate time of frequency transfer over fiber is single bidirectional optical path including optical amplifiers in order to achieve the best available accuracy. The main obstacle of this bidirectional lies in missing optical isolators, widely used in data communications to avoid propagation of back-scattering and reflections. Majority of accurate time transfer projects aim at decreasing of reflection as much as possible and operate bidirectional optical amplifiers in low gain mode to avoid line lase. Demand of low gain determines fiber spans with excessive attenuation must be split into the more spans with lower attenuation. We establish simultaneous transmission of accurate time and stable frequency over of 310 km (192 mi) long path with two excessive segments of attenuation over 28 dB. This paper will describe results including path stability and operational issues of services over such path.

Sparse reconstruction of compressed sensing multispectral data using a cross-spectral multilayered conditional random field model

Edward Li, Mohammad Javad Shafiee, Farnoud Kazemzadeh, Alexander Wong, Univ. of Waterloo (Canada)

The broadband spectrum contains more information than what the human eye can detect. Spectral information from different wavelengths can provide unique information about the intrinsic properties of an object. Recently, compressed sensing imaging systems with low acquisition time have been introduced. These systems capture a sparse, under-sampled, set of measurements which is sufficiently representative of the target being observed. To utilize compressed sensing strategies, strong reconstruction algorithms that can reconstruct a complete signal from sparse observations are required. This work proposes a Cross-Spectral Multilayered Conditional Random Field (CS-MCRF) approach for sparse reconstruction of multispectral compressive sensing data in multispectral vision and imaging systems. The CS-MCRF will use information between neighboring spectral bands to better utilize available information for a more robust reconstruction of each independent spectral band image. This method was evaluated using simulated compressed sensing multispectral acquisitions. Results show improvement over existing techniques in preserving spectral fidelity while effectively inferring missing information from sparsely available observations. The availability of such reconstruction algorithms will enable fast acquisition of multispectral data with reduced imaging hardware cost and complexity.

Optical character recognition of camera-captured images based on phase features

Julia Diaz, Vitaly Kober, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico)

Nowadays most of digital information is obtained using mobile devices specially smartphones. In particular, it brings the opportunity for character recognition (OCR) in camera-captured images. For this reason many recognition applications have been recently developed, for example: license plates, business cards, receipts and street signal recognition; document classification; augmented reality; language translator; etc. But also new challenges are appeared. Camera-captured images are usually affected by geometric distortions, nonuniform illumination, shadows, noise, etc., which make difficult the recognition task of existing systems. It is well known that the Fourier phase contains a lot of important information regardless of Fourier intensities. So, in this work we propose to use a phase-based recognition system. First we use a pre-processing stage to remove sensors noise and to align the text. Then we use phase-congruency features to provide illumination/scale invariance. The algorithm performance is tested in terms of miss classifications and false alarms. Finally, computer simulation results obtained with the proposed system are presented and discussed.

Performance evaluation of correlation filters for target tracking

Leopoldo N. Gaxiola, Víctor H. Díaz-Ramírez, Juan Jose Tapia Armenta, Ctr. de Investigación y Desarrollo de Tecnología Digital (Mexico); Pascuala García-Martínez, Univ. de València (Spain); Andres Cuevas, CITEDI-IPN (Mexico)

The use of correlation filters for target tracking has increased in recent years. This is because these filters can estimate with high accuracy the position of a moving target in noisy scenes. Additionally, correlation filters are robust to noise and yield low computational complexity. In this work, we present a performance evaluation of several state-of-the-art correlation filters within the context of target tracking. The filters are tested using an introduced algorithm that is adapted online using information of current and past scene frames of the scene. The suggested algorithm achieves a high-rate operation by focusing signal processing only on a small fragment of every frame. For performance evaluation, the algorithm is tested in several video test sequences that contain geometric modifications of the target, partial occlusions and clutter. The performance of the tested filters is presented and discussed in terms of detection efficiency, tracking accuracy, and computational complexity. The results obtained with the suggested algorithm based on correlation filtering are discussed compared with those obtained with existing state-of-the-art target tracking algorithms in terms of objective metrics.

Shearlet-based edge detection: flame fronts and tidal flats

Emily J. King, Rafael Reisenhofer, Univ. Bremen (Germany)

Shearlets are wavelet-like systems which are better suited for handling geometric features in multi-dimensional data than traditional wavelets. A novel method for edge detection which is in the spirit of phase congruency but is based on a complex shearlet transform will be presented. This approach to edge detection yields an approximate tangent direction of detected edges as a byproduct of the edge measure computation.

Two applications of the edge detection method will be discussed. First, the tracking and classification of flame fronts is a critical component of research in technical thermodynamics. Quite often, the flame fronts are transient or weak and the images are noisy. The standard methods used in the field for the detection of flame fronts do not handle such data well. Fortunately, using the shearlet-based edge measure yields dramatically better results.

Second, the Wadden tidal flats are a biodiverse region along the North Sea coast. One approach to surveying the delicate region and tracking the topographical changes is to use pre-existing Synthetic Aperture Radar (SAR) images. Unfortunately, SAR data suffers from multiplicative noise as well as sensitivity to environmental factors. The first large-scale mapping project of that type showed good results but only with a tremendous amount of manual interaction because there are many edges in the data which are not boundaries of the tidal flats but are edges of features like fields or islands. A method using a combination of the shearlet-based edge measure with a diffusion-based image segmentation will be presented.

9599-5, Session 1

The impact of privacy protection filters on deep learning-based gender recognition by machines and crowdsourced evaluation by humans

Pavel Korshunov, Ecole Polytechnique Fédérale de Lausanne (Switzerland); Natacha Rachaud, EURECOM (France); Anne-Flore Perrin, Ecole Polytechnique Fédérale de Lausanne (Switzerland); Grigory Antipov, Jean-Luc Dugelay, EURECOM (France); Touradj Ebrahimi, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Deep learning-based algorithms are becoming increasingly efficient in recognition and detection tasks, especially when using large-scale datasets. Such recent success has led to a speculation that deep learning methods are comparable or even outperform human visual system in its ability to detect and recognize objects and their features. In this paper, we focus on the task of gender recognition in images when they have been processed by privacy protection filters (e.g., blurring, masking, pixelization) applied at different strengths. Assuming a privacy protection scenario, we compare the performance of state of the art deep learning algorithms with a subjective evaluation obtained via a crowdsourcing evaluation to understand how privacy protection filters affect both computer vision and human vision.

9599-6, Session 1

Detection of smoke plume for a land-based early forest fire detection system

John A. Saghri, California Polytechnic State Univ., San Luis Obispo (United States); John T. Jacobs, Timothy M. Davenport, Raytheon Space and Airborne Systems (United States); David Garges, California Polytechnic State Univ., San Luis Obispo (United States)

This paper examines several processing schemes to detect early forest fire via a 24/7 monitoring infrared and visible video data. Both the temporal and the spectral signatures of fire and smoke plume are exploited. The methods include principle component transformation and clustering of the spectral and temporal imagery data. The methods are compared based on video data from several staged test forest fries. It is shown that the resulting difference images can be effectively exploited to detect and classify heat plumes which are expelled at the early stages of the forest fire.

9599-7, Session 1

Localization of tumors using edge detectors

Felipe Lopez-Velez, Univ. EAFIT (Colombia)

The edge of an image is a set of points organized in a curved line, where in each of these points the brightness of the image changes abruptly, or has discontinuities, in order to find these edges there will be four different mathematical methods to be used and later on compared with its peers, this is with the aim of finding which of the methods is the one that can find the edges of any given image.

In this paper these four methods will be used for medical purposes in order to find which one is capable of finding the edges of a scanned image more accurately than the others.

The problem consists in analyzing the following two biomedical images. One of them represents a brain tumor and the other one a liver tumor.

These images will be analyzed with the help of the four methods described and the the results will be compared in order to determine the best method to be used.

It was decide to use different algorithms of edges detection in order to obtain the results shown below; Bessel algorithm, Morse algorithm, Hermite algorithm, Weibull algorithm and Sobel algorithm.

After analyzing the appliance of each of the methods to both images it impossible to determine that in each case the better method changed, i.e., for the brain tumor image it can be noticed that the Morse method was the best at finding the edges of the image but for the liver tumor image it was the Hermite method.

Making further observations it is found that Hermite and Morse have for these two cases the lowest standard deviations, concluding that these two are the most accurate method to find the edges in analysis of biomedical images.

9599-8, Session 1

Inpaiting using Airy diffusion

Sara Lourduy-Hernandez, Univ. EAFIT (Colombia)

One inpainting procedure based on Airy diffusion is proposed, implemented via Maple and applied to some digital images. Airy diffusion is a partial differential equation with spatial derivatives of third order in contrast with the usual diffusion with spatial derivatives of second order. Airy diffusion generates the Airy semigroup in terms of the Airy functions which can be rewritten in terms of Bessel functions. The Airy diffusion can be used to smooth an image with the corresponding noise elimination via convolution. Also the Airy diffusion can be used to erase objects from an image. We build an algorithm using the Maple package ImageTools and such algorithm is tested using some images. Our results using Airy diffusion are compared with the similar results using standard diffusion. We observe that Airy diffusion generates powerful filters for image processing which could be incorporated in the usual packages for image processing such as ImageJ and photoshop. Also is interesting to consider the possibility to incorporate the Airy filters as applications for smartphones and smart-glasses..

9599-10, Session 2

Performance and complexity of color gamut scalable coding

Yuwen He, Yan Ye, Xiaoyu Xiu, InterDigital, Inc. (United States)

Wide color gamut such as BT.2020 allows pictures to be rendered with sharper details and more vivid colors. It is considered an essential video parameter for next generation content generation, and has drawn significant commercial interests recently. As the upgrading cycle of content production work flow and consumer displays takes place, current generation and next generation video content are expected to co-exist. Thus, maintaining backward compatibility becomes an important consideration for efficient content delivery systems. The Scalable Extension of HEVC (SHVC) was recently finalized in the second version of the HEVC specifications. SHVC provides a color mapping tool to improve scalable coding efficiency when the base layer and the enhancement layer video signals are in different color spaces. The SHVC color mapping tool uses a 3D Look-Up Table (3D LUT) based cross-color linear model to efficiently convert the video in base layer color space into enhancement layer color space. Due to complexity concerns, certain limitations, including limiting the maximum 3D LUT size to 8x2x2, were applied to the color mapping process in SHVC. In this paper, we investigate the complexity and performance trade-off of the 3D LUT based color mapping process. Specifically, we explore the performance benefits of enlarging the size of the 3D LUT. In order to reduce computational complexity, we use a simplified cross-color linear model within each 3D LUT partition. Simulation results are provided to detail the various performance vs complexity trade-offs achievable in the proposed design.

9599-11, Session 2

Implication of high dynamic range and wide color gamut content distribution

Taoran Lu, Fangjun Pu, Peng Yin, Tao Chen, Walter J. Husak, Dolby Labs., Inc. (United States)

High Dynamic Range (HDR) and Wider Color Gamut (WCG) content represents a greater range of luminance levels and a more complete reproduction of colors found in real-world scenes. The current video distribution environments deliver Standard Dynamic Range (SDR) signal, typically created to represent a range of brightness of around 0.1 to 100 cd/m2 and a color gamut defined by BT. 709. Compared to SDR, new HDR and WCG content may cover a luminance range of 0.005 to 10000 cd/ m2, and significantly wider color gamut (e.g. BT. 2020). Therefore, there might be some significant implication on today's end-to-end ecosystem from content creation to distribution and finally to consumption. One strong

candidate for HDR/WCG signal compression is the state-of-the-art video compression standard - HEVC main 10 profile, which requires the input to be in 10-bit and 4:2:0 chroma sampling format. For SDR content, the common practice is to apply compression on Y'CbCr 4:2:0 using gamma transfer function and non-constant luminance 4:2:0 chroma subsampling. For HDR and WCG content, it is desirable to examine if such signal format still works well for compression, and it is interesting to know if the overall system performance can be further improved by exploring different signal formats and processing workflows. In this paper, we will provide some of our insight into those problems. Specifically, we will focus on the compression performance using different color space containers and with various chroma resampling workflows, and present analysis on their possible implication to the overall system.

9599-12, Session 2

HEVC for high dynamic range services

Seung-Hwan Kim, Jie Zhao, Kiran M. Misra, Andrew Segall, Sharp Labs. of America, Inc. (United States)

Displays capable of showing a greater range of luminance values can render content containing high dynamic range information in a way such that the viewers have a more immersive experience. This paper considers the end-to-end design and performance aspects of a high dynamic range (HDR) system. Specifically, we examine the performance of critical components in the HDR processing chain including the design of the opto-electrical transfer function, compression codec, electro-optical transfer function and the tone mapping and rendering operation of a display. We then propose a method to extend the existing high efficiency video coding (HEVC) framework to compress and render HDR video content on an HDR capable display. Additionally, the method supports the rendering of HDR video content on a display capable of showing only a lower range of luminance values; thereby allowing existing and future deployments of standard dynamic range (SDR) displays to render HDR content while preserving much of the content authors intended viewing experience. Results are presented comparing the efficiency of the current approach versus simulcast of HDR and SDR content to a display.

9599-13, Session 2

Chroma sampling and modulation techniques in high dynamic range video coding

Pankaj Topiwala, Wei Dai, Madhu Krishnan, FastVDO Inc. (United States)

High Dynamic Range (HDR) and Wide Color Gamut (WCG) video presents an interesting new challenge in media communication, and in presentation. Existing solutions for compression and communication of video, such as the ITU/H.265 | ISO/IEC High Efficiency Video Coding (HEVC) Standard, apply mainly to Standard Dynamic Range video sources, and to standard color gamuts (such as Rec. 709). In HDR/WCG, both of these dimensions are broadened, and new tools may be required to efficiently represent such data in compressed form. In this paper, we explore several novel techniques of color spaces, chroma sampling, and luminosity scaling, to compress such data efficiently. Such innovations, built on top of the existing HEVC infrastructure, can provide state of the art performance in the compression and representation of such video, while also providing valuable backwards compatibility with existing infrastructure based on the Main and Main 10 Profiles of HEVC.

9599-14, Session 2

High dynamic range and wide color gamut in HEVC Main10

Chad Fogg, MovieLabs (United States); Bill Mandel, Universal Pictures (United States); James L. Helman, MovieLabs (United States)

In Spring of 2013, five Motion picture studios launched an industry initiative to find near-term technical solutions that deliver the High Dynamic Range (HDR) and Wide Color Gamut (WCG) aspects of Ultra High Definition (UHD) video content to end consumers. The first platform is Blu-Ray 2.0. Some over the top (OTT) services have already begun HDR services, customized to traditional gamma transfer functions that are hardwired into the display driver DAC's of traditional flat panel monitor designs. This paper describes the experiments and solutions explored during this project, and an analysis of bitstream efficiency sensitive system elements, including workflow steps far upstream from the codec, and downstream from the decoder, that interact to affect the rendered outcome. It was discovered that the system philosophy of HDR/WCG that best describes the independence of major variables are those expressed by the existing Video Usability Information (VUI) metadata dimensions present in most AVC and HEVC bitstreams. The key role of the transfer function is to map the conceptual floating-point linear video sensor signal into integer video with visually uniform quantization steps steps, at least in luminance, in which video encoders best traditionally work. The color space derivation from the primary signal, such as YCbCr, has also been motivated for compression efficiency. Benefits from alternative spaces, that have been found to be more ideal in human and machine vision such as La*b*, were overshadowed by desirable properties intentionally designed into the simpler color difference equations. This interacts well with the residual block transform coder's deadzone quantizer to eliminate minor, but costly noise in color prediction errors. This paper is a technical background of the short, high-level summary of the solution provided in the May 2015 IEEE CVST paper "HDR and WCG Video Coding in HEVC: Status and Potential Future Enhancements."

9599-15, Session 2

On metrics for objective and subjective evaluation of high dynamic range video

Koohyar Minoo, Zhouye Gu, David Baylon, Ajay Luthra, ARRIS Group, Inc. (United States)

In High Dynamic Range (HDR) video, it is possible to represent a wider range of intensities and contrasts compared to the current Standard Dynamic Range (SDR) video. HDR video can simultaneously preserve details in very bright and very dark areas of a scene whereas these details become lost or washed out in SDR video. Because the perceived quality due to this increased fidelity may not fit the same model of perceived quality in the SDR video, it is not clear whether the objective metrics that have been widely used and studied for SDR visual experience are reasonably accurate for HDR cases, in terms of correlation with subjective measurement for HDR video quality. This paper investigates several objective metrics (e.g. PSNR, weighted-MSE, VIF, HDR-VDP2) and their correlation to subjective quality for a variety of HDR video content. For some metrics, attention is given to the domain in which they are applied, such as color space and linear vs. nonlinear domains. Results are given for the case of HDR content compressed after using different transfer functions and quantization parameters. In addition to rating the relevance of each objective metric in terms of its correlation to the subjective measurements, comparisons are also presented to show how closely different objective metrics can predict the results obtained by subjective quality assessment in terms of coding efficiency provided by different coding tools or processes.

9599-16, Session 2

Towards high dynamic range extensions of HEVC: subjective evaluation of potential coding technologies

Philippe Hanhart, Touradj Ebrahimi, Ecole Polytechnique Federale de Lausanne (Switzerland); Martin ?e?ábek, Anne-Flore Perrin, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Since the completion of the first edition of the High Efficiency Video Coding (HEVC) standard, several key extensions of its capabilities have been developed to address the needs of an even broader range of applications. Recognizing the rise of High Dynamic Range (HDR) applications and the lack of a corresponding video coding standard, the Moving Picture Experts Group (MPEG) has released in February 2015 a Call for Evidence (CfE) for HDR and Wide Colour Gamut (WCG) video coding. The purpose of this CfE is to explore whether the coding efficiency and/or the functionality of HEVC can be significantly improved for HDR and WCG content. This paper describes the details and the results of the subjective quality evaluation performed to benchmark the potential coding technologiessubmitted in response to the CfE.

9599-17, Session 3

Digital signal processing of light in holographic 3D imaging *(Invited Paper)*

Kyoji Matsushima, Kansai Univ. (Japan)

Techniques in digital holography are gradually evolved over a past decade. Recently, the techniques allow us to capture wide spatial information of light and handle it as digital data that includes not only optical intensity distribution like conventional digital imaging but also phase distribution. This can be interpreted as A/D conversion of light. Recent techniques in computer holography also make it possible to generate real light from digital data. This provides D/A conversion of light. This means that the both ends of common digital processing are now available in the field of holography. In this report, we present several techniques for holographic digital signal processing of light, which is specialized for 3D imaging.

Holographic 3D imaging, however, has the problem of an enormous space-band product. This is caused by the requirement for optical reconstruction with a wide screen and large viewing-angle. Therefore, the techniques presented include (a) capturing optical wave fields in extremely high-definition, e.g. more than billion samplings, (b) creation of high-definition computer-generated holograms (CGH), also composed of more than billion pixels, and (c) numerical techniques for various field-propagations of this gigantic wave field, which provide basic signal processing of light.

Some of actual high-definition CGHs created by using the techniques is demonstrated for verifying the techniques. These high-definition CGHs can reconstruct impressive fine 3D images that give strong sensation of depth to viewers.

9599-18, Session 3

Compression of digital holographic data: an overview

Frederic Dufaux, Yafei Xing, Beatrice Pesquet-Popescu, Télécom ParisTech (France); Peter Schelkens, Vrije Univ. Brussel (Belgium) and iMinds (Belgium)

Existing 3D video systems based on the principle of stereoscopic vision exploit limited depth cues. In addition, the accommodation/vergence conflict is an inherent limitation of such solutions. In contrast, by fully reconstructing the object wavefront, holography offers all depth cues. It has therefore the potential to become the ultimate 3D experience. Nevertheless, in order to achieve practical working systems, major scientific and technological challenges have to be tackled.

In particular, as digital holographic data represents a huge amount of information, the development of efficient compression techniques is a key component. This problem has gain significant attention by the research community during the last 10 years. In this paper, we will review and analyze past and on-going work in the compression of digital holographic data.

9599-19, Session 3

Fast generation of complex modulation video holograms using temporal redundancy compression and hybrid point-source/wave-field approaches

Antonin Gilles, Institut de recherche technologique B-Com (France); Patrick Gioia, Institut de recherche technologique B-Com (France) and Orange SA (France); Rémi Cozot, Institut de recherche technologique B-Com (France) and Univ. de Rennes 1 (France); Luce Morin, Institut de recherche technologique B-Com (France) and Institut National des Sciences Appliquées de Rennes (France)

Hybrid point-source/wave-field method is a newly proposed approach for Computer-Generated Hologram (CGH) calculation, based on the slicing of the scene into several depth layers parallel to the hologram plane. The complex wave scattered by each depth layer is then computed either using a wave-field or a point-source approach according to a threshold criterion on the number of points within the layer. Finally, the complex waves scattered by all the depth layers are summed up in order to obtain the final CGH.

Although outperforming both point-source and wave-field methods without producing any visible artifact, this approach has not yet been used for animated holograms, and the possible exploitation of temporal redundancies has not been studied. In this paper, we propose a fast computation of video holograms by taking into account those redundancies. Our algorithm consists of three steps. First, intensity and depth data of the current frame of the 3D video are extracted and compared with those of the previous frame in order to remove temporally redundant data. Then the CGH pattern for this compressed frame is generated using the hybrid point-source/wave-field approach. The resulting CGH pattern is finally transmitted to the video output as well as stored in the previous frame buffer. Experimental results reveal that our proposed method is able to produce video holograms at interactive rates without producing any visible artifact.

9599-20, Session 3

Evaluation inter- and intra-channel correlations of representations for the compression of holograms

Ayyoub Ahar, David Blinder, Tim Bruylants, Colas Schretter, Adrian Munteanu, Peter Schelkens, Vrije Univ. Brussel (Belgium)

The signal properties of holograms differ considerably from natural photographs, which causes conventional image codecs to perform sub-optimally on this type of data. In this paper, we investigate how to effectively code interference patterns in the hologram domain. The complex amplitudes can be encoded using various multi-channel representations such as real-imaginary, amplitude-phase, and off-axis real-valued or multiple phase-shifted hologram recordings. The specific choice of representation significantly affects the compressibility of the signal when compressing fringes in the hologram domain. For this purpose, we analyzed both inter- and intra-channel correlations for each representation. We encode several holograms using a JPEG 2000-based image codec that supports additional wavelet packet decompositions and directional transforms. Finally, we evaluate how the various compression settings affect the quality of the hologram, both in the image as well as in the reconstruction domain.

9599-22, Session 4

The image registration of multi-band images by geometrical optics

Yung-Jhe Yan, Hou-Chi Chiang, National Chiao Tung Univ. (Taiwan); Yu-Hsiang Tsai, Industrial Technology Research Institute (Taiwan); Ting-Wei Huang, Ou-Yang Mang, National Chiao Tung Univ. (Taiwan)

The image fusion is combination of two or more images into one image. The fusion of multi-band spectral image has been in many applications, such as thermal system, remote sensing, medical treatment, etc. Before fusion, these images are mostly taken from different camera modules. If camera modules take an image from the different optical path in the same time, it must be in different position. It comes into the problem of the image registration. Because the images are in different field of views, also called FOV, different resolution and different view angles. It is important to build the relationship of view point in one image to the other image.

In this paper, we focus on the problem of different field of views and different resolution for two non-pinhole camera modules. The affine transformation between a 2-D image and the 3-D real world can be derived from the geometrical optics of the camera modules. In the other word, the geometrical affine function of two image are also derived from the intrinsic and extrinsic parameter of two camera modules. Through deriving the affine function, the overlap of the FOV in two images can be calculated and resample two images in the same resolution. Finally, we construct the image registration model by the affine function. It merge images for different camera sensors. And, camera sensors absorb different wavebands of electromagnetic spectrum at different position in the same time.

9599-23, Session 4

Restoration of remotely sensed images through bilevel multiobjectives programming

Soo Mee Wong, National Space Agency (ANGKASA) (Malaysia); Chee Seng Chan, Univ. of Malaya (Malaysia)

Finding a compromise between regularity to remove noise and preserving image fidelity for remotely sensed imagery is unarguably a non-trivial problem. This paper proposes a new image restoration algorithm that executes an optimal tradeoff between sharpness and noise to warrant an acceptable result of image restoration based on bilevel multiobjectives programming. The algorithm demands two objective functions for the lower-level problem; to derive the degradation function and to perform denoising on the degraded image, while the upper-level problem with ultimate objective function that is to obtain restored image by performing deblurring to the denoised image using the knowledge of the degradation function. Points of sharp variations and discontinuities are two important properties for analyzing an image or signal. Due to this consideration, in the lower-level problem, curvelet multiscale transform is employed to decompose degraded image into different scale, where the low and high frequency sub-band are used to derive the degradation function and remove image noise, respectively. Ideally the denoised image from lower level problem will contain no noise; however, in practice it will always contain some noise, therefore, the upper-level objective must be regularized. The upper-level problem is solved using an improved empirical Wiener filter to attenuate the leaked noise if any. Experiment was conducted for natural and synthetically blurred satellite imagery. The experimental result shows that the algorithm successfully restores image detail. Numerical measurements of the image quality reveal that the algorithm is comparable with other state-of-the-art methods and has advantage for image contrast and preserving edge strength.

9599-24, Session 4

Quick matching of binary images

Adnan A. Mustafa, Kuwait Univ. (Kuwait)

Matching images is a central problem in image processing. The most common technique used to compare binary images is to calculate the correlation between two images or simply to subtract them. Both of these methods require some type of similarity operation to be applied to the whole image, i.e. they are image size dependent. This implies that as image size increases, more processing time is required. However, with image sizes already exceeding 20 mega-pixels and standard image sizes doubling every five years, the need to find a size invariant image matching method is becoming crucial. In this paper, we present a faster way to compare and match binary images by using the Probabilistic Matching Model (PMM) that is image size invariant. We present two simple image size invariant algorithms based on PMM: one for fast detection of dissimilar binary images and another for matching binary images. For detecting dissimilar binary images we introduce the Dissimilar Detection via Mapping method (DDM). We compare DDM to other popular methods used in the image processing arena and show that DDM is magnitudes faster than any other method. For binary image matching, we use DDM as a preprocessor for other popular methods to speed up their matching speed. In particular, we use DDM with cross correlation to speed it up. Results are shown with real images varying in size from 16k images to 10 mega-pixel images to show the method's size invariance.

9599-25, Session 4

Airy-Kaup-Kupershmidt filters applied to image processing

Laura Hoyos, Univ. EAFIT (Colombia)

The Kaup-Kupershmidt operator is applied to the two-dimensional solution of the Airy-diffusion equation and the resulting filter is applied via convolution to image processing. The full procedure is implemented using Maple code with the package ImageTools. Some experiments were performed using a wide category of images including biomedical images generated by magnetic resonance, computarized axial tomography, positron emission tomography, infrared and photon diffusion. The Airy-Kaup–Kupershmidt filter can be used as a powerful edge detector and as powerful enhancement tool in image processing. It is expected that the Airy-Kaup–Kupershmidt could be incorporated in standard programs for image processing such as ImageJ.

9599-26, Session 4

Compression and denoising in image processing via SVD on the Fourier domain using computer algebra

Felipe Díaz Jaramillo, Ana M. Ospina-Duque, Univ. EAFIT (Colombia)

Magnetic resonance (MR) data reconstruction can be computationally a challenging task. The signal-noise ratio might also present complications, especially with high-resolution images. In this sense, data compression can be useful not only for reducing the complexity and memory requirements, but also to reduce noise, even to allow eliminate spurious components.

This paper proposes the use of a system based on singular value decomposition of low order for noise reconstruction and reduction in MR imaging system. The Akaike information criterion is used to estimate the model order, which is used to remove noise components and reduce the amount of data processed and stored. The proposed method is evaluated using in vivo MRI data. Rebuilt images with less than 20% of the original data and with similar quality in terms of visual inspection are presented. Also a quantitative evaluation of the method is presented. The full procedure is implemented using Computer Algebra, specifically the Maple package Image Tools.

9599-27, Session 4

An adaptive spatio-temporal bilateral filter for video denoising

Ehsan Nadernejad, Apical (United Kingdom); Sara Saravi, Eran A. Edirisinghe, Loughborough Univ. (United Kingdom)

In image processing and computer vision, denoising is one of the most important topics. A bilateral filter is a non-linear filter, which the intensity of each pixel in an image replaces by a weight average of intensity values from neighboring pixels. This paper presents a new denoising algorithm that exploits the characteristics of the spatial and temporal frames.

The bilateral filter is extended for noise reduction in noisy video sequences. To increase the correlation between pixels, the surrounding frames are motion compensated before applying spatio-temporal bilateral filter. To obtain accurate motion vectors, an adaptive bilateral filter enhances each frame before motion estimation phase. Next, the spatio-temporal filter is applied to a set w (window size) of spatio-temporal surrounding pixels.

For denoising, all spread parameters (spatial, intensity and time) of the filter should be chosen carefully to ovoid over-smoothing in the texture regions and to preserve edges. The spread parameters are proportional with noise level, which is calculated using patch based noise level estimation method by employing principal component analysis.

First an adaptive bilateral filter is applied to the current, previous and next frames. Next, motion compensation is applied to the previous and next frames. The motion vectors are estimated by exhaustive search block matching algorithm with Half-Pel accuracy. Finally, the spatio-temporal bilateral filter is applied to a three dimensional image to remove the noise.

Experimental results indicate that the performance of the proposed approach is competitive when compared to state-of-the-art video denoising algorithms based on objective evaluations.

9599-28, Session 5

Effects of display rendering on HDR image quality assessment

Emin Zerman, Giuseppe Valenzise, Télécom ParisTech (France); Francesco Banterle, Consiglio Nazionale delle Ricerche (Italy); Francesca De Simone, Frederic Dufaux, Télécom ParisTech (France)

The quality of experience of High Dynamic Range (HDR) content is influenced by many factors, such as the way pictures are generated and displayed. For the same acquisition and rendering conditions, HDR pictures of diverse scenes may actually entail a radically different visual experience, depending on the content of the scene. In order to select video content for the evaluation of HDR processing techniques, it is therefore necessary to develop computational methods able to measure the HDR characteristics of a scene, similarly to what the Spatial Information (SI) or Temporal Information (TI) do for LDR spatial and temporal complexity, respectively. In this paper we propose a dynamic range index (DRI) which quantifies the characteristics related to the dynamic range of HDR video sequences.

9599-29, Session 5

Color transfer between high-dynamic-range images

Hristina Hristova, Remi Cozot, Olivier Le Meur, Kadi Bouatouch, Univ. de Rennes 1 (France)

Color transfer domain aims at transferring the color and light features of a reference image to a source image. So far, the proposed color transfer methods have been limited to LDR images. Unlike LDR images, which are display-dependent, HDR images contain real physical values and are able to capture high luminance variations and finer details of real world scenes. Therefore, there exists a strong discrepancy between the two types of images. In this paper, we introduce the first solution for bridging the gap between HDR imaging and the existing LDR color transfer methods. We propose a framework which tackles the main issues of applying a color transfer between two HDR images. First, to address the nature of light and color distributions in the context of HDR imaging, we carry out modifications of traditional color spaces. Furthermore, our framework ensures high precision in the quantization of the dynamic range for histogram computations. As image clustering (based on light and colors) proved to be an important aspect of color transfer, we analyze and adapt it to the HDR domain. Our framework has been applied to several state-of-the-art color transfer methods. Qualitative experiments have shown that results obtained with the proposed adaptation approach exhibit less artifacts and are visually more pleasing than results obtained when applying straightforwardly existing color transfer methods to HDR images.

9599-30, Session 5

The JPEG XT suite of standards: status and future plans

Thomas Richter, Univ. Stuttgart (Germany); Tim Bruylants, Peter Schelkens, Vrije Univ. Brussel (Belgium) and iMinds (Belgium); Touradj Ebrahimi, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

The JPEG standard has known an enormous market adoption. Daily, billions of pictures are created, stored and exchanged in this format. The JPEG committee acknowledges this success and spends continued efforts in maintaining and expanding the standard specification. JPEG XT is a standardization effort that targets the expansion of the JPEG functionality, enabling support for high dynamic range imaging, lossless and near-lossless coding and alpha channel coding while guaranteeing backward compatibility with JPEG legacy decoders.

This paper gives an overview of the current status of the JPEG XT standards suite. It discusses the JPEG legacy specification, and details how higher dynamic range support is facilitated both for integer and floating-point color representations. JPEG XT includes support for lossless and near-lossless coding of low and high dynamic range images, while providing backward JPEG compatibility. In addition, the extensible boxed-based JPEG XT file format on which all following and future extensions of JPEG will be based on is introduced. This article also details how the lossy and lossless representation of alpha channels, thus enabling the coding of transparency information and coding of arbitrarily shaped images, is supported. Finally, this paper concludes with giving prospects on future JPEG standardization initiatives.

9599-31, Session 5

Live HDR video streaming on commodity hardware

Alan Chalmers, Joshua McNamee, Jon Hatchett, Kurt Debattista, The Univ. of Warwick (United Kingdom)

High Dynamic Range (HDR) video provides a step change in viewing experience, for example the ability to clearly see the football when it is kicked from the shadow of the stadium into sunshine. To achieve the full potential of HDR video, so-called true-HDR, it is crucial that all the dynamic range that was captured or generated is delivered to the display device and tone mapping does not occur anywhere in the pipeline prior to the display. This paper describes a system for capturing, encoding and streaming high-definition HDR video in real-time to a variety of displays using only commodity hardware.

9599-32, Session 5

Study of high dynamic range video quality assessment

Manish Narwaria, Matthieu Perreira Da Silva, Patrick Le Callet, Institut de Recherche en Communications et en Cybernétique de Nantes (France)

In recent years, High Dynamic Range (HDR) imaging has attracted significant attention from industry and academia. As a result, there are currently several on-going efforts towards standardization and benchmarking of existing tools for HDR image and video. However, one key aspect that has probably not received enough attention is that HDR visual quality measurement (both subjective and objective approaches). This paper aims to fill that gap by first identifying the key challenges in the said area and discuss few existing solutions. Specifically, the paper targets three main aspects of HDR quality assessment. First, we discuss a few important practical aspects that make HDR video quality measurement potentially challenging. Second, we report our recent efforts towards developing HDR datasets that have been subjectively annotated for visual quality. Finally, we analyze and compare the effectiveness of existing solutions for objective quality prediction.

Automatic HDR merging algorithm based on GPU-assisted optimization for technical vision applications

Igor V. Guryev, Cesar Alejandro Martinez Hernandez, Natalia Gurieva, Carlos Rodriguez Doñate, Eduardo Cabal Yepez, Univ. de Guanajuato (Mexico)

In the work, there has been proposed a highly-tunable algorithm for creating an HDR image. The algorithm is based on main principles of manual image rendering. It does not involve image recognition techniques and implements weighted patches summation based on their histograms only. For an automation of an HDR merging it has been proposed the algorithm involving four parameters. The parameters are optimized using the genetic algorithm. An optimization criterion is based on the final image histogram analysis.

To avoid the color and intensity confusion another criterion has been introduced. Namely, the intensities of each pixel of the final image as respect to the average intensity of surrounding pixels should be close to the ones of the image with normal exposition. This criterion is introduced into an algorithm as a multiplication by the number of pixels where the intensity relation is inverted.

Because of high picture resolution on modern cameras even a single HDR merging takes minutes. An optimization procedure always requires hundreds of steps which makes this idea unreal. Therefore we have introduced several simplifications and assumptions to accelerate the process. Namely, when the image does not contain small essential details its histogram as well as intensities distribution is similar to the one with lower resolution. We run an optimization procedure for low-resolution image and after this apply the same parameters to generate high-resolution image.

After this we have implemented the algorithm using GPU parallelization, the optimization had become several timer faster with the same result quality.

9599-34, Session 5

Rendering of HDR content on LDR displays: an objective approach

Luká? Krasula, Czech Technical Univ. in Prague (Czech Republic) and Institut de Recherche en Communications et en Cybernétique de Nantes (France); Manish Narwaria, Institut de Recherche en Communications et en Cybernétique de Nantes (France); Karel Fliegel, Czech Technical Univ. in Prague (Czech Republic); Patrick Le Callet, Institut de Recherche en Communications et en Cybernétique de Nantes (France)

Dynamic range compression (or tone mapping) of HDR content is a an essential step towards rendering them on traditional LDR displays in a meaningful way. This is however non-trivial and one of the reasons is that tone mapping operators (TMOs) usually need content-specific parameters to achieve the said goal. While subjective TMO parameter adjustment is the most accurate, it may not be easy deployable in many practical applications. Thus, there is need for objective TMO parameter selection to automate the rendering process. To that end, we investigate into a new objective method for TMO parameters optimization. Our method is based on quantification of contrast reversal and naturalness. As an important advantage, it does not require any prior knowledge about the input HDR image and works for both global and local TMOs. Experimental results using a variety of HDR images and several popular TMOs demonstrate the value of our method in comparison to default TMO parameter settings.

9599-35, Session 6

Objective video presentation QoE predictor for smart adaptive video streaming

Zhou Wang, Kai Zeng, Abdul Rehman, Hojatollah Yeganeh, Shiqi Wang, Univ. of Waterloo (Canada)

How to deliver videos to consumers over the network for optimal quality-of-experience (QoE) has been the central goal of modern video delivery services. Surprisingly, regardless of the large volume of videos being delivered everyday through various systems attempting to improve visual QoE, the actual QoE of end consumers is not properly assessed, not to say using QoE as the key factor in making critical decisions at the video hosting, network and receiving sites. Real-world video streaming systems typically use bitrate as the main video presentation quality indicator, but using the same bitrate to encode different video content could result in drastically different visual QoE, which is further affected by the display device and viewing condition of each individual consumer who receives the video. To correct this, we have to put QoE back to the driver's seat and redesign the video delivery system. To achieve this goal, a major challenge is to find an objective video presentation QoE predictor that is accurate, fast, easy-to-use, display device adaptive, and provides meaningful QoE predictions across resolution and content. We propose to use the newly developed SSIMplus index (https://ece.uwaterloo.ca/~z70wang/research/ssimplus/) for this role. We demonstrate that based on SSIMplus, one can develop a smart adaptive video streaming strategy that leads to much smoother visual QoE impossible to achieve using existing adaptive bitrate video streaming approaches. Furthermore, SSIMplus finds many more applications, in live and file-based quality monitoring, in benchmarking video encoders and transcoders, and in guiding network resource allocations.

9599-36, Session 6

Experimental design and analysis of JND test on coded image/video

YuChieh Lin, Lina Jin, Sudeng Hu, The Univ. of Southern California (United States); Ioannis Katsavounidis, Zhi Li, Anne M. Aaron, Netflix, Inc. (United States); C.-C. Jay Kuo, The Univ. of Southern California (United States)

The Just-Noticeable-Difference (JND) metric is characterized by the detectable minimum amount of two stimuli. JND has been used to enhance perceptual video quality in the context of image/video compression. For the context video coding, given a set of coding parameters, a video JND test is designed to determine the JND level against a reference video, which is called the anchor video. In other words, the JND metric can be used to save

coding bit rates by exploiting the special characteristics of the human visual system (HVS). The task of video JND testing is labor and time intensive. In this work, we present a novel human-computer interactive method for video JND test.

The proposed JND test is based on two alternative forced choice, which is a commonly used psychophysical method to discriminate the difference in perception. The assessors are asked to compare video pairs and determine the impairment of each pair. A ladder-climbing process is designed to help assessors find the pair with the smallest difference and terminate the test. The video pairs are seamlessly combined and presented so that assessors are confident in their decisions. We will show some statistics to demonstrate the efficiency of the proposed video JND test.

9599-37, Session 6

Predicting the visibility of dynamic DCT distortion in natural videos

Jeremy P. Evert, Md Mushfiqul Alam, Damon M. Chandler, Oklahoma State Univ. (United States)

Compression has enabled years of exponential growth in global video consumption, providing video everywhere we live, with few perceptible artifacts.

A key enabler of compression is automated Video Quality Assessment (VQA).

However, current VQA algorithms are hindered by a limited understanding of artifact visibility, based mainly on a few idealized psychophysical experiments or popular still image compression heuristics.

An extremely limited number of studies quantify artifact detection in still images (e.g., Chandler and Hemami JOSA 2003, Alam et al. JOV 2014), and only our recent studies have quantified video masked compression-artifact visibility (Evert and Chandler ACSSC 2013, Pending submission: Evert and Chandler JEI 2015).

Experiment result analyses show both target properties and video content affect artifact visibility, and existing VQA models have limited artifact visibility threshold prediction capability.

Here we present new data showing a positively correlated relationship between video contrast and artifact visibility thresholds.

Increasing video contrast amplifies differences between video masking abilities, and artifact visibility is still a function of artifact spatiotemporal frequencies.

Based on our data, we suggest a contrast-gain-control VQA model, with target spatiotemporal property weighting, to overcome performance limitations of previous VQA.

We demonstrate how using our data can tune various objective VQA algorithms, including ViS3, MOVIE, and VQM, for improved artifact threshold predictions.

This paper provides much needed data on the relationship between natural video mask contrast and artifact visibility, and provides important insights for improving existing VQA algorithms for better compression artifact visibility prediction in the high-quality regime

9599-38, Session 6

A time-varying subjective quality model for mobile streaming videos with stalling events

Deepti Ghadiyaram, Janice Pan, Alan C. Bovik, The Univ. of Texas at Austin (United States)

Over-the-top mobile video streaming is invariably influenced by volatile network conditions which cause playback interruptions (stalling events) and impair a viewer's quality of experience (QoE). The ability to accurately predict a viewer's QoE can help in the design of efficient solutions for video streaming networks that can reduce network operational costs while still delivering high-quality video content to customers. Existing objective models that predict QoE are based on simple, global video features, such as the number of stall events and their lengths, and are trained and validated on a small pool of ad hoc video datasets, most of which are not publicly available. Aside from these aforementioned global features, the model we propose in this work differs from previous models as it also accounts for the fundamental effect that a viewer's recent level of satisfaction or dissatisfaction has on their overall viewing experience. In other words, the proposed model accounts for and adapts to the recency, or the hysteresis effect caused by a stall event in addition to accounting for the lengths, frequency of occurrence, and the positions of stall events - all factors which interact complexly and affect a user's QoE. We train and validate our model on the recently created LIVE-Avvasi Mobile Video Database, which consists of 180 distorted videos of varied content that are afflicted solely with over 25 unique realistic stalling events.

9599-39, Session 6

The effect of texture granularity on texture synthesis quality

S. Alireza Golestaneh, Mahesh M. Subedar, Lina J. Karam, Arizona State Univ. (United States)

Natural and artificial textures occur frequently in images and in video sequences. In a general framework for imagevideo coding based on texture synthesis, the input image or a frame of video is first segmented into texture and non-texture regions. The texture regions are further analyzed to extract the data needed for texture synthesis. This data may be constraint parameters in parametric texture synthesis approaches or it could be seed-pixel regions in exemplar-based synthesis approaches. The quality assessment unit uses the synthesized and the original texture to estimate the fidelity of the synthesized texture. The texture synthesis process is repeated in an iterative manner until a prescribed quality is met. Existing objective visual quality assessment methods do not perform satisfactorily when predicting the synthesized texture quality. In our previous work, we showed that texture regularity can be used as an attribute for estimating the quality of synthesized textures. In this paper, we study the effect of another texture attribute, namely texture granularity, on the quality of synthesized textures. For this purpose, subjective studies are conducted to assess the quality of synthesized textures with different levels (low, medium, high) of perceived texture granularity using different types of texture synthesis methods.

9599-40, Session 6

Objective video quality for video on mobile devices

Louis J. Kerofsky, Yuriy A. Reznik, Rahul Vanam, InterDigital, Inc. (United States)

Background on visual models and influence of viewing distance and ambient light on visibility of high frequency detail. Description of critical viewing frequency and associated low-pass filter. Extension of objective image quality metrics by modification of test and reference images based on viewing conditions. We evaluate the PSNR, SSIM, MS-SSIM under changing viewing conditions. A subjective study examines the visibility of compression artifacts on a mobile device under changing viewing conditions.

9599-41, Session 6

Neurophysiological assessment of perceived image quality using steady-state visual evoked potentials

Sebastian Bosse, Fraunhofer-Institut für

Nachrichtentechnik Heinrich-Hertz-Institut (Germany); Laura Aqualagna, Anne K. Porbadnigk, Technische Univ. Berlin (Germany); Gabriel Curio, Univ. Berlin, Charite (Germany); Klaus-Robert Müller, Technische Univ. Berlin (Germany) and Korea Univ. (Korea, Republic of); Benjamin Blankertz, Technische Univ. Berlin (Germany); Thomas Wiegand, Fraunhofer-Institut für Nachrichtentechnik Heinrich-Hertz-Institut (Germany)

A neurophysiological approach of assessing the perceived quality of images exploiting steady state visual evoked potentials (SSVEP) as neural correlates of quality changes is proposed. We presented images degraded through compression by High Efficiency Video Coding (HEVC) at different distortion level in rapid alternation with the original uncompressed images to 16 observers. In this setting, SSVEPs are evoked as neural markers of perceived image quality objectively indicating visual perception of the image quality. We find the MOS values of the presented images significantly correlated to the neural response at presentation frequency and its harmonics. Our findings are in line with neurophysiology.

9599-42, Session 6

Optimal sequence duration for subjective video quality assessment

Felix J. Mercer Moss, Fan Zhang, Ke Wang, Roland Baddeley, David Bull, Univ. of Bristol (United Kingdom)

Subjective quality assessment is an essential component of modern image and video processing, both for the validation of objective metrics and for the comparison of coding methods. However, the standard procedures used to collect data can be prohibitively time-consuming. One way of increasing the efficiency of data collection is to reduce the duration of test sequences from the 10 second length currently used in most subjective video quality assessment experiments. Here, we explore the impact of reducing sequence length upon perceptual performance when identifying compression artefacts. A group of four reference sequences, together with five levels of HEVC distortion, are used to compare the subjective ratings of viewers watching videos between 1.5 and 10 seconds long. We identify a smooth function indicating that perceptual performance increases linearly as the length of the sequences increases from 1.5 seconds to 7 seconds. However, the performance of observers viewing 10 second sequences was not significantly superior to observers viewing 7, 5 or 3 second sequences. We argue that sequences between 3 seconds and 10 seconds produce satisfactory levels of human performance but the practical benefits of acquiring more data lead us to recommend the use shorter sequences for future subjective video quality assessment studies.

9599-114, Session 6

3D meshes compression performance benchmarking

Christian Tulvan, Télécom SudParis (France); Lazar M. Bivolarski, Albena Technologes Ltd. (United Kingdom)

In this paper we discuss the benchmarking of 3D mesh encoders compression performance. The tested encoders are the MPEG-SC3DMC codec (Scalable Complexity 3D Mesh Compression) based on the TFAN codec (Open3DGC implementation) and also we discuss the benchmarking of OpenCTM (Open Compressed Triangle Mesh) implementation. The geometry is compressed to a fraction of comparable file formats (3DS, STL, VRML, COLLADA...), and the format is easily accessible through a simple, portable API. The OpenCTM is a file format for storing 3D triangle meshes and is not for handling scenes, which make it versatile and widely used from online e-shopping system to game engines, and medical application to phone widgets. In comparison the 3D scene formats tend to be application specific.

9599-43, Session 7

Video streaming with SHVC to HEVC transcoding

Srinivas Gudumasu, Aricent, Inc. (India); Yuwen He, Yan Ye, Xiaoyu Xiu, InterDigital, Inc. (United States)

Adaptive streaming is a popular solution for video on-demand services, but requires the server to store multiple copies (bit-rate, resolution, etc) of the same content, which increases server storage cost severely. To reduce server storage requirement, one can store only the highest quality stream and apply real-time video transcoding to convert the content to a suitable lower quality stream as requested by the client. However, transcoding can also put significant computational burden on the servers. In order to properly balance computational load and storage cost, we propose a joint strategy of scalable HEVC video coding and fast SHVC to HEVC transcoding. In particular, the representation with basic quality settings is coded as the base layer, and higher quality representations are coded as enhancement layers. When the basic quality stream is requested, it is simply extracted without the need for transcoding. When a higher quality stream is requested, transcoding is applied to convert the scalable bit-stream into a single layer bit-stream to reduce the scalable coding overhead. The proposed transcoding algorithm reuses and refines the quadtree depth, mode and motion information of each coding unit available in the scalable bit-stream to ease computational load. Different transcoding strategies are applied according to coding modes to increase the speed further. Simulation results confirm that significant speed-up can be achieved with satisfactory rate distortion performance.

9599-44, Session 7

A perceptual quantization strategy for HEVC based on a convolutional neural network trained on natural videos

Md Mushfiqul Alam, Tuan Nguyen, Damon M. Chandler, Oklahoma State Univ. (United States)

A crucial requirement for effective video coding is the ability to accurately and efficiently predict the local visibility of coding artifacts. Such predictions could help guide the allocation of bits or the determination of quality for each spatiotemporal region. However, previous approaches to predicting artifact visibility exhibit two primary shortcomings. First, they are based on heuristics from overly controlled psychophysical studies using unnatural videos. Second, and more importantly, they are largely impractical for real-time applications due to prohibitive computational/memory demands. Thus, predicting artifact visibility in a manner which is simultaneously more accurate and more efficient than existing models remains an open research challenge. Here, we propose an HEVC-based quantization scheme based on a fast model of local artifact visibility designed specifically for natural videos. The model uses a convolutional-neural-network (CNN) architecture for predicting local artifact visibility and quality of each spatiotemporal region of a video. We trained the CNN model using our recently published database of local masking and quality in natural scenes (Alam et al. JOV 2014 and Alam et al. HVEI 2015, respectively). When coupled with an HEVC encoder, our results provide 5-10% more compression over baseline HEVC when matched in visual quality, while requiring almost half the computational time and memory footprint of an equivalent gain control model. We demonstrate how by integrating a fast model of artifact visibility within natural videos lead to better compression efficiency for the same quality. Our work opens the doors for similar techniques which may work for different forthcoming compression standards.

Classification for skin cancer using the intensity-based, texture-based and fractal-based features with optical coherence tomography

Wei Gao, Valery P. Zakharov, Oleg O. Myakinin, Ivan A. Bratchenko, Dmitry N. Artemyev, Dmitry V. Kornilin, Samara State Aerospace Univ. (Russian Federation)

Optical coherence tomography (OCT) is employed in the diagnosis of skin tumors. Particularly, quantitative image features extracted from OCT images might be used as indicators to classify skin tumors. In the present paper, we investigated intensity-based, texture-based and fractal-based features for automatically differentiating the melanomas from basal cell carcinomas and pigment nevi. Generalized estimating equations were used to test for differences between the skin tumors. A modified p value of <0.001 was considered statistically significant. Significant increase of mean and median of intensity and significant decrease of mean and median of absolute gradient were observed in basal cell carcinomas and pigment nevi as compared with melanomas. Significant decrease of contrast, entropy and fractal dimension were also observed in basal cell carcinomas and pigment nevi as compared with melanomas. Our results suggest that the selected quantitative image features of OCT images could provide useful information to differentiate melanomas from basal cell carcinomas and pigment nevi. Further research is warranted to determine how this approach may be used to improve the classification of skin tumors.

9599-59, Session PWed

A novel teaching-learning-based optimization for image enhancement

Xiaojun Bi, Harbin Engineering Univ. (China)

Image enhancement is considered as a complex optimization problem. In order to make the enhancement of the image more suitable than the original image from the perceptual viewpoint of human, a novel teaching-leaching based optimization (TLBO) for image enhancement is proposed to enhance gray-level images. Firstly a transformation function which combines local information and global information of the image is used to convert the original image into the enhanced image. Then, TLBO algorithm is applied to maximize the objective function of measuring image enhancement in order to enhance the image contrast by maximizing the parameters like edge intensity, edge pixels and entropy of the enhanced image. The main goal of us is to achieve the best enhanced image according to the objective function through optimizing the parameters used in the transformation function with the help of TLBO. Finally experimental results are compared with the state-of-the-art approaches such as particle swarm optimization for image enhancement and differential evolution for image enhancement and TLBO for image enhancement has obtained better image contrast.

9599-60, Session PWed

Registration of point cloud data for HDD stamped base inspection

Sungho Suh, Hansang Cho, SAMSUNG Electro-Mechanics (Korea, Republic of)

As part of the HDD manufacturing process, HDD stamped base, an exterior container, is one of the most essential components in which various parts become assembled to compose a hard disk drive (HDD). Because it is designed by a stamping method, height errors that are caused by pressing, breaking or cracking can occur on the base. In order to detect these height errors, the inspection process is essential in production fields. In the current industry, CMM (Coordinate Measurement Machine) is one of the most widely used inspection machines that inspect certain areas on a product.

This machine examines a designated point with a probe and finds defects by comparing its height with the originally designed height. However, this method takes a long time to inspect each designated point resulting in total of 17 minutes In order to reduce this total inspection time , we propose an inspection method using 3D point cloud data acquired from a holographic sensor. To compare the height from the acquired 3D point cloud data with the one from the originally designed CAD data, the exact registration of point cloud data is important.

The difference between 2D image registration and 3D point cloud registration is that the latter requires that three things be considered: translation on each plane, rotation and tilt. The relationship between the acquired 3D point cloud data and the originally designed CAD data can be known by Affine transformation. If Affine transformation matrix between 3D point cloud data and the CAD data is obtained, 3D point cloud data registration can be performed.

In order to calculate 3D Affine transformation matrix, corresponding points between 3D point cloud data and CAD data are required. To find corresponding points, we use the height map which is projected from 3D point cloud data onto the XY plane. The height map has pixel intensity from the height value of each point. If the height map from 3D point cloud data and CAD data are matched, corresponding points can be known.

In this paper, we find the corresponding points between 3D point cloud data and CAD data using circle fitting since there are multiple circles on the base, and obtain 2D Affine transformation matrix from these corresponding points. By applying 2D Affine transformation matrix to the height map, the corresponding points on the 3D coordinate can be obtained. Using such points, we propose the method designed to achieve 3D Affine transformation matrix. To find the proper 3D Affine transformation matrix, we formulate a cost function which uses the relationship of corresponding points. Also the proper 3D Affine transformation matrix can be calculated by minimizing this cost function. Then the 3D point cloud data can be matched to CAD data and the height values of each point of 3D point cloud can be compared to those of CAD data. The experiment result shows two types of errors: (1) error observed by comparing CAD data with artificially transformed data, (2) error observed by comparing CAD data with the actual 3D point cloud data. The average error observed by comparing CAD data with artificially transformed data is 0.2557, but the average error by the proposed method is 0.0005. Considering this result, the average error is dramatically decreased. Additionally, we compare the proposed method to the other methods. The experiment result shows that the proposed method gives better performance.

Robust illumination-invariant tracking algorithm based on HOGs

Daniel Miramontes-Jaramillo, Vitaly Kober, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico); Víctor H. Díaz-Ramírez, Ctr. de Investigación y Desarrollo de Tecnología Digital (Mexico)

Common tracking systems are usually affected by environmental and technical interferences such as nonuniform illumination, sensors' noise, geometrical scene distortion, etc. Among these issues, the former is particularly interesting because it destroys important spatial characteristics of objects in observed scenes. A poor illumination of a scene hides edges and texture which are essential for tracking of a target in video sequence. Actually, real applications such as video surveillance, robot vision, automated manufacturing and augmented and virtual reality are very sensible to nonuniform illumination of scenes. We propose a two-step tracking algorithm: first, a preprocessing locally normalizes the illumination difference between the target object and observed frames; second, the normalized object is tracked by means of a designed template structure based on histograms of oriented gradients and kinematic prediction model. The algorithm performance is tested in terms of recognition and localization errors in real scenarios. In order to achieve high rate of the processing, we use GPU parallel processing technologies. Finally, our algorithm is compared with other state-of-the-art trackers.

9599-62, Session PWed

Adaptive codebook selection schemes for image classification in correlated channels

Chia-Chang Hu, Xiang-Lian Liu, Kuan-Fu Liu, National Chung Cheng Univ. (Taiwan)

The multiple-input multiple-output (MIMO) system with the use of transmit and receive antenna arrays achieves diversity and array gains via transmit beamforming. Due to the absence of full channel state information (CSI) at the transmitter, the transmit beamforming vector can be quantized at the receiver and sent back to the transmitter by a low-rate feedback channel, called limited feedback beamforming. One of the key roles of Vector Quantization (VQ) is how to generate a good codebook such that the distortion between the original image and the reconstructed image is the minimized. In this paper, a novel adaptive codebook selection scheme for image classification is proposed with taking both spatial and temporal correlation inherent in the channel into consideration. The new codebook selection algorithm is developed to select two codebooks from the discrete Fourier transform (DFT) codebook, the generalized Lloyd algorithm (GLA) codebook and the Grassmannian codebook to be combined and used as candidates of the original image and the reconstructed image for image transmission. The channel is estimated and divided into four regions based on the spatial and temporal correlation of the channel and an appropriate codebook is assigned to each region. The proposed method can efficiently reduce the required information of feedback under the spatially and temporally correlated channels, where each region is adaptively. Simulation results show that in the case of temporally and spatially correlated channels, the bit-error-rate (BER) performance can be improved substantially by the proposed algorithm compared to the one with only single codebook.

Research of improved sparse grid non-uniformity correction technologies for infrared resistor array

Huijie Du, Beijing Simulation Ctr. (China)

Abstract: Infrared resistor arrays perform a vital role in the hardware in the loop testing of infrared seekers. Infrared resistor arrays composed of large numbers of suspended resistor elements are commonly used to produce dynamic two-dimensional images of infrared radiation. Due to inconsistencies in the fabrication process of the resistor arrays, the temperature each resistor elements reaches for a given input voltage is variable and this leads to more significant radiance differences, these differences result in spatially-distributed radiance non-uniformity. Therefore, in order to obtain an available infrared image, non-uniformity correction (NUC) is necessary. In this paper, the non-uniformity characters of the infrared resistor arrays are analyzed base on measured data and then an improved sparse grid method for engineering are discussed and analyzed. First of all, the NUC camera has a strong influence on the effectiveness of the infrared resistor arrays NUC procedure. According to the actual fact and the laboratory condition, we presented an alternative method for collecting resistor arrays intended to reduce the influence causing by the NUC camera. Secondly, based on the measured non-uniformity data, we obtain the response characteristics of the infrared resistor arrays. In each gray level, we take two points or several points correction algorithm to calculate the gain data and the offset data, and then the linear look-up table is established. Finally, through MATLAB we develop the correction software, and we can obtain the driving output conveniently. The result shows that the image quality has a remarkable improvement after non-uniformity correction, the non-uniformity correction flow and algorithm preferably satisfies the requirement of the high confidence infrared imaging simulation.

Digital image database processing to simulate image formation in ideal lightning conditions of the human eye

Jessica Castañeda Santos, Univ. Technológica de la Mixteca (Mexico); Agustín Santiago-Alvarado, Angel S. Cruz-Félix, Arturo Hernández Méndez, Univ. Tecnológica de la Mixteca (Mexico)

The pupil size of the human eye has a large effect in the image quality due to inherent aberrations. Several studies have been performed to calculate its size relative to the luminance as well as considering other factors, i.e., age, size of the adapting field and mono and binocular vision. Moreover, ideal lighting conditions are known, but software suited to our specific requirements, low cost and low computational consumption, in order to simulate radiation adaptation and image formation in the retina with ideal lighting conditions has not yet been developed. In this work, a database is created in the course of three days consisting of 70 photographs corresponding to the same scene with a fixed target at different times of the day with a span of 30 minutes between each photograph. By using this database, characteristics of the photographs are obtained by measuring the luminance average initial threshold value of each photograph by means of an image histogram. Also, we present the implementation of a digital filter for both, image processing on the threshold values of our database and generating output images with the threshold values reported for the human eye in ideal cases. Some potential applications for this kind of filters may be used in artificial vision systems.

Inverse ill-posed problems in sensing with terahertz pulsed spectroscopy: from non-destructive evaluation of materials to non-invasive diagnosis of dysplastic skin nevi

Egor Yakovlev, Kirill I. Zaytsev, Nikita V. Chernomyrdin, Arsenii A. Gavdush, Irina N. Dolganova, Stanislav O. Yurchenko, Bauman Moscow State Technical Univ. (Russian Federation)

Terahertz pulsed spectroscopy (TPS) recently attracts considerable interest as a perspective instrument of applied physics. TPS allows solving the problems of remote sensing, non-destructive evaluations of materials and constructions, material characterization and studying of the phase transitions in media, and non-invasive medical diagnosis. Many factors could impact on the process of sensing, including noises in TPS waveforms and various instabilities of TPS set-up parameters. All factors should be considered during the processing of TPS data. Thus, development of novel techniques for accurately solution of the TPS inverse ill-posed problems, as well as studying the accuracy of TPS inverse problem solution are very important tasks for all applications of TPS. In our work we consider some novel results in sensing with TPS. We show the results of non-destructive evaluations of composite materials at the stages of material processing and exploitation. Moreover, we study the ability for non-invasive medical diagnosis of dysplastic skin nevi. Dysplastic nevus of the skin is a precursor of melanoma, which is reported to be the most dangerous skin cancer. We discuss the ability to study phase transitions and glassing of media via TPS. Finally the problems of TPS signal processing, related to the applications listed above, are considered in this work.

A position, rotation, and scale invariant image descriptor based on rays and circular paths

Selene Solorza, Univ. Autónoma de Baja California (Mexico)

In this paper a rotation, scale and translation (RST) invariant gray-level image descriptor based on 1D signatures is presented. The position invariant is achieved from the amplitude spectrum of the Fourier transform of the given image. The Fourier's amplitude spectrum is introduced in the analytical Fourier-Mellin (AFM) transform. This transform is not scale invariance yet. The AFM transform is normalized by its dc-value to obtain an amplitude spectrum invariant to scale. From the normalized AFM amplitude spectrum two 1D signatures are constructed. The first 1D signature is obtained from circle path binary masks. The circle masks are used to filter the normalized AFM amplitude spectrum, by this manner to build the 1D circle signature. The second 1D signature results from ray path binary masks that filter the normalized AFM amplitude spectrum. These two 1D signatures are rotation, scale and translation invariant image descriptors. In the descriptor training phase, confidence intervals of 95% for the instantaneous amplitude of the 1D RST signatures are built using the statistical method of bootstrap with constant replacement B=1000 and normal distribution. Those confidence intervals are utilized to generate a single classifier output plane, reducing in this form the comparison cost time in the classification step. The Latin alphabet letters in Arial font style were employed to test the descriptor efficiency obtaining a confidence level at least of 95%.

ROI-preserving 3D video compression method utilizing depth information analysis

Chunli Ti, Guodong Xu, Yudong Guan, Yidan Teng, Harbin Institute of Technology (China)

The demand of extra information to render or directly display several different views simultaneously is becoming a key challenge in the field of three dimensional (3D) TV. The 2D plus depth representation occupies a lower bandwidth than most 3D video representations; besides the depth information in it can provide convenience for region of interest (ROI) selection. In this paper, we proposed a ROI-preserving compression method for the 2D plus depth representation to ensure visual effects of viewer-concerned parts at a higher overall compression ratio. The main contribution of this work is introducing an automatic ROI extraction method via processing the depth map which is a valuable index of the visual attention model and not fully developed by the methods mentioned earlier. By meanshift based image segmenting of the depth map, the foreground of the 3D video is obtained. For its higher degree of color contrast, texture richness movement details, the foreground attracts more attention in the Human Visual System (HVS). Then the depth mutation region, which contains significant high frequency information of 2D video and its depth perception, is determined utilizing the edge detection and morphological filtering of the depth map. After the ROI extraction, a ROI based preprocessing filter is applied to both 2D video and the depth map to be compatible with existing video channel. Experiments show obvious effects on ROI preserving in a lower bit rate both visually and statistically. And the result of ROI selection is more reasonable than the conventional approaches.

New visual sensitivity based error concealment algorithm in wireless stereo video communication

Yue Sun, Mei Yu, Keseng Yan, Gangyi Jiang, Ningbo Univ. (China)

Coding techniques may result in reducing stereo video transmission fault tolerance due to network congestion and channel disturbance, when the packet loss or bit error portion, affect directly the quality of decoded image at the receiver. In this paper, a new visual sensitivity based error concealment algorithm is proposed for partially lost macroblocks (MBs) in wireless stereo video communication. The characteristics of coding structure and temporal, spatial and interview relativities in stereo video coding are firstly analyzed. The lost MBs are classified into obscured and non-obscured boundary MBs according to MB's occlusion characteristics, and the non-obscured boundary MBs are further defined into moving MBs and static MBs according to their moving ability. Binocular just noticeable distortion (BJND) indicates that human being cannot perceive some distortions when watching a stereo image if the distortions of one view are less than the BJND value. The characteristics of MBs' BJND values are computed and used to analyze the lost MBs and stereo image. Then, on the basis of human visual sensitivity and texture characteristics of stereo image, the moving MBs are divided into sensitive and insensitive MBs, texture and smooth MBs, respectively. Finally, adaptive error concealment operations with different types of lost MBs are given and used to recover the lost MB according to MB's characteristic analyses. Experimental results with classical test stereo videos show that the proposed algorithm can effectively improve the subjective and objective quality of the error stereo videos compared with other state-of-the-art error concealment methods.

Korteweg-de Vries-Kuramoto-Sivashinsky filters for image processing

Juan C Arango, Universidad EAFIT (Colombia)

The Kuramoto- Sivashinsky operator is applied to the two-dimensional solution of the Korteweg–de Vries equation and the resulting filter is applied via convolution to image processing. The full procedure is implemented using an algorithm: prototyped with the Maple package named Image Tools. Some experiments were performed using biomedical images, infrared images obtained with smartphones and images generated by photon diffusion. The results from these experiments show that the Kuramoto–Sivashinsky-Korteweg–de Vries Filters are excellent tools for enhancement of images with interesting applications in image processing at general and biomedical image processing in particular. It is expected that the incorporation of the Kuramoto–Sivashinsky-Korteweg–de Vries Filters in standard programs for image processing will led to important improvements in various fields of optical engineering.

System of scale-selective tomography of myocardium birefringence

Alexander G. Ushenko, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

Laser polarimetry enabling to obtain information about optical anisotropy of biological tissues (BT) is an important direction of non-invasive diagnostics of organic phase-heterogeneous layers. For statistic analysis of such polarimetric information a model approach has been worked out based on the following conditions:

• morphological structure of BT is regarded as a two-component amorphous-crystalline one;

• the crystalline component or extracellular matrix is formed by the network of optically uniaxial birefringent protein (collagen, myosin, elastine, etc.) fibrils or biological liguid crystals;

A new approach to description of the BT laser images based on the analysis of coordinate distributions of polarization singularities (linearly (S-points) and circularly (C-points) polarized states; - the fourth parameter of the Stokes vector) became developed the above mentioned statistical.

Three groups of histological sections of the myocardium tissue were used as the objects of investigation:

• biopsy of the myocardium tissue of deaths from cancer (type "A");

• biopsy of the myocardium tissue of deaths from coronary heart disease (type "B");

• biopsy of the myocardium tissue of deaths from acute coronary insufficiency (type "C").

Analytical conditions of forming the singularity elements of Jones matrix of birefringent liquid crystal networks of biological tissues are determined. Correlation between the coordinate locations of characteristic points of 2D elements of Mueller matrix of optically thin layer of myocardium tissue and the network of S- and C-points in its laser image is defined.

Mueller-matrix invariants of optical anisotropy of the bile polycrystalline films in the diagnosis of human liver pathologies

Olexander V. Dubolazov, Vladimir A. Ushenko, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

Biological tissues and liguids represent structurally inhomogeneous optically anisotropic media with absorption. To describe the interaction of polarized light with such sophisticated systems, more general approximation based on Mueller-matrix formalism is required. Nowadays many practical techniques based on measuring and analyzing the Mueller-matrices of the samples under investigation are being used in biological and medical researches. During recent 10-15 years a separate direction – laser polarimetry – has been formed in matrix optics. On its basis the interconnections between the set of statistical moments of the 1st-4th order, correlation, fractal parameters were determined, which characterize the distributions of Mueller matrix elements and the parameters of linear birefringence of fibrillar protein networks of human biological tissues. The diagnostics of pathological changes of skin derma, epithelial and connective tissues of the women's reproductive organs, etc. was realized on this basis.

This research work is focused on determining the potentialities of diagnostics of pathological changes in human liver basing on polarization analysis of Mueller – matrix images of polycrystalline networks of blood plasma albumins and globulins.

1. The model of blood plasma layer considering the mechanisms of optically anisotropic absorption – linear and circular dichroism of protein networks was suggested.

2. Mueller-matrix rotation invariants characterizing polarization manifestations of biological network optical anisotropy are determined.

3. The interconnections between the statistical, correlation and fractal parameters characterizing the Mueller-matrix images of blood plasma layer and the peculiarities of the mechanisms of optically anisotropic absorption biological crystals network were found.

Autofluorescent polarimetry of bile films in the liver pathology differentiation

Olexander V. Dubolazov, Yuriy A. Ushenko, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

Biological tissues represent structurally inhomogeneous optically anisotropic media with absorption. To describe the interaction of polarized light with such sophisticated systems, more general approximation based on Mueller-matrix formalism are required. Nowadays many practical techniques based on measuring and analyzing the Mueller-matrices of the samples under investigation are being used in biological and medical researches. At the same time there practically no data concerning polarization manifestations of fluorescence effects in biological tissues in modern literature. Therefore, the task of complex uniting the diagnostic potentialities of the techniques of laser polarimetry and laser fluorescence proves to be topical.

In this research the model of complex optical anisotropy, possessed by protein networks of the tissues of liver is suggested, and on this ground the

method of Mueller-matrix mapping of laser polarization fluorescence of bile films is developed.

1. The model of laser polarization fluorescence of biological tissues and fluids considering the mechanisms of optically anisotropic absorption – linear and circular dichroism of optical anisotropic networks was suggested.

2. Mueller-matrix rotation invariants characterizing polarization manifestations of laser fluorescence are determined.

3. The interconnections between the statistical, correlation and fractal parameters characterizing the Mueller-matrix images of laser polarization fluorescence and the peculiarities of the mechanisms of optically anisotropic absorption of bile films were found.

Polarization-correlation microscopy of human liquid polycrystalline films in infertility diagnosis

Olexander V. Dubolazov, Artem O. Karachevtsev, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

Among the methods of optical diagnostics of human biological tissues the techniques of laser polarimetry diagnostics of their optical anisotropic structure became widely spread. The main information for these methods is obtained from coordinate distributions of polarization azimuths and ellipticity (polarization maps) with the following correlation (auto- and mutually correlation functions and fractal dimensions analysis). As a result, several techniques of early diagnostics and differentiation of pathological changes in biological tissue (BT) structure with their degenerative, dystrophic and oncological changes were developed.

Besides, there is a widely spread group of optically anisotropic biological objects, for which the techniques of laser polarimetry diagnostics are not efficient enough. Optically thin layers of different biological fluids (bile, urine, liquor, synovial fluid, blood plasma, etc.) belong to such objects.

This research is focused on the analysis of potentiality of diagnostics infertility by means of new technique of polarization correlometry of human blood plasma layers laser images.

1. A new technique of estimating the structure of laser images based on measuring coordinate distributions of mutual polarization degree is suggested that characterizes the homogeneity of optically isotropic and optically anisotropic components in biochemical composition of blood plasma.

2. The statistical (mean, dispersion, asymmetry and excess), correlation (correlation area of distribution of mutual polarization degree values) and fractal (dispersion of extremes of log-log dependencies of power spectra of mutual polarization degree values distribution) criteria of polarization-correlation diagnostics of all groups of blood plasma layers.

Volumetric liquid flow measurement through thermography to simulate blood flow in an artery

Carlos Villaseñor-Mora, Adela Rabell-Montiel, Arturo González-Vega, Gerardo Gutierrez-Juarez, Univ. de Guanajuato (Mexico)

Exist a variety of methods to measure the flow of a liquid through a conduit; however, most of those methods significantly interfere with the flow, which affects the measurement. In medical applications the measurement of blood flow is essential when peripheral artery disease want to diagnose. The use of non-invasive techniques for flow measurement has been developed very little, especially which are based on infrared thermography that has not shown significant improvement. In this work is developed a methodology to measure flow in a conduit, based on thermal images acquired with an infrared camera in the middle infrared range adjusted at ambient characteristics. The experimental setup proposed was studied at external disturbances such as: ambient temperature and humidity, and infrared camera stability in order to find their error contribution during the measurement. To study the sensitivity of the measurement system, it was used a flow control capable of causing small changes in this, allowing to measure flows with a resolution of milliliters per second with the proposed setup. It is analyzed and discussed how the variations in flow due to changes in temperature or vice versa affect the thermal images acquired, which could lead to an incorrect interpretation of the flow velocity. Additionally, it is discussed how the effects of turbulence produced by curved hoses, and the change in the emissivity of the conduit as a function of the temperature can also affect the measurement.

Multifunctional polarization tomography of optical anisotropy biological layers in diagnosis of endometriosis

Olexander V. Dubolazov, Yuriy A. Ushenko, Artem O. Karachevtsev, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

Among the various optic and physical methods of diagnosing the structure and properties of the optical anisotropic component of various biological objects a specific trend has been singled out - multidimensional laser polarimetry of microscopic images of the biological tissues with the following statistic, correlative and fractal analysis of the coordinate distributions of the azimuths and ellipticity of polarization in approximating of linear birefringence polycrystalline protein networks. At the same time, in most cases, experimental obtaining of tissue sample is a traumatic biopsy operation. In addition, the mechanisms of transformation of the state of polarization of laser radiation by means of the optic anisotropic biological structures are more varied (optical dichroism, circular birefringence). Here at, real polycrystalline networks can be formed by different types, both in size and optical properties of biological crystals.

Our research is aimed at developing experimental method of the Fourier polarimetry and a spatial-frequency selection for distributions of the azimuth and the ellipticity polarization of blood plasma laser images with a view of diagnosing prostate cancer.

A method of polarization mapping of the optic-anisotropic polycrystalline networks of the blood plasma albumin and globulin proteins with adjusted spatial-frequency filtering of the coordinate distributions of the azimuth and ellipticity of the polarization of laser radiation in the Fourier plane is proposed and substantiated.

Comparative studies of the effectiveness of direct methods of mapping and a spatial-frequency selection in differentiating polarization azimuth and ellipticity maps of the field of laser radiation converted by the networks of albumin - globulin crystals of the blood plasma in healthy people and patients with prostate cancer have been carried out.

A set of criteria of diagnosing prostate cancer based on the statistical (statistical moments of the 1st - 4th orders), correlation (correlation moments) and fractal (the slope of approximating curves and the dispersion of the distribution of extreme log - log dependences of power spectra) analysis of the spatial - frequency filtered polarization distributions generated by dendritic networks of albumin and globulin and spherolithic networks has been detected and substantiated.

Spectrometry techniques of differential diagnosis of benign and malignant prostate tumor

Sergey B. Yermolenko, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine); Olexander Fedoruk, Dmytro Voloshynskyi, Bukovinian State Medical Univ. (Ukraine)

Medical and social problems of modern urology is the prevalence of various pathologies of the prostate, such as cancer and benign prostatic hyperplasia (BPH). BPH has become one of the most common diseases of the elderly men. In the structure of cancer diceases prostate cancer in a number of some countries takes the 2-3 rd place after stomach cancer, and in the USA and Sweden it takes the 1st place. There are many works devoted to the comparison of histological studies in the evaluation of prostate biopsies and tissue samples after transurethral resection (TUR) of the prostate. We discuss the relevance of different morphological parameters in assessing the prognosis of benign and malignant tumors of the prostate. According to this, an important problem is the standardization of histological studies. Leading role in the objectification diagnosis of the pathological processes of prostate cancer can play spectrometric studies of prostate that can make the conclusion that the development of spectrometry methods may be relevant for solving above mentioned problems.

The aim of this work is to develop spectrometric criteria of differential diagnosis in patients with benign and malignant tumors of the prostate through conducting a comparative evaluation of clinical, laboratory and biophysical studies.

We will present the results of diagnostic possibilities of the spectrometry method in benign and malignant tumors of the prostate; determine the diagnostic value of PSA in the blood; develope spectrometric diagnostic criteria.

Explicit solutions of one-dimensional total variation problem

Artyom Makovetskii, Sergei Voronin, Chelyabinsk State Univ. (Russian Federation); Vitaly Kober, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico)

In this work we consider denosing of a one-dimensional signal corrupted by additive white Gaussian noise. A common way to solve the problem is to utilize the total variation (TV) method. Basically, the TV regularization minimizes a functional that consists of the sum of fidelity and regularization terms. We derive explicit solutions of the one-dimensional TV regularization problem that help us to better understand how the TV regularization restores signals. On the base of the solutions, a non-iterative algorithm for the one-dimensional TV can be obtained. The one-dimensional TV algorithm is extended for denoising of images degraded by additive Gaussian noise. In this case topological and metrical characteristics of the degraded image are used. The topological characteristics of a function of two variables are linear variations. Computer simulation results are provided to illustrate the performance of the proposed algorithm for restoration of noisy images.

Performance evaluation of image deconvolution techniques in space-variant astronomical imaging systems with nonlinearities

Karel Fliegel, Petr Janout, Jan Bednar, Czech Technical Univ. in Prague (Czech Republic); Jan Švihlík, Faculty of Chemical Technology (Czech Republic); Lukáš Krasula, Stanislav Vítek, Petr Páta, Czech Technical Univ. in Prague (Czech Republic)

There are various deconvolution methods for suppression of blur in images. In this paper a survey of image deconvolution techniques is presented with focus on methods designed to handle images acquired with wide-field astronomical imaging systems. Image blur present in such images is space-variant especially due to space-variant nature of the lens. In special cases, an imaging system contains non-linear electro-optical elements. Analysis of non-linear and space-variant imaging systems is usually simplified so that the system is considered as LSI (Linear and Space-Invariant) under specific constraints. Performance analysis of selected image deconvolution methods is presented in this paper, while considering space-variant nature of wide-field astronomical imaging system. Impact of nonlinearity on the overall performance of image deconvolution technique is also analyzed. Artificially generated test images and images obtained from the real astronomical imaging system are used for the performance analysis. The real astronomical imaging system, used as a source of test image data, contains space-variant wide-field input lens and non-linear image intensifier.

Implementation of cost-effective diffuse light source mechanism to reduce specular reflection and halo effects for resistor-image processing

Yung-Sheng Chen, Jeng-Yau Wang, Yuan Ze Univ. (Taiwan)

Light source plays a significant role to acquire a qualified image from objects for facilitating the image processing and pattern recognition. For objects possessing specular surface, the phenomena of reflection and halo appear in the acquired image will increase the difficulty of information processing. Such a situation may be improved by the assistance of valuable diffuse light source. Consider reading resistor via computer vision, due to the resistor's specular reflective surface it will face with a severe non-uniform luminous intensity on image yielding a higher error rate in recognition without a well-controlled light source. A measurement system including mainly a digital microscope embedded in a replaceable diffuse cover, a ring-type LED embedded onto a small pad carrying a resistor for evaluation, and an Arduino microcontroller connected with PC, is presented in this paper. Several replaceable cost-effective diffuse covers made by paper bowl, cup and box inside pasted with white paper are presented for reducing specular reflection and halo effects and compared with a commercial diffuse some. The ring-type LED can be flexibly configured to be a full or partial lighting based on the application. For each self-made diffuse cover, a set of resistors with 4 or 5 color bands are captured via digital microscope for experiments. The signal-to-noise ratio from the thresholded resistor-image is used for performance evaluation. The detected principal axis of resistor body is used for the partial LED configuration to further improve the lighting condition. Experimental results confirm that the proposed mechanism can not only evaluate the cost-effective diffuse light source but also be extended as an automatic recognition system for resistor reading.

A fusion algorithm for building three-dimensional maps

Aleksandr Vokhmintcev, Artyom Makovetskii, Chelyabinsk State Univ. (Russian Federation); Vitaly Kober, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico); Ilya Sochenkov, Russian Academy of Sciences (Russian Federation); Vladislav Kuznetsov, Rambler (Russian Federation)

Dense three-dimensional maps of indoor environments have various applications in navigation, manipulation and semantic mapping. In this work we use a Kinect camera that captures RGB images along with per-pixel depth information for building dense three-dimensional maps of indoor environments. Commonly three-dimensional mapping systems contain three components, that is, first, the spatial alignment of consecutive data frames; second, the detection of loop closures; and third, the globally consistent alignment of the complete data sequence. It is known that three-dimensional point clouds are well suited for frame-to-frame alignment and for dense three-dimensional reconstruction; however, they ignore valuable information contained in images. Color cameras capture visual information and are very suitable for loop closure detection. A novel fusion

algorithm combining visual features and depth information for view-based loop closure detection followed by pose optimization to achieve globally consistent maps is proposed. The performance of the proposed system is tested in real indoor environments and discussed.

Mueller imaging of white blood cells

Shirsendu Sarkar, Ajay Ghosh, Univ. of Calcutta (India)

Mueller imaging of white blood cells for medical purposes is presented here. Based on the input and output Stokes vectors of the interaction of polarized light with elements which can change its state of polarization, Mueller matrix is the transfer function of optical system such as linear media described by 4x4 real matrix. Development of optical techniques using polarized light has received considerable recent attention because the polarization properties of photons contain morphological and functional information of potential bio-medical importance and additional diagnostic information on linear media which cannot be achieved from polarization blind measurements. Defected white blood cells contain the morphological information with optically active birefringent property. The 36 different intensity states obtained from experimental results are used for the construction of the Mueller matrix in each pixel. The elements of that matrix corresponding to that pixel of the final image will show functional as well as diagnostic information which has medical importance. It is interesting to note that using this imaging technique, white blood cells are also detected and blood cell size is also determined.

Dermoscopy analysis of RGB-images based on comparative features

Oleg O. Myakinin, Valery P. Zakharov, Ivan A. Bratchenko, Dmitry N. Artemyev, Samara State Aerospace Univ. (Russian Federation); Evgeny Y. Neretin, Sergey V. Kozlov, Samara State Medical Univ. (Russian Federation)

In this paper, we propose an algorithm for color and texture analysis for dermoscopic images of human skin based on Haar wavelets, Local Binary Patterns (LBP) and Histogram Analysis. This approach is a modification of «7-point checklist» clinical method. Thus, that is an “absolute” diagnostic method because one is using only features extracted from tumor’s ROI (Region of Interest), which can be selected manually and/or using a special algorithm. We propose additional features extracted from the same image for comparative analysis of tumor and healthy skin. We used Euclidean distance, Cosine similarity, and Tanimoto coefficient as comparison metrics between color and texture features extracted from tumor’s and healthy skin’s ROI separately. A classifier for separating melanoma images from other tumors has been built by SVM (Support Vector Machine) algorithm. Classification’s errors with and without comparative features between skin and tumor have been analyzed. Significant increase of recognition quality with comparative features has been demonstrated. Moreover, we analyzed two modes (manual and automatic) for ROI selecting on tumor and healthy skin areas. We have reached 91% of sensitivity using comparative features in contrast with 77% of sensitivity using the only “absolute” method. The specificity was the invariable (94%) in both cases.

Meteor localization via statistical analysis of spatially: temporal fluctuations in image sequences

Jaromír Kukal, Institute of Chemical Technology (Czech Republic); Martin Klimt, Czech Technical Univ. in Prague (Czech Republic); Jan Švihlík, Institute of Chemical Technology (Czech Republic); Karel Fliegel, Czech Technical Univ. in Prague (Czech Republic)

Meteor detection is one of the most important procedure in astronomical imaging. Meteor path in Earth’s atmosphere is traditionally reconstructed from double station video observation system generating 2D image sequences.

However, the atmospheric turbulences and other factors cause spatially - temporal fluctuations of image background, which makes the localization of meteor path more difficult. Our approach is based on non-linear preprocessing of image intensity using Box-Cox and logarithmic transform as its particular case. The transformed image sequences are then differentiated along discrete coordinates to obtain statistical description of sky background fluctuations, which can be modeled by multivariate normal distribution. After verification and hypothesis testing, we use the statistical model for outlier detection. Meanwhile the isolated outlier points are ignored, the compact cluster of outliers indicates the presence of meteoroids after ignition.

Virtual spectral multiplexing for applications in in-situ imaging microscopy of transient phenomena

Farnoud Kazemzadeh, Mohammad Javad Shafiee, Jason Deglint, Edward Li, Iman Khodadad, Simarjeet S. Saini, Alexander Wong, David A. Clausi, Univ. of Waterloo (Canada)

Multispectral sensing is specifically designed to provide quantitative spectral information about various materials or scenes. Using spectral informatio, various properties of objects can be measured and analysed. Microscopy, or observing and imaging objects at the micron- or nano-scale is one application where multispectral sensing can help tremendously, as there are many fields of science and research that use microscopy that would benefit from observing a specimen in multiple wavelengths. Multispectral microscopy is available but often requires the operator of the device to switch filters which is a labor intensive process. Furthermore, the need for filter switching makes such systems particularly limiting in cases where the sample contains live species that are constantly moving or exhibit transient phenomena. Direct methods for capturing multispectral data simultaneously of a live sample can also be challenging for microscopy applications as it requires elaborate optical systems design using beamsplitters and a number of detectors, proportional to the number of bands sought after. Such devices can therefore be quite costly to build and difficult to maintain, particularly for microscopy. Here, we present the concept of virtual spectral multiplexing imaging (VSMI) microscopy for low-cost, in-situ multispectral microscopy of transient phenomena. In VSMI microscopy, the spectral response of a color detector in the microscope is characterized and virtual spectral multiplexing is performed on the simultaneously-acquired detector measurements based on the developed spectral characterization model to produce microscopic imagery at multiple wavelengths. The proposed VSMI microscope was used to observe nano-reflectors at various wavelengths simultaneously to illustrate its efficacy.

Additive discrete 1D linear canonical transform

Liang T. Zhao, John J. Healy, John T. Sheridan, Univ. College Dublin (Ireland)

The continuous linear canonical transforms (LCT) can describe a wide variety of wave field propagations through paraxial first order optical systems. Digital algorithms to numerically calculate the LCT are therefore important in modelling scalar wave field propagations and are also of interest for many digital signal processing applications. The continuous

LCTs are additive, but discretization can remove this property. In this paper we discuss several special cases of the LCT for which constraints can be identified to ensure the DLCTs are additive.

Color normalization for robust evaluation of microscopy images

Jan Švihlík, Jan Kybic, Czech Technical Univ. in Prague (Czech Republic); David Habart, Institute for Clinical and Experimental Medicine (Czech Republic)

This paper deals with color normalization of microscopy images of Langerhans islets to increase robustness of the islet segmentation to illumination changes. The main application is automatic quantitative evaluation of the islet parameters, useful for determining the feasibility of islet transplantation in diabetes. The microscopy image intended for color normalization is firstly normalized due to nonuniform profile of illumination. It means that we have to find background profile for all color channels. We found that image background could be fitted by second order polynomial. Hence, the islets must be approximately identified by preliminary mask created as a preliminary segmentation of image. The mask areas where the islets were identified are interpolated to obtain smooth background surface.

Color normalization were done in logarithmic RGB and l-alpha-beta color spaces. We consider color normalization for two classes (islet and background). The method normalizes colors of two classes in source image according to colors of corresponding classes in reference images. To identify classes we used mask created by k-means algorithm. The classifier based on logistic regression was trained using 46 images and corresponding fully manual segmentation (ground truth).

There are 141 clinical images (Z set) in our database taken under different light conditions. Approximately 17% images from this database cannot be segmented satisfactorily using trained classifier. Hence, we apply color normalization to selected clinical images, where the fully manual segmentations were created. ROC curve computed for images normalized in color showed considerable improvement of segmentation results.

Inference of dense spectral reflectance images from sparse reflectance measurement using non-linear regression modeling

Jason Deglint, Farnoud Kazemzadeh, Alexander Wong, David A. Clausi, Univ. of Waterloo (Canada)

One method to acquire multispectral images is to sequentially capture a series of images where each image contains information from a different bandwidth of light. Another method is to use a series of beamsplitters and dichroic filters to guide different bandwidths of light onto different cameras. However, these methods are very time consuming and expensive and perform poorly in dynamic scenes or when observing transient phenomena. An alternative strategy to capturing multispectral data is to infer this data using sparse spectral reflectance measurements captured using an imaging device with overlapping bandpass filters, such as a consumer digital camera using a Bayer filter pattern. Currently the only method of inferring dense reflectance spectra is the Wiener adaptive filter, which makes Gaussian assumptions about the data. However, these assumptions may not always hold true for all data. We propose a new technique to infer dense reflectance spectra from sparse spectral measurements through the use of a non-linear regression model. The non-linear regression model used in this technique is the random forest model, which is an ensemble of decision trees and trained via the spectral characterization of the optical imaging system and spectral data pair generation. This model is then evaluated by spectrally characterizing different patches on the Macbeth color chart, as well as by reconstructing virtual multispectral images. Results show that the proposed technique can produce inferred dense reflectance spectra that correlate well with the true dense reflectance spectra, which illustrates the merits of the technique.

A digital architecture for striping noise compensation in push-broom hyperspectral cameras

Wladimir Valenzuela, Miguel Figueroa, Jorge E. Pezoa Nunez, Univ. de Concepción (Chile)

We present a striping noise compensation architecture for hyperspectral push-broom cameras, implemented on a Field-Programmable Gate Array (FPGA). The circuit is fast, compact, low power, and is capable of eliminating the striping noise in-line during the image acquisition process

The architecture implements a multidimensional neural-network algorithm for striping noise compensation previously reported by our group. The algorithm relies on the assumption that the amount of light impinging at the neighboring photo-detectors is approximately the same in the spatial and spectral dimensions. Under this assumption, two striping noise parameters are estimated using spatial and spectral information from the raw data.

We implemented the circuit on a Xilinx ZYNQ XC7Z2010 FPGA and tested it with images obtained from a NIR N17E push-broom camera, with a frame rate of 25fps and a band-pixel rate of 1.888 MHz. The setup consists of a loop of 320 samples of 320 spatial lines and 236 spectral bands between 900 and 1700 nanometers, in laboratory condition, captured with a rigid push-broom controller. The computation core can run at 100 MHZ and consumes less than 25mW of dynamic power, using less than 10% of the logic resources available on the chip. It also uses one of two ARM processors available on the FPGA for data acquisition and communication purposes.

Blind identification of linear degradation operators in the Fourier domain

Victor N. Karnaukhov, Vitaly Kober, Institute for Information Transmission Problems (Russian Federation)

Digital images are often affected by environmental and technical interferences such as linear homogeneous distortion, nonuniform illumination, sensors' noise, geometrical scene distortion, etc. Among these issues, the former is particularly interesting because various physical problems can be modeled by such degradations. In this work we propose a blind algorithm for identification of the linear distortion operator based on the analysis of zero-crossings and phase distribution of the distorted image spectrum. The proposed blind identification algorithm is tested with common real linear distortion operators and its identification rate is discussed.

Support plane method applied to ground objects recognition using modelled SAR images

Denis A. Zherdev, Vladimir A. Fursov, Samara State Aerospace Univ. (Russian Federation) and Image Processing Systems Institute (Russian Federation)

The solution of electromagnetic scattering radiation problem is very important and has a wide application in practice, e.g. in navigation systems, in problem of target type determining. We can interpret radar system measuring in different manner such as making 1D radar cross section diagram or making 2D synthetic aperture radar (SAR) image. In this investigation we are concentrate our discuss on a target recognition

using modelled SAR images. We are using the same FDTD method for electromagnetic scattering modelling which is presented at work [1]. In our work, we are modelling airborne SAR image scenario of ground objects electromagnetic field scattering. The modelling approach is very useful in a target recognition problem, when we do not exactly known about the electromagnetic properties of the underlying surface. In this study, we are show recognition quality of support plane method [2] and discuss the results.

A custom hardware classifier for bruised apple detection in hyperspectral images

Javier Cárdenas, Miguel Figueroa, Jorge E. Pezoa Nunez, Univ. de Concepción (Chile)

We present a custom digital architecture for bruised apple classification using hyperspectral images in the near infrared (NIR) spectrum. The algorithm classifies each pixel in an image into one of three classes: bruised, non bruised, and background. We extract two 5-element feature vectors for each pixel using only 10 out of the 236 spectral bands provided by the hyperspectral camera, which greatly reduces the requirements of the imager and the computational complexity of the algorithm. We then use two linear-kernel support vector machines (SVMs) to classify each pixel. Each SVM was trained with 504 17x17-pixel windows taken from 14 hyperspectral images of 320x320 pixels each, for each class. The architecture then computes the percentage of bruised pixels in each apple in order to adequately classify the fruit.

We implemented the architecture on a Xilinx ZYNQ XC7Z210 Field-Programmable Gate Array (FPGA) and tested it on images from a NIR N17E push-broom camera with a frame rate of 25fps, a band-pixel rate of 1.888 MHz, and 236 spectral bands between 900 and 1700 nanometers in laboratory conditions. Using 12-bit fixed-point arithmetic, the circuit accurately discriminates 95.2% of the pixels corresponding to an apple, 81% of the pixels corresponding to a bruised apple, and 93.4% of the background. With the default threshold settings, the highest false-positive for a bruised apple is 18.7%. The circuit operates at the native frame rate of the camera, consumes 88mW of dynamic power, and uses less than 20% of the logic resources on the FPGA.

GPU accelerated processing of astronomical high frame-rate videosequences

Stanislav Vítek, Czech Technical Univ. in Prague (Czech Republic); Jan Švihlík, Faculty of Chemical Technology (Czech Republic); Lukáš Krasula, Karel Fliegel, Petr Páta, Czech Technical Univ. in Prague (Czech Republic)

This work deals with GPU accelerated processing of high frame-rate astronomical video-sequences, mostly originating from experiment MAIA. MAIA (Meteor Automatic Imager and Analyser) is an double station system primarily focused to observing of faint meteoric events with a high time resolution. Using the double station data of the meteor we can calculate its atmospheric trajectory and the heliocentric orbit. The meteor light curve provides us with information about the mass of the original particle. Both the shape of this curves as well as the height interval where the meteor radiates correspond to the structure of the parent meteoroid.The instrument with price bellow 2000 euro consists of image intensifier (typical gain is about 30000 to 60000 lm/lm) and gigabite ethernet camera with resolution 767x576 pixels running at 61 fps. The biggest bottleneck of the device is built-in automatic gain control of the image intensifier - gain is rapidly decreasing if any bright stellar object appears in the field of view. With resolution better than VGA the system produces up to 2TB of possible scientifically valuable video data on both stations. Main goal of the paper is to propose and evaluate parallel GPU algorithms able to classify huge amount of video-sequences in order to delete all uninteresting data – there is limited storage capacity on the station. Paper shows that it is possible to reduce algorithms' complexity and process the data in almost real-time.

Pattern recognition descriptor using the Z-Fisher transform

Carolina Barajas-Garcia, Selene Solorza-Calderón, Univ. Autónoma de Baja California (Mexico); Josué Álvarez-Borrego, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico)

In this work a pattern recognition digital image descriptor invariant to rotation, scale and translation (RST), which classify images using the Z-Fisher transform is presented. The descriptor uses binary rings masks obtained from the Fourier transform (called Fourier masks) to build 1D signatures. In this manner the computational cost time is reduced because the relevant data is contained in a vector (the 1D signature) instead of a matrix (an image). The 1D signature is invariant to rotation, scale and translation. The descriptor uses the amplitude spectrum of the Fourier transform, which is translation invariance. The amplitude spectrum of the normalized analytic Fourier-Mellin transform (AFM) is utilized in the scale invariance. The rings masks filter this normalized AFM amplitude spectrum to achieve the rotation invariance. The comparisons of the signatures were calculated using the normalized linear correlation, that is, the Pearson correlation coefficient (PCC). If the PCC value of a problem image is similar to the PCC value of the target image, then the problem image is the same as the target otherwise they are different. In general, those PCC values do not satisfy a normal distribution, hence the Fisher's Z distribution is employed to determine the confidence level of the RST invariant descriptor. A Matlab program was develop to classify gray-scale digital images of fossil diatoms. Those images were selected due to the similarity in their morphology. The descriptor presents a confidence level of 95%; moreover it works when the images have some noise or non-homogeneous illumination.

Fourier based detection of microcalcifications in mammograms

Elizabeth López Meléndez, Luis David Lara-Rodríguez, Gonzalo Urcid, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico)

This paper presents a Fourier transform approach to detect microcalcifications in digital mammograms. The basic idea consists in the design of parametric Butterworth bandpass filters in the Fourier domain used to extract sharpened border like structures that correspond to detected mammographic microcalcifications. Image thresholding of the filtered image is accomplished, first by homogenizing the background (fibroglandular tissue) with a median filter, after which a gamma correction is applied to change the global contrast. Second, by postprocessing the resulting image using histogram based local and global criteria we obtain a properly binarized image that signals the desired objects (microcalcifications) and final segmentation is achieved using a sequence of morphological binary operations. Several illustrative examples taken from a clinical database are included to demonstrate the capability of the proposed approach in comparison with other edge detection techniques such as the difference of Gaussians (DOG) and the Laplacian of a Gaussian (LOG).

A dendritic lattice neural network for color image segmentation

Gonzalo Urcid, Luis David Lara-Rodríguez, Elizabeth López Meléndez, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico)

A two-layer dendritic lattice neural network is proposed to segment color images in RGB space. The two layer neural network is a fully interconnected feedforward net consisting of an input layer that recieves color pixel values, an intermediate layer that computes pixel interdistances, and an output layer used to classify colors by hetero-association. The two-layer net is first initialized with a finite small subset of the colors present in the input image. These colors are obtained by means of an automatic clustering procedure such as k-means, fuzzy c-means, or as derived from the column vectors and main diagonals of the dual lattice min and max auto-associative memories. In the second stage the color image is scanned on a pixel by pixel basis where each picture element is treated as a vector and feeded into the network. For illustration purposes we use public domain color images to show the performance of our proposed image segmentation technique.

True-color image encoding technique for segmented RF transmission using limited bandwidth

Yuriy Kotsarenko, Gustavo Urquiza, Svetlana V. Koshevaya, Univ. Autónoma del Estado de Morelos (Mexico)

In this work a new technique for encoding true-color image data is described, where individual segments of color pixels provided in one of perceptually accurate color spaces are encoded into digital bits suitable for RF transmission over long distances such as volcano monitoring or high-altitude photography. The data in its simplest form can be taken linearly or by using certain patterns such as Hilbert curve to improve overall image recovery in case of data loss or corruption. Color information is encoded into bits by allocating higher bandwidth to overall brightness while still providing limited amount of color information sufficient to reconstruct the image with decent visual quality after transmission. Experimental results are provided, where different high-quality images are processed using the described technique, including noise and data loss simulation, comparing and analyzing the resulting images with their original counterparts. Performance benchmarks are also provided running on a variety of embedded and desktop hardware compared with other classical encoding techniques such as JPEG and YUYV. The resulting experiments show that the proposed technique provides reasonable balance between image quality, bandwidth usage and real-time performance, while also being tolerant to data loss and corruption during transmission.

Analysis of the palm vein distribution for people recognition

Raúl Castro-Ortega, Carina Toxqui-Quitl, Univ. Politécnica de Tulancingo (Mexico); Gabriel Cristóbal Perez, Instituto de Óptica “Daza de Valdés” (Spain) and Consejo Superior de Investigaciones Científicas (Spain); José Victor Marcos-Martín, Instituto de Óptica “Daza de Valdés” (Spain); Alfonso Padilla-Vivanco, Univ. Politécnica de Tulancingo (Mexico)

The shape of the hand vascular pattern contains useful and unique features that can be used for identifying and authenticating people, with applications in access control, medicine and financial services. In this work, an optical system for the image acquisition of the hand vascular pattern is implemented. It consists of a CCD camera with sensitivity in the IR and a light source with emission in the 880 nm. The IR radiation interacts with the desoxyhemoglobin, hemoglobin and water present in the blood of the veins, making possible to see the vein pattern underneath skin. The segmentation of the Region Of Interest (ROI) is achieved using geometrical moments locating the centroid of each image. To enhancement the image of the vein pattern, a preprocessing step is given by spatial filtering that remove unnecessary information such as body hair and skinfolds. After that, a method of adaptive thresholding and mathematical morphology operations are used in order to get a binary image. A feature extraction method based on subsampled binary image is proposed. The classification task is achieved using K-Nearest Neighbors (KNN) and Artificial Neural Networks (ANN). Experimental results using the PolyU Multispectral Palmprint database show a percentage of correct classification, higher of 97% with KNN and ANN for 2,400 images of 200 people with 12 versions each one.

Correlation peak analysis applied to a sequence of images using two different filters

Veronica Patron, Univ. de Sonora (Mexico); Josué Álvarez-Borrego, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico); Ángel Coronel Beltrán, Univ. de Sonora (Mexico)

Eye tracking has many useful applications that range from biometrics to face recognition and human-computer interaction. The analysis of the characteristics of the eyes has become one of the methods to accomplish the location of the eyes and the tracking of the point of gaze. Characteristics such as the contrast between the iris and the sclera, the shape, and distribution of colors and dark/light zones in the area, are the starting point for these analyses. In this work, we will focus on the contrast between the iris and the sclera, performing a correlation in the frequency domain. The images are acquired with an ordinary camera, with the aid of thirty volunteers. The reference image is an image of the subjects looking to a point in front of them at 0° angle. Then sequences of images are taken with the subject looking at different angles. These images are processed in MATLAB, obtaining the correlation peak maximum for each image, using two different filters. Each filter is analyzed and then we selected the filter that gives us the best performance in terms of the utility of the data, which is displayed in graphs that shows us the decay of the correlation peak as the eye moves progressively at different angle. This data will be used to obtain a mathematical model or function that establishes a relationship between the angle of vision and the correlation peak. This model will be tested using different input images than the ones used to create the initial database, being able to predict angle of vision using the correlation peak maximum data.

Robust template matching using run-length encoding

Hunsue Lee, Sungho Suh, Hansang Cho, SAMSUNG Electro-Mechanics (Korea, Republic of)

In this paper, we introduce a template matching algorithm using Run-length Encoding (RLE). In manufacturing process, visual inspection is essential to prevent customers from receiving defective products. Since template matching is the fundamental step for visual inspection, the procedure should be not only fast but also accurate. Conventionally, our template matching approach was based on the convolution which is fast, relatively accurate, and easy to apply on greyscale images. However, due to variations in real products, cases where template images are mismatched or not found in captured images can occur.

As a description for the problem, we assumed as follows: 1) Only one

template image exists in the region of interest (ROI), 2) There are differences between the template image and the captured image in size, shape, and other features due to the factors such as manufacturing processes.

The matching procedures are as follows. First, the template image is blurred by a 5x5 box filter. Second, two sets of accumulated data, both foreground and background of the blurred image, are generated. Third, make RLE data from these data. Finally, find each offset that minimizes the cost function.

We verified the performance of the proposed algorithm by comparing it with the pattern matching function provided by Matrox Imaging Library (MIL). As a result, the processing duration was almost the same. However, the proposed algorithm was able to find several templates in the images whereas MIL was not. Consequently, our proposed algorithm was verified more promising results than the conventional template matching method for visual inspection.

Discrete Wigner distribution function of a circular aperture displaced of the origin of space coordinates using coherent light

Sergio Mejia-Romero, Luis Raúl Berriel-Valdos, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico)

In this work we have applied the experimental Discrete Wigner Distribution Function (DWD) to a circular aperture in order to know the behavior of the Quasi-Point Sources (QPS) placed outside of the origin over the object space. In the experimental setup we placed the circle aperture with radius a in the object space. This aperture is coherently illuminated. Then the optical system form the DWD resultant in the focal image plane which is detected by the CCD sensor. The aperture is displaced over the object space and the DWD is observed in real-time for each point of object space. When the DWD has been captured with the CCD sensor we digitally verified the positivity criterion, thus we can assess if the object is a QPS for the optical system used in the experimental setup. For the computational simulation we use the numerical aperture (NA) of the optical system. From NA obtained, we evaluate the Airy disc. This information allows us to calculate the maximum radius of the circular aperture that still supports this aperture act as QPS. Finally, we compared both theoretical and experimental results thus discard systematic errors in the experiment.

This analysis of the experimental results allows us to conclude that if a circular aperture is a QPS in the origin then the same circular aperture can be a QPS in any point of the object space. Otherwise, if it is proved that the circular aperture in the origin is not a QPS then neither will be in any other point of the object space.

Reconstruction of digital holograms from three intensity measurements

Liang T. Zhao, Univ. College Dublin (Ireland); Yang Wu, Damien P. Kelly, Technische Univ. Ilmenau (Germany); John T. Sheridan, Univ. College Dublin (Ireland)

In this paper, we develop a new practical technique based on digital holography for the reconstruction of a wave front from three intensity recordings. Combining the off-axis Fourier filtering technique with boundary detection and iterative phase retrieval algorithm, it is shown how problems such as elimination of the twin image can be achieved. Our proposed method overcomes the issues of feasibility and accuracy associated with off-axis Fourier filtering, cost and alignment associated with Phase shifting interferometry, and also the issues associated with working with diffuser objects. In order to further test the performance of our proposed method, simulation results for both non-diffuser and diffuser objects are presented.

Non-destructively reading out information embedded inside real objects by using far-infrared light

Ayumi Okada, Masahiro Suzuki, Hideyuki Torii, Kazutake Uehira, Kanagawa Institute of Technology (Japan); Youichi Takashima, Nippon Telegraph and Telephone Corp. (Japan)

This paper presents a technique that can non-destructively read out information embedded inside real objects by using far-infrared light. We proposed a technique that could protect the copyrights of digital content for homemade products using digital fabrication technologies such as those in 3D printers. It embeds information on copyrights inside real objects produced by 3D printers by forming fine structures inside the objects as a watermark that cannot be observed from the outside. Fine structure is formed near the surface inside the real object during its fabrication. Information embedded inside the real object is required to be read out non-destructively. We used a technique that can non-destructively read out information from inside real objects by using far-infrared light. We conducted experiments where we structured fine cavities inside the objects. The disposition of the fine domain expressed information. We used the flat and curved surface of the object. The results obtained from the experiments demonstrated that the disposition pattern of fine structure was appeared on the surface of the object as temperature profile when irradiating far-infrared light on the surface of the object. Embedded information could be read out successfully by analyzing temperature profile image of the surface of the object that is captured with thermography. These results demonstrated the feasibility of the technique we propose.

9599-106, Session PWed

Information embedding in real object image using temporally brightness-modulated light

Piyarat Silapasuphakornwong, Hiroshi Unno, Kazutake Uehira, Kanagawa Institute of Technology (Japan)

We propose a new technology that can embed information invisibly into the image of the object in a real space that is captured with video camera. This technique uses illumination that invisibly contains some information. As the illumination for the object contains information, the image of the object taken by the video camera also contains information although it cannot be seen. This information can be extracted by image processing. It uses temporally luminance modulated pattern as invisible information. Amplitude of the modulation is too small to perceive. Frequency of modulation is the same as the frame frequency of the projector that is used as a lighting device. Frame images over some period are added up after changing the sign of the even- or odd-numbered frames. Brightness changes by modulation in each frame are accumulated over the frames used in addition. On the other hand, the object and background image is removed because the even and odd frame are opposite in a sign. AS a result, the patterns become visible. We conducted experiment and the results from these revealed that invisible patterns could be read out extremely accurately. Moreover, we evaluated invisibility of the embedded pattern and confirmed that there existed conditions where both invisibility and readability of the patterns were satisfied at the same time. This paper also describes some application of this technique such as invisible QR code that is on the real object.

Tutte polynomial applied to processing of functional magnetic resonance images

Marlly Garcia-Castillon, Univ. EAFIT (Colombia)

Methods of graph theory are applied to the processing of functional magnetic resonance images. Specifically the Tutte polynomial is used to analyze such kind of images. Functional Magnetic Resonance Imaging provide us connectivity networks in the brain which are represented by graphs and the Tutte polynomial will be applied. The problem of computing the Tutte polynomial for a given graph is #P-hard even for planar graphs. For a practical application the maple packages "GraphTheory" and "SpecialGraphs" will be used. We will consider certain diagram which is depicting functional connectivity, specifically between frontal and posterior areas, in autism during an inferential text comprehension task. The Tutte polynomial for the resulting neural networks will be computed and some numerical invariants for such network will be obtained. Our results show that the Tutte polynomial is a powerful tool to analyze and characterize the networks obtained from functional magnetic resonance imaging.

Detecting curvatures in digital images using filters derived from differential geometry

Juanita Toro-Giraldo, Univ. EAFIT (Colombia)

Detection of curvature in digital images is an important theoretical and practical problem in image processing. Many important features in an image are associated with curvature and the detection of such features is reduced to detection and characterization of curvatures. Differential geometry studies many kinds of curvature operators and from these curvature operators is possible to derive powerful filters for image processing which are able to detect curvature in digital images and videos. The curvature operators are formulated in terms of partial differential operators which can be applied to images via convolution with gaussian kernels. We present an algorithm for detection of curvature in digital images which is implemented using the Maple package ImageTools. Some experiments were performed and the results wee very good. We compare the results using gaussian derivatives with the results obtained using Airy derivatives. It is claimed that the resulting curvature detectors could be incorporated in standard programs for image processing.

An image registration technique based on BWB mask

Ihtsham U. Haq, Pakistan Council of Scientific & Industrial Research (Pakistan) and Pakistan Institute of Engineering and Applied Sciences (Pakistan); Asloob A. Mudassar, Pakistan Institute of Engineering and Applied Sciences (Pakistan)

Image registration has now become a pre-processing stage in many of the image processing tasks such as geometric super-resolution, image reconstruction, ... etc – having applications in the field of medical imaging, machine vision, industrial inspection, metrology, motion detection,...etc.

In this paper, we are presenting a registration technique for indoor targets – whose digital images are collected from a digital imager under jittering or motion. For this a Black-White-Black (BWB) mask is pasted over a region of less or no interest on the target. This BWB mask is made by pasting a white sticker concentric over a wider black sticker – having nearly same width of these three regions. Minimum mask widths required for this are described in paper.

The masked object/target is then imaged through a jittering/moving camera and many images are recorded. For registering these images, the subpixally equivalent digital images are first discarded. The rest of the unique images are then detected for BWB mark in them. The relative contrast in x and y direction within the BWB images of the selected images are then sorted in ascending or descending order. The images are then ordered corresponding to these sorted contrasts. This yields us a subpixally-ordered registered set of images. Simulation results are presented.

This technique can be applied to indoor and remote targets as well – which have inherent relatively-immovable high contrast marks/objects in it – assuming any of them as equivalent BWB mask. On this assumption, the applications of this technique can be extended to remote targets also – such as defense, astronomy, image mosaicing, space imaging, mobile imaging.

Face recognition using the most representative sift images

Issam J. Dagher, Univ. of Balamand (Lebanon)

In this paper, face recognition using the most representative SIFT images is presented. It is based on obtaining the SIFT (SCALE INVARIANT FEATURE TRANSFORM) features in different regions of each training image. Those regions were obtained using the K-means clustering algorithm applied on the key-points obtained from the SIFT algorithm. Based on these features, an algorithm which will get the most representative images of each face is presented. In the test phase, an unknown face image is recognized according to those representative images. This algorithm is compared to other algorithms for different databases.

Improvements for hot pixels in digital imagers using lossless approximation techniques

Ofer Hadar, Ariel Shleifer, Ben-Gurion Univ. of the Negev (Israel)

During the last twenty years, digital imagers have spread into industrial and everyday devices such as satellites, security cameras, cell phones, laptops and more. "hot pixels" are the main defects in remote digital cameras. Previous studies led by Prof. Israel Koren, have shown that these defects are permanent, their number increases continuously over the sensor's lifetime, and they eventually manifest themselves in all captured images and reduce significantly the image quality.

We will show improvements in the prediction of the pixel using lossless compression techniques.

We shall use the study of Prof. Koren as our basis.

These defects pose a serious problem for applications that demand high image quality. The defect rate was shown to increase dramatically as the pixel size falls from 2 microns. Prof. Koren's group developed a Bayesian technique for detecting and tracing defects based on a series of images taken by the imager.

A linear correction technique presented is able to correct a large percentage of the hot pixels up to the level of the noise floor using exposure time, illumination and an average of the neighboring pixels.

We shall use known prediction methods on top of the algorithm, namely the CALIC algorithm, which shows the greatest accuracy in the prediction of the pixel. Still, all of the lossless algorithms assume input of pixels in the way of a raster scan but we can use the entire information from the image except for one hot pixel. Thus we intend to re-engineer the lossless algorithm to use all the surrounding pixels.

An overview of new video coding tools under consideration for VP10: the successor to VP9

Debargha Mukherjee, Google (United States)

Google has recently embarked on an ambitious open-source project to develop a next generation royalty-free video codec VP10 that achieves at

least 30-40% bit-rate reduction over the current generation codec VP9. While the project is still in early stages, a set of new coding tools has been added to baseline VP9 to achieve at least about 6% coding gain already over a large enough test set. This talk will provide an in-depth technical overview of these coding tools, along with information on how other parties can be involved in this project.

Cyber attack/defense algorithms based on data hiding in compressed video stream

Ofer Hadar, Y. Amsalem, Ben-Gurion Univ. of the Negev (Israel)

This research presents several algorithms to generate a fast, robust, sophisticated and hard to detect cyber attack/defense over trusted video streams.

More specifically, we focus on H.264 coded video over MPEG2 Transport Stream (ISO/IEC standard 13818-1 or ITU-T Rec. H.222.0), which is the most common protocol for video streaming now days.

Those video streams are very attractive access points (for attackers) into organizations internal secured network, and they highly compromise the network security.

Main research outcomes:

• Defense tool - which proactively defends against incoming cyber-attacks. This tool is based on causing random location damage to the original Image/Video, such that the probability of damaging the embedded malicious code will be high enough to destroy its capabilities in one hand, on the other hand causing only unnoticeable degradation of the image or video quality.

The tool will be located next to the network gateway.

• Attack tool - which embeds malicious shell code into the video payload (establishing a covert channel), injects malicious malware into a highly sensitive network, extracts the hacker shell code from the video payload on the victim servers and executing it.

Those tools are based on data hiding algorithms that was developed exclusively for purposes of attacking/defending the information system through compressed video streams.

Overview of MPEG internet video coding

Ronggang Wang, Sang-hyo Park, Peking Univ. (China); Jae-Gon Kim, Korea Aerospace Univ. (Korea, Republic of); Tie-jun Huang, Peking Univ. (China); Euee S. Jang, Hanyang Univ. (Korea, Republic of); Wen Gao, Peking Univ. (China)

MPEG has produced standards that have provided the industry with the best video compression technologies. In order to address the diversified needs of the Internet, MPEG issued the Call for Proposals (CfP) for internet video coding in July, 2011 and April, 2013. It is anticipated that any patent declaration associated with the Baseline Profile of this standard will indicate that the patent owner is prepared to grant a free of charge license to an unrestricted number of applicants on a worldwide, non-discriminatory basis and under other reasonable terms and conditions to make, use, and sell implementations of the Baseline Profile of this standard in accordance with the ITU-T/ITU-R/ISO/IEC Common Patent Policy. There three different codecs responded to the above requirements, which are WVC, VCB and IVC. WVC was proposed jointly by Apple, Cisco, Fraunhofer HHI, Magnum Semiconductor, Polycom and RIM etc. it's in fact AVC baseline. VCB was proposed by Google, and it's in fact VP8. IVC was proposed by several Universities (Peking University, Tsinghua University, Zhejiang University, HKUST, Hanyang University etc.) and its coding tools was developed from Zero. In this paper, we give an overview of the developing process, coding tools and IPR analysis of IVC, and evaluate its performance by comparing it with other competitors of WVC and VCB.

3D objects sensing and coding for real virtual reality applications in the IoT and future media internet

Lazar Bivolarsky, Albena Technologies Ltd. (United Kingdom)

Deep learning is motivated by neuroscience and has a significant impact on

various applications such as computer vision. The multidisciplinary nature of deep learning led to advances in learning architectures and coding models. Artificial intelligence has gone through some dismal periods in the past, but now is not one of those times. The current excitement about AI stems, in great part, from groundbreaking advances in the areas involving neural networks. This machine learning technique promises dramatic improvements in computer vision exploring the bridge between bits and atoms aimed to make a path between the digital world and the physical one we populate, turning the environment we occupy into a digital model what connects virtual reality, augmented reality and reality. The future of IoT is in the coexistence of the physical world, cyber world and the machine-human interface. The possibilities of virtual reality and IoT are in next step of information sharing and the evolution immersive video environments that allows for even more social experiences of ubiquitous applications that move beyond the computer, tablet and smartphone and into everything else. The future of computing lays into the new understanding of an intelligent data objects that interact with each other and the environment, including virtual and augmented reality, wearables, and collaboration applications.

Objective and subjective quality assessment of geometry compression of reconstructed 3D humans in a 3D virtual room

Rufael N Mekuria, Pablo Cesar, Centrum Wiskunde en Informatica (Netherlands); Ioannis Doumanis, CTVC (United Kingdom); Antonella Frisiello, ISMB Instituto Superiore Mario Boella (Italy)

Compression of 3D object based video is relevant for 3D Immersive applications.

Nevertheless, the perceptual aspects of the degradation introduced by codecs for meshes and point clouds are not well understood.

In this paper we evaluate the subjective and objective degradations introduced by such codecs in a state of art 3D immersive virtual room.

In the 3D immersive virtual room users are captured with multiple cameras, and their surfaces are reconstructed as photorealistic colored/textured 3D Meshes or point clouds.

To test the perceptual effect of compression and transmission, we render degraded versions with different frame rates in the scene in different contexts (near/far). The results show that simplified surfaces do not degrade the quality.

Conference 9600: Image Reconstruction from Incomplete Data VIII

SPIE. OPTICS+ PHOTONICS OPTICAL ENGINEERING+ APPLICATIONS

Image reconstruction in serial femtosecond nanocrystallography using x-ray free-electron lasers *(Invited Paper)*

Rick P. Millane, Romain Arnal, Joe Chen, David Wojtas, Philip J. Bones, Univ. of Canterbury (New Zealand); Rick Kirian, Arizona State Univ. (United States); Ken Beyerlein, Richard Bean, Henry N. Chapman, Ctr. for Free-Electron Laser Science (Germany); John C. H. Spence, Arizona State Univ. (United States)

Serial femtosecond nanocrystallography (SFX) is a form of x-ray coherent diffraction imaging that utilises a stream of tiny nanocrystals of the biological assembly under study, in contrast to the larger crystals used in conventional x-ray crystallography using conventional x-ray synchrotron x-ray sources. Nanocrystallography utilises the extremely brief and intense x-ray pulses that are obtained from an x-ray free-electron laser (XFEL). A key advantage is that some biological macromolecules, such as membrane proteins for example, do not easily form large crystals, but spontaneously form nanocrystals. There is therefore an opportunity for structure determination for biological molecules that are inaccessible using conventional x-ray crystallography. Nanocrystallography introduces a number of interesting image reconstruction problems. Weak diffraction patterns are recorded from hundreds of thousands of nancocrystals in unknown orientations, and these data have to be assembled and merged into a 3D intensity dataset. The diffracted intensities can also be affected by the surface structure of the crystals that can contain incomplete unit cells. Furthermore, the small crystal size means that there is potentially access to diffraction information between the crystalline Bragg peaks. With this information, phase retrieval is possible without resorting to the collection of additional experimental data as is necessary in conventional protein crystallography. We report recent work on the diffraction characteristics of nanocrystals and the resulting reconstruction algorithms.

9600-2, Session 1

Dynamic optically multiplexed imaging

Yaron Rachlin, Vinay Shah, R. Hamilton Shepard, Tina Shih, MIT Lincoln Lab. (United States)

Optically multiplexed imagers overcome the tradeoff between field of view and resolution by superimposing images from multiple fields of view on a single focal plane. In this paper, imaging modes enabled by dynamically modified encoding of each field of view with high precision are investigated. Dynamic encoding functions allow for both the reconstruction of sparse scenes from a snapshot, compressive measurement, as well as the reconstruction of temporally varying dense scenes by capturing a sequence of encoded frames. The image quality and frame rate of a dynamic optically multiplexed imager are compared to conventional methods for achieving high resolution over a wide field of view. To demonstrate the feasibility of the sensor concept, a compact pupil-division multiplexed sensor capable of precisely changing its encoding functions was prototyped. Experimental results obtained with this sensor are presented.

9600-3, Session 1

Restoration of defocused images using quasi-point sources which are detected with coherent light

Rosalinda Ortiz Sosa, Luis Raúl Berriel-Valdos, J. Félix Aguilar, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico)

Since the intensity point spread function (ipsf) characterizes an imaging optical system (OS), it contains all the possible present aberrations in the image. However, the ipsf is an abstraction, useful for modeling the image formation process, but it cannot be experimentally realizable. Instead, the characterization of the OS could be estimated by means of the image of a quasi point source (qps), this is an aperture so small that cannot be resolved by the OS.

In this work, the use of the image of a qps illuminated with coherent light for restoring out-of-focus images detected with incoherent light is presented. An optical-digital method for the restoration is implemented, and consists of the characterization of the OS (which in this case is a conventional microscope), with a qps is illuminated with coherent light and detected out-of-focus. The obtained image is then introduced in the Wiener filter for the deconvolution of the image of an extended object, provided this has been detected with the same amount of defocus but illuminated with incoherent light. The results of the restored images are shown and compared with those images restored when the qps is illuminated with incoherent light. Finally, a numerical evaluation of the quality of the restoration, using the RMSD (root mean square deviation) method, was made for both cases.

9600-4, Session 1

United estimation of blur distribution for space-variant rotation motion deblurring

Ziyi Shen, Tingfa Xu, Ziwei Liu, Hongqing Wang, Guokai Shi, Beijing Institute of Technology (China)

In recent years, many successful image deblurring algorithms have been proposed. A single kernel just has to be estimated in the situation of space-invariant deblurring. However, considering the space-variant blurs taken by nonlinear motion, such as influenced by the camera linear shaken and rotation, we could not estimate a kernel for the whole image and deblur it accurately, for a majority of models in our real situation, uniform deblurring is not usable or practical. In this paper, we present a method for estimating the space-varying kernel for rotation motion. After dividing several sector modules of the motion blur image into such blocks with different size, we estimate the rotary direction and the movement for each block in Fourier domain. An improved optimization for both direction and scale of different parts around the rotation center we estimated with the same radius, through a constraint of United Least square Filter is taken in our algorithm to structure the blur path accurately. Aiming at the different position of the rotary region, combining the blur distribution estimated with an operator which we create related to the spatial location, character and degree of rotation motion, we build a model to estimate a space-varying kernel for the rotation motion which is replaced by such pixels on the motion-blur-path with uniform and separate influence during the exposure in the original algorithm, it also could be used for space-variant deblurring. Experimental results for synthetic and real images demonstrate the effectiveness of this algorithm.

9600-5, Session 1

Geometric superresolution using double rect mask

Ihtsham U. Haq, National Physical and Standard Lab. (Pakistan) and Pakistan Institute of Engineering and Applied Sciences (Pakistan) and Pakistan Council of Scientific and Industrial Research (Pakistan); Asloob A. Mudassar, Pakistan Institute of Engineering and Applied Sciences (Pakistan); Ihtram U. Haq, Univ. of Karachi

(Pakistan); Asma A. Mirza, Federal Urdu Univ. of Arts, Sciences and Technology (Pakistan); Shakeel A. Khan, Government College Jaranwala, Faisalabad (Pakistan); A. Ikram, Univ. of Karachi (Pakistan); E. Hameed, Space and Upper Atmosphere Research Commission of Pakistan (Pakistan)

Today, in everyday imaging in science and research, a digital imager – despite of its lower resolution than conventional film camera, is the first choice due to its obvious advantages. Assuming the imaging system to be diffraction limited, this low resolution is due to two geometrical characteristics of the detector array (CCD/CMOS) used in it at image plane. These two characteristics are pitch and non-zero pixel size – which do sampling and averaging of optical information over pixel spatial area respectively and dictates geometric resolution limit of digital imager.

In this paper, we are proposing a geometric superresolution technique based on Double Rect Mask (DRM) – which are scanned over CCD by a half pixel in subpixel steps. The width of DRM are made relative to pixel such that max SNR is achieved keeping the system deterministic. DRM codes the image optically – which is then decoded computationally to get a super-resolved image – spatially enhanced in resolution by subpixel factor. This virtually replaces each CCD pixel by a matrix of subpixels. The decoding process is executed in just one mathematical step.

The 2D simulation results are presented – showing an improvement in resolution by given super-resolution factor - in both x and y directions. Increasing the super-resolution factor more makes the result more close to original. The given superresolution technique can be applied to microscopy, medical imaging, machine vision, industrial inspection, metrology (dimensional metrology, optical metrology), defense, satellite imaging and astronomy.

9600-6, Session 2

Phase estimation for magnetic resonance imaging near metal prostheses

Philip J. Bones, Laura J. King, Rick P. Millane, Univ. of Canterbury (New Zealand)

Magnetic resonance imaging (MRI) has the potential to be the best technique for assessing complications in patients with metal orthopedic implants. The presence of fat can obscure definition of the other soft tissues in MRI images, so fat suppression is often required. However, the performance of existing fat suppression techniques is inadequate near metal, due to very large magnetic field perturbations induced by the implant. The three-point Dixon technique is potentially a method of choice as it is able to suppress fat in inhomogeneous magnetic fields, but the success of this technique depends on being able to accurately calculate the phase shift. This is generally done using phase unwrapping or iterative reconstruction algorithms. Most current techniques assume that the phase function is slowly varying and phase differences between adjacent points are limited to less than pi radians in magnitude. Much greater phase differences can be present near metal prostheses. We present our experience with three phase estimation techniques which have been adapted to use prior knowledge of the implant. Two methods use phase unwrapping, with the first method identifying phase discontinuities before recovering the phase along paths through the image. Method 2 employs a transform to find the least squares solution to the unwrapped phase. The third method uses an iterative reconstruction technique which is assisted by prior knowledge. Simulation results indicate that all three methods show promise. Initial results obtained with image data acquired from a metal implant, oil and water phantom are presented as well.

9600-7, Session 2

Phase retrieval for multiple objects and undersampled intensity data

Rick P. Millane, Romain Arnal, Joe Chen, Univ. of Canterbury (New Zealand)

The phase retrieval problem for a single object is known to have a unique solution in two or more dimensions, and iterative projection algorithms are generally an effective reconstruction method. More difficult situations can arise however if it is necessary to retrieve phases when there are multiple objects or when the diffraction intensities are undersampled. These situations can arise if weak diffraction data are recorded from a small set of different kinds of object, and the intensities need to be averaged to increase the snr. The data can be undersampled if the object is crystalline. In both of these cases, the solvability, or uniqueness, of the problem can be characterised by an appropriate calculation of the "constraint ratio," that measures the independent data-to-parameter ratio. We show that uniqueness in such cases depends on the nature of the supports of the different objects and their dimensionality. For crystalline objects, uniqueness depends on an interplay between the object support and dimensionality, and the crystal symmetry. In cases where the solution is unique, iterative projection algorithms can be appropriately adapted to invert the data. Uniqueness results will be illustrated by examples and reconstruction algorithms by simulation. Specific applications in coherent diffraction imaging will be described.

9600-8, Session 2

A phase-space approach to imaging from limited data

Markus E. Testorf, Dartmouth College (United States)

The performance of imaging methods is inherently limited by the amount and type of data, which can be used for image reconstruction. Physical constraints may limit the access to information critical for the reconstruction process. Equally critical is the need to consider the amount of data stored, transmitted, and processed with an acceptable amount of resources.

In this contribution a system theory based on a phase-space description of optical signals is developed which provides a framework to analyze and compare imaging techniques, and which serves as the basis to develop efficient numerical image reconstruction algorithms.

This phase-space approach is based on the optical instrument function, where each optical detector is described by a function, and the measurement process by an overlap integral with the optical signal. A phase-space interpretation allows one to interpret the instrument function of optical detectors as an incoherent superposition of individual point detectors. Instruments are analyzed by tracing the detector function to the input plane of the optical instrument, where the measured signal is calculated as the phase-space overlap integral.

This framework provides the basis to analyze both coherent and incoherent imaging systems. Shack-Hartman sensors, plenoptic cameras, and phase retrieval, and compressive imaging methods are shown to measure domains in phase-space of finite size and finite resolution. It is demonstrated, how a sufficient diversity between measurements minimizes the number of data points required for solving a particular imaging problems. Both analytic as well as numeric methods for optimizing imaging methods from limited data sets are discussed.

9600-9, Session 2

Combination of genetic algorithms and FSD applied to fringe pattern demodulation

Ulises H. Rodríguez-Marmolejo, Univ. de Guadalajara (Mexico) and Instituto Tecnológico de Aguascalientes (Mexico); Tania A. Ramirez del Real, Jesús Muñoz-Maciel, Miguel Mora-González, Univ. de Guadalajara (Mexico)

In optical interferometry are several optimization methods applied to estimate the phase of a closed fringe pattern. There are several optimization techniques which play an important role in finding the phase interferogram parameters. In this work, a Genetic Algorithm in combination with Frequency guided Sequential Demodulation are implemented to estimation the phase of synthetic fringe pattern. The method gives good results in demodulation of closed fringe patterns. Results in processing time are similar to traditional optimization techniques, but the method presents computer simplifications to others algorithms.

9600-10, Session 3

Exploiting reciprocity for imaging

Morteza Karami, Michael A. Fiddy, The Univ. of North Carolina at Charlotte (United States)

We have considered the scattering and conversion of high spatial frequency (evanescent) waves into propagating waves by a complex scattering structure originally conceived as a metamaterial. The scattering structure thus serves as an encoder of that information. A metamaterial designed to have complementary scattering characteristics can be made to serve as a decoder. We explain how this structure might be used remotely to provide the reconstruction or decoding scattering mechanism to recover high resolution information, without the need for intermediate detection and numerical time reversal. We have investigated the application of the generalized reciprocity theorem to design complementary structures. Reciprocity in wave propagation refers to symmetry of the propagation under the interchange of the source and the observer. The dielectric tensors of the medium must satisfy certain symmetry properties for this to be true. S matrix methods show that reciprocity with or without evanescent waves is equivalent to time reversal invariance provided there are no losses. Reciprocity with losses is possible but is then not invariant under time reversal. We present some metamaterial designs which produce scattered fields that are phase conjugates of each other and relate this to time reversal and reciprocal scattering. These structures are then investigated to illustrate their use for remote imaging.

9600-11, Session 3

Joint sparse recovery in inverse scattering

Ok Kyun Lee, Jong Chul Ye, KAIST (Korea, Republic of)

Inverse scattering problems of various bio and medical imaging applications are required to solve the nonlinear integral equations accompanied with the nonlinear coupling between the target of recovery and the unknown data. Conventionally, linear approximation or iterative approach has been widely used to solve this non-linearity, however, they suffer from the approximation error or the computational burden, respectively. In this abstract, we propose a novel reconstruction method that solves the non-linearity in the inverse scattering problem using a joint sparsity in the compressed sensing theory. Based on the assumption that the target is sparse, the nonlinear coupling discussed above rather gives a clue to change the original inverse scattering problem into the joint sparse recovery problem under the multiple source and fixed detector geometry. Now, the entire procedure of the reconstruction can be organized in simple three steps. First, the area of the sparse target and the coupled nonlinear signal are estimated from the joint sparse recovery, and then they are utilized to estimate the unknown data using the recursive nature of the forward problem formulation. Finally, the target is reconstructed based on the previous results. Neither approximation nor the time consuming iterative approach is necessary in the proposed method, therefore, we can expect more accurate and faster recovery compared to conventional approaches. We will show how it works for specific imaging techniques such as diffuse optical tomography and electrical impedance tomography.

9600-12, Session 3

Superresolution imaging from nonlinear inverse scattering

Richard S. Ritter, Olivet Nazarene Univ. (United States); Michael A. Fiddy, The Univ. of North Carolina at Charlotte (United States)

Imaging from scattered fields is inherently a nonlinear problem unless weak or single scattering approximations (first Born or Rytov) can be made. Image reconstruction quality also clearly depends on the nature of the illumination used and number of scattered field measurements taken. We have developed a fast inversion method based on cepstral filtering in which an image of the scattering structure can be separated numerically from the associated total internal scattered fields [1]. The ability to do this depends on some prior knowledge of the maximum index or permittivity of the object in order to determine the number of degrees of freedom associated with the scattering-imaging problem. Having done this and recovered an image, we routinely see subwavelength scale features of the scattering object. This effect has been reported as far back as 1998 (Chew) and we have routinely observed it. We have conducted a series of numerical experiments using cepstral inversion for a cluster of discrete scatterers which together constitute a strong scatterer and investigated the trade-offs between the calculated number of degrees of freedom and the resolution achievable. The consequences of this study have importance not only for coherent diffraction imaging and superresolution imaging in general, but also for synthesis problems. The design of subwavelength-scale features in a scattering target can be used to define far field properties.

9600-13, Session 4

Feature extraction for 3D object detection from integral imaging data *(Invited Paper)*

Doron Aloni, Yitzhak Yitzhaky, Ben-Gurion Univ. of the Negev (Israel)

Detecting the location of objects in a 3D scene is an interesting challenge, and can be useful for various applications of computer-vision. Recently, a new method was developed for locating objects in a 3D space using computationally-reconstructed integral imaging. In computationally-reconstructed integral imaging, using the multi-view images (recorded at slightly different angles), confocal images of depth planes are computationally reconstructed. In each reconstructed plane, the images of objects located at the depth of that plane appear sharp, while objects at other depths appear blurred, according to their distance from the reconstructed depth. The method for 3D object detection, finds the most focused regions in the reconstructed planes (D. Aloni, Y. Yitzhaky: "Detection of object existence from a single reconstructed plane obtained by integral imaging", IEEE Phot. Tech. Lett., 2014), and occurrence of objects at the depth axis (J.-H. Jung , D. Aloni, Y. Yitzhaky, E. Peli: "Active confocal imaging for visual prostheses", Vision Research, 2014). The features extracted and used in the object detection process are edges. Edges are informative and efficient descriptors of objects. Their efficiency results from the small number of edge pixels (relative to the whole intensity image) used in the detection process. In this work we analyze and compare different edge extraction methods for the purpose of 3D object detection and representation. Considerations include: the effect of the edge detection on

the quality of the object detection, the appearance of the detected objects (i.e., how the edge features characterize the detected object) and the computational complexity.

Alternative techniques for high-resolution spectral estimation of spectrally encoded endoscopy

Mahta Mousavi, Univ. of California, San Diego (United States); Lian Duan, Stanford Univ. (United States); Tara Javidi, Univ. of California, San Diego (United States); Audrey K. Ellerbee, Stanford Univ. (United States)

Spectrally encoded endoscopy (SEE) is a minimally invasive optical imaging modality capable of fast confocal imaging of internal tissue structures. Modern SEE systems use coherent sources to image deep within the tissue and data are processed similar to optical coherence tomography (OCT); however, standard processing of SEE data via the Fast Fourier Transform (FFT) leads to degradation of the axial resolution as the bandwidth of the source shrinks, resulting in a well-known trade-off between speed and axial resolution. Recognizing the limitation of the FFT as a general spectral estimation algorithm to only take into account samples collected by the detector, in this work we investigate alternative high-resolution spectral estimation algorithms that exploit information such as sparsity and the general region position of the bulk sample to improve the axial resolution of processed SEE data. Moreover, we demonstrate the ability of high sampling-rate systems to exploit oversampling to yield higher quality A-scans extracted from averaging of sub-sampled datasets. We validate the performance of these algorithms using both MATLAB simulations and analysis of experimental results generated from a home-built SEE system. We also discuss guidelines to design new SEE systems ideally suited for various kinds of SEE data. Our results open a new door towards using non-FFT algorithms to generate higher quality (i.e., higher resolution) SEE images at correspondingly fast scan rates, resulting in systems that are more accurate and more comfortable for patients due to the reduced image time.

9600-16, Session 4

FPGA acceleration by asynchronous parallelization for simultaneous image reconstruction and segmentation based on the Mumford-Shah regularization

Wentai Zhang, Guojie Luo, Li Shen, Peking Univ. (China); Thomas Page, Univ. Bremen (Germany); Peng Li, Univ. of California, Los Angeles (United States); Ming Jiang, Peking Univ. (China); Peter Maass, Univ. Bremen (Germany); Jason Cong, Univ. of California, Los Angeles (United States)

X-ray computed tomography (XCT) is an important technique for clinical diagnose. In many applications a number of image processing steps are needed before the image features of interests are available. Image segmentation is one of such processing steps to generate the edge and structural features of regions of interests. The conventional flow is to first reconstruct images and then apply image segmentation methods on reconstructed images. Recently, an emerging technique is to obtain the tomographic image and segmentation simultaneously, especially in the case of limited data. The Mumford-Shah regularization for image reconstruction provides such an approach. With this approach, it does not only enable the simultaneous reconstructions of tomographic images and their segmentations, but also utilizes the interaction between the edge indicator function for segmentation and the tomographic image to enhance both reconstructions. However, the computation involves an NP-hard problem and is computationally expensive. By the Gamma-convergence approximation, we have established an iterative method for simultaneous reconstruction and segmentation with Mumford-Shah regularization. In this work, to find an energy-efficient solution with the field programmable gate array (FPGA) technology, we propose an asynchronous parallel algorithm to accelerate the implementation in FPGA. Experimental results show that the FPGA implementation achieves a 1.2X speedup with an energy efficiency as great as 58X, over the GPU implementation.

9600-17, Session 5

Imaging fields through heavily scattering random media with speckle correlations over source position *(Invited Paper)*

Jason A. Newman, Kevin J. Webb, Purdue Univ. (United States)

We describe a method whereby coherent optical fields can be imaged on the other side of a randomly scattering medium by recording speckle intensity patterns as a function of the spatially scanned incident beam position. Two constrained phase reconstructions are required to obtain the fields from the measured data. We show example patterned beam reconstruction results to demonstrate the concept. Extensions of this description lead to a method to image moving objects in scattering media. While several methods exist for imaging through thin opaque materials, coherent imaging and sensing in these extreme limits has not been previously possible. Furthermore, through the use of speckle correlations as a function of object position, we are able to exploit the speckled images to provide motion sensitivity on a wavelength scale. Such spatial speckle image correlations should prove valuable for non-ionizing high resolution medical imaging, sensing is heavily cluttered environments, and coherent imaging in and through opaque materials. At a more general level, our work provides a new framework for communication and characterization of scattering media. Natural motion can be exploited, and the approach can be extended to other geometries.

9600-19, Session 5

Imaging through scattering media via Hadamard Illumination and single-pixel detection

Vicente Durán, Chalmers Univ. of Technology (Sweden); Fernando Soldevila Torres, Esther Irles, Pedro J. Clemente Pesudo, Enrique Tajahuerce, Univ. Jaume I (Spain); Pedro Andrés Bou, Univ. de València (Spain); Jesús S. Lancis, Univ. Jaume I (Spain)

One challenge that has long held the attention of scientists is that of clearly seeing objects hidden by turbid media, as smoke, fog or biological tissue, which has major implications in fields such as remote sensing or early diagnosis of diseases.

Photons propagating through a turbid medium experience a certain number of scattering events and, as a result, part of the emerging radiation follows a completely uncorrelated direction. The intensity of the unscattered light component falls off with the medium thickness. As a consequence, imaging

begins to be difficult or unfeasible at a penetration depth larger than the tissue transport mean free path (TMFP), a measurement of the mean distance that photons travel before they completely 'forget' their initial direction.

We present a novel imaging technique, based on the concept of single-pixel camera which enables to image objects embedded at a depth of several times the TMFP of the tissue. Our results demonstrate transillumination imaging of an object embedded within a 6-mm thick sample of chicken breast, light penetration depth of about 3 times the TMFP. A sequence of microstructured light patterns implemented onto a digital micromirror device is launched onto an object completely embedded in the turbid medium. Single-pixel detectors allow us to operate at illumination power levels that are three orders of magnitude lower than the tissue damage threshold. Our technique is noninvasive, does not require coherent sources, raster scanning nor time-gated detection, works without increasing the cost and system complexity, and benefits from the compressive sensing strategy.

9600-24, Session 5

Online submillimeter three dimensional imaging of magnetic and paramagnetic contaminants flow rate in multiphase flow pipelines using magnetic particle imaging technique

K. Bin Said, Mahmoud Meribout, The Petroleum Institute (United Arab Emirates)

In oil fields, crude oil is transported over steel?made pipeline which may carry paramagnetic contaminants (e.g. iron sulfide), generated from corrosion and erosion phenomena, in addition to other diamagnetic organic scales such as naphthenic, acids, and paraffin. For example, practically all oil export pipelines transport can carry up to 0.1% of magnetic contaminants. In addition of causing wrong readings of the actual crude oil flows, these contaminants may gather at various downstream locations causing a drop of production throughput. The online devices used so far for multiphase flow metering do not consider the existence of such contaminants which indeed can provide significant over readings of the meter. Accurately measuring the flow rate of such contaminants will not only compensate the readings of the multiphase flow meters but also can mitigate their source, avoid process shutdown and prevent offline cleanings.

In this paper, submillimeter three dimensional tomography imaging of paramagnetic contaminants flow rate in multiphase flow pipelines is presented. The device, which is based on Magnetic Particle Imaging (MPI), consists of an array of twelve coils and a pair of permanent magnets and is not influenced with the other phases that constitute the crude oil (e.g. oil, water, sand, and gas) and which are mainly diamagnetic materials. The concentration of the paramagnetic particles can be measured in a three dimensional volumetric space with high spatial and temporal sensitivities which are proportional to the strength of the applied magnetic field. This is also influenced by the size and distribution of the particles and the anisotropy of the permanent magnet. To increase the sensitivity and improve the spatio encoding field, a two dimensional Linear Field Scanning (LFS) technique coupled with a two dimensional excitation field is proposed. The results demonstrate that the technique would constitute a breakthrough in the area of solid flow measurements.

9600-21, Session 6

Inter-trial alignment of EEG data and high-frequency phase-locking

Markus E. Testorf, Peter Horak, Andy Connolly, Dartmouth College (United States); Gregory L. Holmes M.D., The Univ. of Vermont (United States); Barbara C. Jobst, Darmouth College (United States)

Neuro-scientific studies typically try to correlate the behavior of human subjects to changes of functional signals, such as fMRI and electroencephalogram (EEG) recordings. Images of brain activity are derived from statistical evaluations of multiple trials time synchronized to a repeated external stimulus.

Even in well-designed experiments the signal component of interest may be recorded in each trial with a different time lag relative to the stimulus. This may be caused by an uncontrolled latency of the equipment. For complex brain activities the response time may also depend on brain processes unrelated to the external stimulus.

This is particularly critical for EEG data. While events manifesting in low frequency bands (<10Hz) may tolerate a time jitter of the order of 100ms, higher frequency signals may be desynchonized by time delays of less than 1ms. This is even more important if the phase of a discrete frequency is compared across trials.

In this contribution we investigate methods for aligning trials based on the recorded signal itself. Cross-correlations between trials serve as the baseline to consider various algorithms, including wavelet based algorithms and iterative optimization algorithms. The bias potentially introduced into the signal recovery process by using the same data for alignment as well as subsequent ensemble averaging will be addressed by the selection of recording sites in the brain.

The trial alignment will be applied to the evaluation of phase-locking across trials. The frequency resolved phase-locking will be computed from inter-cranial EEG data recorded in a clinical setting.

9600-22, Session 6

Precoding design of compressive sensing data based on singular value decomposition criterion

Chia-Chang Hu, Kang-Tsao Tang, Bo-Hung Chen, National Chung Cheng Univ. (Taiwan)

In this paper, joint relay and source precoders for image transmission is proposed for a multiple-input multiple-output (MIMO) multiple-relays system. In mobile devices powered by battery, reducing the sensor's compression energy consumption is critical to extend its lifetime. A novel antenna selection scheme based on the singular value decomposition (SVD) is proposed in order to decrease energy consumption and computational complexity in image transmission. The main purpose of the proposed algorithm is to suppress noise, preserve image details, and have low computational complexity, which are very difficult to achieve simultaneously. It is noticed that the SVD-based joint design of relay-and-source precoders in conjunction with the antenna selection mechanism is capable of achieving superior bit-error-rate (BER) and MSE performance.

9600-23, Session 6

Implementation of an adaptive ictal spike detection algorithm

Stephen Meisenhelter, Peter C. Horak, Andrew Connolly, Barbara C. Jobst, Dartmouth Hitchcock Medical Ctr. (United States)

The identification of epileptiform activity and recording artifacts is crucial for the analysis of electroencephalogram (EEG) data. For imaging the study of human brain activity,, for clinical diagnostics, and study of epilepsy, it is desirable to detect and classify spikes and other epilepsy related signals automatically. For many neuro-scientific studies, the removal of these waveforms is an indispensable pre-processing step. In humans, automatic detection and classification of epileptiform activity remains difficult, since the signal components in question vary considerably between patients. However, epileptiform activity is usually consistent within patients.

Currently, the detection of interictal spikes and other epileptiform activity in clinical EEG data is almost always carried out manually by trained neurologists. This introduces considerable variability in the accuracy of spike

detection from reviewer to reviewer. The problem is further complicated by the lack of a consensus among neurologists on the features which define a spike. Discrepancies in review are explained by subjective variance.

In this study, we demonstrate a clustering-based interictal spike detection algorithm. This algorithm improves upon an earlier method of creating patient-specific pattern matching templates by clustering the results of a generic pattern matching analysis (Nonclerq et al., 2010). This method was extended by expanding the generic pattern matching step and the clustering method. This improved algorithm was evaluated using hippocampal EEG recordings from 11 epilepsy patients.
