Propagating and localized toroidal excitations in free space and metamaterials *(Invited Paper)*

Nikolay I. Zheludev, Optoelectronics Research Ctr. (United Kingdom) and Nanyang Technological Univ. (Singapore); Vassili A. Fedotov, Nikitas Papasimakis, Vassili Savinov, Univ. of Southampton (United Kingdom); Tim A. Raybould, Optoelectronics Research Ctr. (United Kingdom)

Invited: The emerging field of toroidal electrodynamics involves the study and exploitation of peculiar localized and propagating electromagnetic excitations that topologically resemble a torus. Here we present an overview of our recent advances in the field enabled by a metamaterial approach, which includes the engineering of non-trivial non-radiating electromagnetic sources and an exotic type of optical activity. We also present an analytical technique for evaluating the role of the toroidal excitations in material systems. Finally, we examine the propagation of toroidal electromagnetic perturbations in free space (so-called 'focused doughnuts'), which present a platform for observing and studying unique light-matter interactions.

9544-2, Session 1

Observation of an anapole with dielectric nanoparticles *(Invited Paper)*

Andrey E. Miroshnichenko, The Australian National Univ. (Australia)

A possible existence of nonradiating sources has puzzled physicists since the early days of electromagnetic theory, particularly in connection with models of stable atoms and electrons configurations. . One intriguing example of such a nonradiating source is known as "anapole". The term "anapole" (which means "without poles" in Greek) was introduced in the physics of elementary particles by Yakov Zel'dovich. An anapole mode can be considered as a superposition of electric and toroidal dipole moments, resulting in destructive interference of the radiation fields due to similarity of their far- field scattering patterns. We demonstrate experimentally that dielectric nanoparticles can realize a radiationless anapole mode in visible. We achieve a spectral overlap of the toroidal and electric dipole modes through a geometry tuning in silicon nano-discs and observe a highly pronounced dip in the far-field scattering accompanied by the specific near-field distribution associated with the anapole mode. This radiationless excitation makes the nanodisk invisible in the far-field at the anapole mode wavelength. The anapole mode offers a new way to achieve an invisibility condition for lossless dielectric nanostructures based on the cancelation of radiation scattering. The anapole mode is not only limited to the disk geometries but it can also be observed for spheres or other dielectric nanostructures where the electric dipole contribution vanishes due to a switch to a "higher-order dipole" mode. The anapole physics provides a unique playground for the study of electromagnetic properties of nontrivial excitations of complex fields, reciprocity violation, Aharonov-Bohm like phenomena at optical frequencies, and other related phenomena.

9544-3, Session 1

Probing metamaterials with structured light

Yun Xu, Jingbo Sun, Jinwei Zeng, Zhaxylyk Kudyshev, Univ. at Buffalo (United States); Apra Pandey, CST of America, Inc. (United States); Ying Liu, Natalia M. Litchinitser, Univ. at Buffalo (United States)

We propose and demonstrate a reliable and inexpensive tool for optical characterization of photonics metamaterials and metasurfaces. Existing characterization methods of metamaterials (or more precisely negative index metamaterials), including conventional interferometry and ellipsometry, are rather complex and expensive.

The "measurable" difference between, for example, positive index materials and negative index materials is that the former introduces a phase delay to transmitted light beam and the latter one introduces a phase advance. Here, we propose to use optical vortex interferometry to directly "visualize" phase delay or phase advance.

In the proposed setup a laser beams at the wavelength of 633 nm is separated in two by a beam splitter. One beam is transmitted through a spiral phase plate in order to generate a beam with an orbital angular momentum, and the second beam is transmitted through a nanostructured sample. Two beams are subsequently recombined by a beam splitter to form spiral interferogram. Spiral patterns are then analyzed to determine phase shifts introduced by the sample. In order to demonstrate the efficiency of the proposed technique, we fabricated four metasurface samples consisting of metal nano-antennas introducing different phase shifts and experimentally measured phase shifts of the transmitted light using the proposed technique. The experimental results are in good agreement with numerical simulations.

In summary, we report a novel method to characterize metasurfaces and metamaterials using optical vortex interferometry. The proposed characterization approach is simple, reliable and particularly useful for fast and inexpensive characterization of phase properties introduced by metamaterials and metasurfaces.

9544-4, Session 1

Large magnetic to electric field contrast in azimuthally polarized vortex beams generated by a metasurface

Mehdi Veysi, Caner Guclu, Filippo Capolino, Univ. of California, Irvine (United States)

We investigate azimuthally E-polarized vortex beams with enhanced longitudinal magnetic field. Ideally, such beams possess strong longitudinal magnetic field on the beam axis where there is no electric field. First we formulate the electric field vector and the longitudinal magnetic field of an azimuthally E-polarized beam as an interference of right- and left-hand circularly polarized Laguerre Gaussian (LG) beams carrying the orbital angular momentum (OAM) states of -1 and +1, respectively. Then we propose a metasurface design that is capable of converting a linearly polarized Gaussian beam into an azimuthally E-polarized vortex beam with longitudinal magnetic field. The metasurface is composed of a rectangular array of double-layer double split-ring slot elements, though other geometries could be adopted as well. The element is specifically designed to have nearly a 180° transmission phase difference between the two polarization components along two orthogonal axes, similar to the optical axes of a half-wave plate. By locally rotating the optical axes of each metasurface element, the transmission phase profile of the circularly polarized waves over the metasurface can be tailored. Upon focusing of the generated vortex beam through a lens with a numerical aperture of 0.7, a 41-fold enhancement of the magnetic to electric field ratio is achieved on the beam axis with respect to that of a plane wave. Generation of beams with large magnetic field to electric field contrast can find applications in future spectroscopy systems based on magnetic dipole transitions, which are usually much weaker than electric dipole transitions.

9544-5, Session 1

Plasmonic magnetization during circularly polarized excitation

Matthew T. Sheldon, Texas A&M Univ. (United States)

In contrast with linearly polarized excitation, which necessarily has zero magnitude electrical field twice during an optical cycle, the electrical field vector of circularly polarized light has constant magnitude. During an optical cycle the electric field vector rotates in the plane normal to the wave propagation. Consequently, if plasmonic structures are resonant with circularly polarized excitation, it is possible for them to exhibit regions of strongly modified carrier density for the duration of the optical cycle.

Here, we study a class of achiral toroid and 'sun burst' nano-patterned plasmonic surfaces that show persistent, circulating charge density waves during circularly polarized illumination. The direction of the continuously circulating wave (clockwise or counterclockwise) depends on the handedness of the incident beam. Our interest stems from whether these charge density waves can support circular electric currents (DC) manifest experimentally as static magnetic fields during illumination. Using full-wave optical modeling (FDTD method), and mechanistic calculations of the circulating potential acting on electrons in the toroid resonators, we outline the conditions that maximize optical excitation of both circulating displacement currents and electron transport currents. We show that in the limit of very weak coupling to the solenoid-like electron transport, or when < 1 x 10^-6% of the plasmonically active electron population enters the circular transport modes, relatively strong magnetic fields, > 1 G, can be expected. We discuss scanning probe measurements for monitoring the induced magnetic field, as well as the relationship between this phenomenon and the inverse Faraday effect observed in continuous media.

9544-6, Session 2

Enhanced light-matter coupling in Si-based metamaterials *(Invited Paper)*

Luca Dal Negro, Boston Univ. (United States)

I will present our results on the design, nanofabrication and optical characterization of silicon-compatible metamaterials for applications to light sources and highly nonlinear optical components. In particular, I will discuss recent work on loss-reduction in metamaterials with tunable negative permittivity in the near-infrared spectral range. Rare earth doping of conductive oxides and nitrides with different compositions will also be discussed as an alternative approach to active plasmon alloys and epsilon-near-zero (ENZ) media with tunable polaritonic responses across the 1-2 micrometer spectral range. Experiments will be presented addressing change modulation, enhanced light scattering, emission, second and third harmonic generation on a chip.

9544-7, Session 2

Recent advances in metamaterial multi-physics *(Invited Paper)*

Mikhail Lapine, Univ. of Technology Sydney (Australia)

In this contribution, I will present an overview of our recent achievements in exploiting novel degrees of freedom in metamaterial design, which enable sophisticated nonlinear coupling mechanisms and bring enhancement to nonlinear behaviour. One of the paradigms makes use of various types of mechanical feedback, achieved by embedding electromagnetic resonators within elastic medium or engineering explicit elastic links between them — such arrangements lead to broad-band self-adjustable resonances, self-oscillations, chaotic regimes and spontaneous symmetry breaking. With this respect, we have analysed a range of implementations from microwaves to optics. Another concept benefits from multi-frequency operation, where the properties in completely distinct frequency ranges become entangled through specific metamaterial design — for example, direct optical coupling can be introduced between microwave resonators, providing an independent interaction channel which can be exploited for nonlinear "traffic lights" between otherwise independent waveguides so that one signal is suppressed or enhanced depending on the power of a competing signal. Alternatively, such an optical path may be used to achieve nonlinear mutual interaction. Finally, we explore the benefits which hyperbolic metamaterials can bring to classical nonlinear processes. The use of hyperbolic dispersion, which supports arbitrary k-vectors, eventually allows for unusual phase matching solutions, with a rich choice of matching combinations. This design overcomes the limitations of both the conventional birefringent and quasi phase matching, making harmonics generation easily possible with nonlinear materials where the classical approaches fail.

9544-8, Session 2

Coherent effects in nonlinear metamaterial-based devices *(Invited Paper)*

Alessandro Salandrino, The Univ. of Kansas (United States)

Nonlinear optical interactions are at the foundation of ultrafast control of photons with other photons, and are essential for the realization of integrated all-optical processors. The problem posed by the weak nature of nonlinear effects is typically circumvented by designing devices relying on long propagation lengths and operating under high intensity excitation fields. However such an approach precludes dense integration and hardly complies with the low power, low weight, and small size requirements of modern telecommunication systems. Metamaterials can provide novel strategies to address the shortcomings of conventional nonlinear optics.

Nanostructured media and metamaterials have revolutionized the technological landscape, and for this reason a variety of concepts from classical nonlinear optics such as phase-matching should be revisited in order to account for the new properties offered by these artificial media. One unique characteristic of metamaterials and nanostructured media is the possibility of controlling electromagnetic fields over length-scales comparable to, or smaller than the operating wavelength. In addition to field enhancement effects, metamaterials offer an unprecedented control over the phase of electromagnetic fields, which is of paramount importance in coherent optical processes.

Here we explore frequency conversion effects in nanostructured media under structured illumination. The coherent interactions arising in such ensembles of nanostructures lead to a very rich phenomenology and a unique set of degrees of freedom with which to engineer the overall nonlinear response. Here we discuss the control of nonlinear emission direction, the control of nonlinear emission polarization and novel phase-matching schemes.

9544-9, Session 2

Active control of light beam in transformation optics

Hui Liu, Nanjing Univ. (China)

The control of electromagnetic radiation in transformation optical metamaterials brings the development of vast variety of optical devices. Of a particular importance is the possibility to control the propagation of light with light. In this work, we use a structured planar cavity to enhance the thermo-optic effect in a transformation optical waveguide. In the process, a control laser produces apparent inhomogeneous refractive index change inside the waveguides. The trajectory of a second probe laser beam is then continuously tuned in the experiment. The experimental results agree well with the developed theory. The reported method can provide a new approach toward development of transformation optical devices where active all-optical control of the impinging light can be achieved.

9544-91, Session 2

Transparency and coherence in rf SQUID metamaterials *(Invited Paper)*

Steven M Anlage, Univ. of Maryland, College Park (United States)

We have developed active metamaterials based on macroscopic quantum effects capable of quickly tuning their electrical and magnetic responses over a wide frequency range. These metamaterials are based on superconducting elements to form low insertion loss, physically and electrically small, highly tunable structures for the next generation rf electronics. The meta-atoms are rf superconducting quantum interference devices (SQUIDs) that incorporate the Josephson effect. RF SQUIDs have an inductance which includes a contribution from the Josephson inductance of the junction. This inductance is strongly tunable with dc and rf magnetic fields and currents. The rf SQUID metamaterial is a richly nonlinear effective medium introducing qualitatively new macroscopic quantum phenomena into the metamaterials community, namely magnetic flux quantization and the Josephson effect. The coherence of the metamaterials is strongly sensitive to the environment and measurement conditions. The metamaterials also display a unique form of transparency whose development can be manipulated through multiple parametric dependences. Further features such as breathers, superradiance, and self-induced transparency, along with entry into the fully quantum limit, will yield qualitatively new metamaterial phenomena.

This work is supported by the NSF-GOALI and OISE Programs through Grant No. ECCS-1158644 and the Center for Nanophysics and Advanced Materials (CNAM).

9544-10, Session 3

Nanostructured photonic metamaterials reconfigurable with light, nanomechanical, and electromagnetic forces *(Invited Paper)*

Jun-Yu Ou, Univ. of Southampton (United Kingdom); João Valente, Optoelectronics Research Ctr. (United Kingdom); Artemios Karvounis, Univ. of Southampton (United Kingdom); Weiping Wu, Eric Plum, Optoelectronics Research Ctr. (United Kingdom); Kevin F. MacDonald, Univ. of Southampton (United Kingdom); Nikolay I. Zheludev, Univ. of Southampton (United Kingdom) and Nanyang Technological Univ. (Singapore)

Invited: Active and dynamic manipulation of metamaterial optical properties is the foundation for metamaterial devices. Such metadevices will translate metamaterials from fundamental scientific research to practical applications including optical switches, optical modulators, tunable spectral filters, and programmable transformation optics devices. Here we develop reconfigurable photonic metamaterials that offer a flexible platform for fast dynamic control of metamaterial optical properties.

The properties of any metamaterial structure strongly depend on the spatial arrangement of its building blocks. By constructing metamaterials on elastically deformable scaffolds we can dynamically control the nanoscale spacing among constituent elements across the entire metamaterial array. Based on this approach, we use electrostatic, Lorentz and near field optical forces to drive high-contrast, high-speed active tuning, modulation and switching of photonic metamaterial properties and to deliver exceptionally large opto-mechanical nonlinearities.

9544-11, Session 3

Latest progress in spasers *(Invited Paper)*

Mark I. Stockman, Georgia State Univ. (United States)

Nanoplasmonics deals with collective electron excitations at the surfaces of metal nanostructures, called surface plasmons. The surface plasmons localize and nano-concentrate optical energy creating highly enhanced local fields. Nanoplasmonics has numerous applications in science, technology, biomedicine, environmental monitoring, and defense.

There is an all-important need in active devices capable of generating and amplifying coherent optical fields on the nanoscale analogous to lasers and amplifiers of the conventional optics or transistors of microelectronics. Such an active device is the spaser (surface plasmon amplification by stimulated emission of radiation), also called plasmonic nanolaser. We will focus on the newest ideas and achievements in spasers.

We will present two new theoretical ideas in the field of spasers: spaser with electric pumping via quantum wire [D. Li and M. I. Stockman, Electric Spaser in the Extreme Quantum Limit, Phys. Rev. Lett. 110, 106803-1-5 (2013)] and quantum-cascade graphene spaser [V. Apalkov, M. I. Stockman, Proposed graphene nanospaser. Light Sci. Appl. 3, e191-191-196 (2014)]. We will consider the latest progress in applications of spasers. Among them is a recent breakthrough in ultrasensitive detection of explosives using the spaser [R.-M. Ma, S. Ota, Y. Li, S. Yang, X. Zhang, Explosives Detection in a Lasing Plasmon Nanocavity, Nat. Nano 9, 600-604 (2014)]. Another recent breakthrough to be presented is an application of the spaser as an ultrabright nanolabel and an efficient theranostic agent in biomedicine (cancer diagnostics and treatment) [E. I. Galanzha, R. Weingold, D. A. Nedosekin, M. Sarimollaoglu, A. S. Kuchyanov, R. G. Parkhomenko, A. I. Plekhanov, M. I. Stockman, and V. P. Zharov, Spaser as Novel Versatile Biomedical Tool, arXiv:1501.00342, 1-33 (2015)].

9544-12, Session 3

Active hyperbolic metamaterials *(Invited Paper)*

Vinod M. Menon, The City College of New York (United States)

Hyperbolic metamaterials (HMMs) have become one of the most attractive classes of metamaterials due to their wide array of applications in combination with ease of realization. Here we will discuss our recent work on “active hyperbolic metamaterials” where demonstrate enhanced light emission and extraction from metamaterials embedded with quantum dots. We will also discuss our recent efforts on realizing tunable HMMs as well as sub-wavelength cavities.

9544-13, Session 3

Gain-enhanced hyperbolic metamaterials at telecommunication frequencies

Joseph S. T. Smalley, Univ. of California, San Diego (United States); Felipe Vallini, Univ. of California San Diego (United States); Boubacar Kante, Shiva Shahin, Conor Riley, Yeshaiahu Fainman, Univ. of California, San Diego (United States)

Using effective medium theory (EMT), Bloch’s theorem (BT), and the transfer matrix method (TMM), we analyze the possibility of gain-enhanced transmission in metamaterials with hyperbolic dispersion at telecommunication frequencies. We compare different combinations of dissipative metals and active dielectrics, including noble metals, transparent conducting oxides (TCO), III-V compounds, and solid-state dopants. We find that both indium gallium arsenide phosphide (InGaAsP) and erbium-doped silica (Er:SiO2), when combined with silver, show promise as a platform for demonstration of pump-dependent transmission. On the other hand, when these active dielectrics are combined with aluminum-doped zinc oxide (AZO), a low-loss TCO, gain-enhanced transmission is negligible. Results based on EMT are compared to the more accurate BT and TMM. When losses are ignored, quantitative agreement between these analytical techniques is observed near the center of the first Brillouin zone of a one-dimensional periodic structure. Including realistic levels of loss and gain, however, EMT predictions become overly optimistic compared to BT and TMM. We also

discuss the limitations to assumptions inherent to EMT, BT, and TMM, and suggest avenues for future analysis.

9544-14, Session 3

Giant gain enhancement in slow-wave photonic crystals with a degenerate band edge

Mohamed A. K. Othman, Filippo Capolino, Alexander Figotin, Univ. of California, Irvine (United States); Farshad Yazdi, Univ. of California Irvine (United States)

Recent photonic crystal technologies have enabled a new class of low-threshold laser sources that showed a substantial enhancement in the performance utilizing a Fabry-Perot configuration. In the pursuit of higher gain and more efficient sources, we here propose a novel slow-wave Fabry-Perot cavity (FPC) made of a photonic crystal for laser applications that utilizes a degeneracy condition of the structural eigenmodes, namely, the degenerate band edge (DBE) condition. We show here that FPCs operating very close to the DBE can be used to enhance gain in laser devices to unprecedented levels. Light confinement in this configuration allows a huge increase in the photon lifetime in the cavity. Consequently, when active materials are integrated into an FPC with a DBE, round trip gain experienced by photons is significantly increased for photons travel with extremely low group velocities yielding a gigantic transmission gain. We show in particular giant enhancement of the gain in an FPC with a DBE compared to an FPC with a photonic crystal with a regular band edge, up to a few orders of magnitude. We also investigate the role of the local density of states (LDOS) which provides an explanation of the origin of gain enhancement mechanism in the PFC with a DBE. The proposed gain mechanism has a promising potential for many applications, including, but not limited to, high efficiency, low threshold laser devices as well as high power microwave amplifiers.

9544-15, Session 4

Collective Förster energy transfer modified by planar plasmonic mirror *(Invited Paper)*

Alexander N. Poddubny, Ioffe Physical-Technical Institute (Russian Federation)

This is an invited presentation devoted to the Förster energy transfer in plasmonic systems.

Förster energy transfer processes are now actively studied in various fields that bridge physics, biology and medicine. One can try to control the efficiency of the transfer by embedding the donors and acceptors into the structured electromagnetic environment. Available experimental studies yields contradictory reports on suppressed [1], enhanced [2] or unaffected [3] transfer.

We present a rigorous Green function theory of the collective Förster energy transfer between the arrays of donor and acceptor molecules lying on the planar metallic mirror that has been previously available only for spherical nanoparticles [4]. We reveal strong modification of the effective transfer rate by the mirror. The rate can be either suppressed or enhanced depending on the relative positions between acceptor and donor arrays. This is a collective effect, completely absent for a single donor-acceptor pair put above the mirror. Our results may explain the slowdown of the transfer rate recently observed in experiment for dye molecules put on top of plasmonic mirrors and layered hyperbolic metamaterials [1].

9544-16, Session 4

Nitrogen-vacancy single-photon emission enhanced with nanophotonic structures *(Invited Paper)*

Vladimir M. Shalaev, Mikhail Y. Shalaginov, Purdue Univ. (United States); Vadim V. Vorobyov, Photonic Nano-Meta Technologies (Russian Federation); Simeon Bogdanov, Purdue Univ. (United States); Alexey V. Akimov, Russian Quantum Ctr. (Russian Federation); Alexei Lagutchev, Alexander V. Kildishev, Alexandra Boltasseva, Purdue Univ. (United States)

Efficient generation of single photons is essential for the development of photonic quantum technologies. We have demonstrated that coupling a nanodiamond nitrogen-vacancy (NV) center to CMOS-compatible nanophotonic structures results in significant reduction of the excited state lifetime, increase in the collected single–photon emission, and modification of radiation pattern. In addition, we studied the effect of increased photonic density of states on spin dependent fluorescence contrast.

9544-17, Session 4

Super-coulombic Van der Waals interactions in metamaterials *(Invited Paper)*

Cristian L. Cortes, Ward D. Newman, Zubin Jacob, Univ. of Alberta (Canada)

We use Rytov's fluctuational electrodynamics to show that Van Der Waals interactions are fundamentally modified by metamaterials. We verify the conditions under which the effect is strongest and also show initial experimental results to prove the same. En route to developing the van der waals theory in metamaterials we have also adopted a unique approach to quantization in lossy dispersive media.

9544-18, Session 4

Effect of nonlocal dielectric environments on chemical reactions

Vanessa N. Peters, Norfolk State Univ. (United States); Thejaswi U Tumkur, Guohua Zhu, Mikhail A Noginov, Norfolk State Univ (United States)

Proximity to metallic surfaces, plasmonic structures, cavities and other inhomogeneous dielectric environments is known to control spontaneous emission, energy transfer, scattering, and many other phenomena of practical importance. The aim of the present study was to demonstrate that, in spirit of the Marcus theory, the rates of chemical reactions can, too, be influenced by nonlocal dielectric environments, such as metallic films and metal/dielectric bilayer or multilayer structures. We have experimentally shown that metallic and composite metal/dielectric substrates can, indeed, control ordering as well as photodegradation of thin poly-3-hexylthiophene (p3ht) films. In many particular experiments, p3ht films were separated from metal by a dielectric spacer, excluding conventional catalysis facilitated by metals and making modification of the nonlocal dielectric environment a plausible explanation for the observed phenomena. This first step toward understanding of a complex relationship between chemical reactions and nonlocal dielectric environments is to be followed by the theory development and a broader scope of thorough experimental studies.

9544-19, Session 4

Effect of photonic density of states on spin-flip induced fluorescence contrast in diamond nitrogen-vacancy center ensembles

Mikhail Shalaginov, Simeon Bogdanov, Jing Liu, Alexei Lagutchev, Alexander V. Kildishev, Dimitrios Peroulis, Joseph M. Irudayaraj, Alexandra Boltasseva, Vladimir M. Shalaev, Purdue Univ. (United States)

Diamond based nitrogen-vacancy (NV) centers are promising solid state defects for applications in quantum information technologies. On the one hand, there is a growing interest in enhancing their single-photon emission by coupling them to plasmonic structures. On the other hand, the dependence of emission intensity on the electron spin state enables room temperature quantum information readout. We study the fluorescence contrast resulting from the spin resonance in the conditions of an increased photonic density of states. Fluorescence observations from NV center ensembles in diamond nanocrystals coupled to structures supporting plasmonic modes experimentally confirm the analytical results.

9544-500, Session Plen

Extreme Imaging and Beyond

Keisuke Goda, The Univ. of Tokyo (Japan)

Imaging is an effective tool in scientific research, manufacturing, and medical practice. However, despite its importance, it is not easy to observe dynamical events that occur much faster or slower than the human time scale (found in photochemistry, phononics, fluidics, MEMS, and tribology). Unfortunately, traditional methods for imaging fall short in visualizing them due to their technical limitations. In this talk, I will introduce radically different approaches to imaging. I will first discuss ultrafast imaging and then talk about ultraslow imaging. I will show how these imaging tools help us better understand dynamical processes.

9544-501, Session Plen

Nano-bio-optomechanics: nanoaperture tweezers probe single nanoparticles, proteins, and their interactions

Reuven Gordon, Univ. of Victoria (Canada)

Nanoparticles in the single digit nanometer range can be easily isolated and studied with low optical powers using nanoaperture tweezers. We have studied individual proteins and their interactions with small molecules, DNA and antibodies. Recently, using the fluctuations of the trapped object, we have pioneered a new way to “listen” to the vibrations of nanoparticles in the 100 GHz – 1 THz range; the approach is called extraordinary acoustic Raman (EAR). EAR gives unprecedented low frequency spectra of individual proteins in solution, allowing for identification and analysis, as well as probing their role in biological functions. We have also used EAR to study the elastic properties, shape and size of various individual nanoparticles.

9544-502, Session Plen

Device Applications of Semiconductor Nanoantennas and Metafilms

Mark L. Brongersma, Geballe Lab. for Advanced Materials (GLAM) (United States)

Semiconductor nanostructures are at the heart of modern-day electronic devices and systems. Due to their high refractive index, they also provide a myriad of opportunities to manipulate light. When properly sized and shaped, they can support strong optical resonances that boost light-matter interaction over bulk materials and enable their use in controlling the flow of light at the nanoscale. In this presentation, I will discuss the use of individual, resonant nanostructures and dense arrays thereof (metafilms) in a variety of optoelectronic devices and illustrate how the performance of these devices can be improved by engineering the constituent nanostructure, size, shape, and/or spacing.

9544-20, Session 5

Photonic hypercrystals *(Invited Paper)*

Evgenii E. Narimanov, Purdue Univ. (United States)

We introduce a new “universality class” of artificial optical media - photonic hyper-crystals. These hyperbolic metamaterials with periodic spatial variation of dielectric permittivity on subwavelength scale, combine the features of optical metamaterials and photonic crystals.

9544-21, Session 5

Non-resonant hyperlens in the visible range *(Invited Paper)*

Natalia M. Litchinitser, Jingbo Sun, Mikhail I. Shalaev, Univ. at Buffalo (United States)

A metamaterial hyperlens offers a unique solution to overcome the diffraction limit by transforming evanescent waves responsible for imaging subwavelength features of an object into propagating waves. However, the first realizations of optical hyperlenses were limited by a narrow working bandwidth and significant resonance-induced loss. Here, we report the first experimental demonstration of a non-resonant waveguide-coupled hyperlens operating in the visible wavelength range that was fabricated using a combination of top-down and bottom-up fabrication approaches. A detailed investigation of various materials systems proves that a radial fan-shaped configuration is superior to the concentric layer-based configuration in that it relies on non-resonant negative dielectric response, and, as a result, enables broadband and low-loss performance in the visible range. While the majority of applications of a hyperlens is expected to be in optical frequency range, the challenge of fabricating non-resonant radial structures at optical frequencies has not been overcome until now.

9544-22, Session 5

Sub-diffractional, volume-confined polaritons in a natural hyperbolic material: hexagonal boron nitride

Joshua D. Caldwell, U.S. Naval Research Lab. (United States); Andrey V. Kretinin, The Univ. of Manchester (United Kingdom); Yiguo Chen, Vincenzo Giannini, Imperial College London (United Kingdom); Michael M. Fogler, Univ. of California, San Diego (United States); Yan Francescato, Imperial College London (United Kingdom); Chase T. Ellis, Joseph G. Tischler, U.S. Naval Research Lab. (United States); Colin R. Woods, The Univ. of Manchester (United States); Alexander J. Giles, U.S. Naval Research Lab. (United States); Kenji Watanabe, Takashi Taniguchi, National Institute for Materials Science (Japan); Stefan A. Maier, Imperial College London (United Kingdom); Kostya S. Novoselov, The Univ. of Manchester (United Kingdom)

Strongly anisotropic media where principal components of the dielectric tensor have opposite signs are called hyperbolic. These materials permit highly directional, volume-confined propagation of slow-light modes

at deeply sub-diffractional size scales, leading to unique nanophotonic phenomena. The realization of hyperbolic materials within the optical spectral range has been achieved primarily through the use of artificial structures typically composed of plasmonic metals and dielectric constituents. However, while proof-of-principle experiments have been performed, the high plasmonic losses and inhomogeneity of the structures limit most advances to the laboratory. Recently, hexagonal boron nitride (hBN) was identified as a natural hyperbolic material (NHM), offering a low-loss, homogeneous medium that can operate in the mid-infrared. We have exploited the NHM response of hBN within periodic arrays of conical nanoresonators to demonstrate 'hyperbolic polaritons,' deeply sub-diffractional guided waves that propagate through the volume rather than on the surface of a hyperbolic material. We have identified that the polaritons are manifested as a four series of resonances in two distinct spectral bands that have mutually exclusive dependencies upon incident light polarization, modal order, and aspect ratio. These observations represent the first foray into creating NHM building blocks for mid-infrared to terahertz nanophotonic and metamaterial devices. This talk will also discuss potential near-term applications stemming from these developments.

9544-23, Session 5

Practical realization of deeply subwavelength multilayer metal-dielectric nanostructures based on InGaAsP

Joseph S. T. Smalley, Univ. of California, San Diego (United States); Felipe Vallini, Univ. of California San Diego (United States); Sergio Montoya, Eric E. Fullerton, Yeshaiahu Fainman, Univ. of California, San Diego (United States)

Using established nanofabrication techniques, we realize deeply subwavelength multilayer metal-dielectric nanostructures composed of silver and indium gallium arsenide phosphide (InGaAsP). In contrast to most, if not all, subwavelength multilayer metal-dielectric systems to date, the Bloch vector of the fabricated structure is parallel to the plane of the substrate, making it suitable for waveguide integration. InGaAsP multiple quantum wells (MQWs) are epitaxially grown on InP normal to the Bloch vector of the resulting multilayer. The associated carrier population of the MQWs allows for active control of the behavior of the nanostructure via external optical pumping. Individual layer thicknesses of 30nm are repeatedly achieved via electron-beam lithography, reactive ion etching of InGaAsP, and sputter deposition of silver. Resulting 60nm periods of the one-dimensional periodic structure are 25 times smaller than telecommunication wavelengths in vacuum. The realized multilayer nanostructures hold promise as a platform for active and tunable hyperbolic metamaterials at telecommunication frequencies.

Semiconductor-dielectric Multilayer surface magnetoplasmon planar hyperlens

Bo Han Cheng, Academia Sinica (Taiwan); Hong Wen Chen, Yung-Chiang Lan, National Cheng Kung Univ. (Taiwan); Din Ping Tsai, Academia Sinica (Taiwan)

The magnetically controlled planar hyperlens which consists of an InSb-PMMA multilayered structure is proposed and analyzed. The ability of the proposed hyperlens to resolve subwavelength structures at THz region is demonstrated by electromagnetic numerical simulation. The asymmetric field pattern in the hyperlens is caused by the surface magnetoplasmon (SMP) propagating in the InSb-PMMA waveguide. By using transfer matrix method and the effective medium approach of the investigated components, the role of SMP played in the super-resolution is elucidated. Furthermore, the super-resolution of the proposed device under various frequencies is accomplished by merely changing the value of external magnetic field. The proposed device would provide a practical route for multi-functional material, real-time super-resolution imaging, photolithography, and THz imaging.

9544-25, Session 5

Probing the ultrathin limit of hyperbolic metamaterial: nonlocality induced topological transitions

Long Chen, Cheng Zhang, Jing Zhou, L. Jay Guo, Univ. of Michigan (United States)

An ideal hyperbolic metamaterial (HMM), which has a perfect hyperbolic dispersion curve, theoretically can support modes with indefinite wavenumbers, leading to large photon local density of states (LDOS) and many applications such as enhancing light-matter interactions, spontaneous emission and thermal radiation. Here in this presentation, HMMs based on ultrathin metal-dielectric multilayers have been studied by considering the nonlocal response of electrons in metal. Based on the hydrodynamic model of the nonlocal response, we investigate the effect of nonlocality on the performance (dispersion relation, ray refraction, LDOS and spontaneous emission) of HMMs when gradually approaching the ultrathin limit of the unit cell. We show that nonlocality will induce topological transitions of the iso-frequency surfaces and limit the wavenumber as well as LDOS for both type I and type II HMMs. Under nonlocal treatment, the iso-frequency surface of type II HMM transforms from a hyperbola to a bullet shape, while for type I HMM, the surface splits into two branches: a cylindrical-like branch at high k region and an elliptical branch at the low k region. In the high k region, the nonlocality set a cut-off k for the allowed wavenumbers in both type I and type II HMMs. This cut-off k which is defined by the electron Fermi velocity of the metal intrinsically limits the LDOS and light-matter interactions. These results indicate that in the aim of achieving high performance HMMs, merely thinning the constituent films according to the local theories is no longer valid.

9544-26, Session 5

Tunable VO2/Au hyperbolic metamaterial

Srujana Prayakarao, Norfolk State Univ. (United States); Brock Mendoza, Andrew Devine, Cornell Univ. (United States) and Norfolk State Univ. (United States); Chan Kyaw, Morehouse College (United States) and Norfolk State Univ. (United States); Robert B. Van Dover, Cornell Univ. (United States); Mikhail A. Noginov, Norfolk State Univ. (United States)

Vanadium oxide (VO2) is known to undergo a semiconductor-to-metal transition at 68°C. Therefore, it can be used as a tunable component of an active metamaterial. The lamellar metamaterial designed and studied in this work is composed of subwavelength VO2 and Au layers and is predicted to have the temperature controlled transition from the hyperbolic phase to the metallic phase. The VO2 films and VO2/Au lamellar metamaterial stacks have been fabricated and studied in the electrical conductivity as well as optical (transmission, reflection) experiments. The temperature depended changes in the absorption and transmission spectra of metamaterials and films have been observed experimentally and compared with the theory predictions.

9544-27, Session 6

Infrared spectroscopy with tunable graphene plasmons *(Invited Paper)*

Andrea Marini, Iván Silveiro, Javier Garcia de Abajo, ICFO - Institut de Ciències Fotòniques (Spain)

We propose the exploitation of plasmons in graphene nanoislands as

a promising platform for sensing through surface-enhanced infrared absorption and Raman scattering. Our calculations indicate that the large electrical tunability of graphene enables the identification of molecular resonances by recording broadband absorption or inelastic scattering, replacing wavelength-resolved light collection by a signal integrated over photon energy as a function of the graphene doping level. Our results pave the way for the development of novel cost-effective sensors capable of identifying spectral signatures of molecules without using spectrometers and laser sources.

9544-28, Session 6

Nano-photonic phenomena in van der Waals heterostructures *(Invited Paper)*

Dmitri N. Basov, Univ. of California, San Diego (United States)

van der Waals (vdW) crystals consist of individual atomic planes coupled by vdW interaction, similar to graphene monolayers in bulk graphite. We investigated van der Waals heterostructures assembled from atomically thin layers of graphene and hexagonal boron nitride (hBN). We launched, detected and imaged plasmonic, phonon polaritonic and hybrid plasmon-phonon polariton waves in a setting of an antenna based nano-infrared apparatus. Hyperbolic phonon polaritons in hBN enabled sub-diffractional focusing in infrared frequencies. Because electronic, plasmonic and phonon polaritonic properties in van der Waals heterstructures are intertwined, gate voltage and/or details of layer assembly enable efficient control of nano-photonic effects.

9544-29, Session 6

Second-harmonic generation from atomic-scale ABC-type laminate optical metamaterials *(Invited Paper)*

Luca Alloatti, Massachusetts Institute of Technology (United States) and Institute of Photonics and Quantum Electronics Karlsruhe Institute of Technology (Germany); Clemens M. Kieninger, Andreas M. Frölich, Matthias Lauermann, Tobias Frenzel, Kira Köhnle, Wolfgang Freude, Karlsruher Institut für Technologie (Germany); Juerg Leuthold, ETH Zürich (Switzerland); Christian Koos, Martin Wegener, Karlsruher Institut für Technologie (Germany)

We introduce ABC laminate metamaterials composed of layers of three different dielectrics. Each layer has zero bulk second-order optical nonlinearity, yet centro-symmetry is broken locally at each inner interface. To achieve appreciable effective bulk metamaterial second-order nonlinear optical susceptibilities, we densely pack many inner surfaces to a stack of atomically thin layers grown by conformal atomic-layer deposition. For the ABC stack, centro-symmetry is also broken macroscopically. Our experimental results for excitation at around 800 nm wavelength indicate interesting application perspectives for frequency conversion or electro-optic modulation in silicon photonics.

9544-111, Session 6

Metamaterials with magnetic hyperbolic dispersion

Sergey S. Kruk, The Australian National Univ. (Australia); Zi Jing Wong, Univ. of California, Berkeley (United States); Ekaterina Pshenay-Severin, Friedrich-Schiller-Univ. Jena (Germany) and The Australian National Univ. (Australia); Kevin O'Brien, Univ. of California, Berkeley (United States); Dragomir N. Neshev, Yuri S. Kivshar, The Australian National Univ. (Australia); Xiang Zhang, Univ. of California, Berkeley (United States)

Strongly anisotropic media, where the principal components of the dielectric permittivity and/or permeability tensor have opposite signs, are called hyperbolic media. The study of hyperbolic media and hyperbolic metamaterials have attracted significant attention in recent years for their interesting properties such as high density of states, all-angle negative refraction, and hyperlens imaging beyond the resolution of conventional systems. In previous studies hyperbolic media were realized as uniaxial materials whose axial and tangential dielectric permittivities have opposite signs. Such media are typically realized using the metamaterial concept in the form of metal-dielectric multilayered structures, or arrays of conducting nanowires, while several examples of natural hyperbolic media have been demonstrated as well. However, the hyperbolic dispersion in all artificial and natural optical media demonstrated to date has its origin in the electric response. This restricts fundamentally the functionality of these materials for only one polarization of light and places severe limitation for the impedance matching with a free space. Importantly, the concept of generalized hyperbolic media with both electric and magnetic response does not have these restrictions. Here we present the first demonstration of a magnetic hyperbolic dispersion in a three-dimensional metal-dielectric multilayer metamaterial with principal components of the effective magnetic permeability tensor having opposite signs. We provide a systematic direct measurement of a topology-driven transition between elliptic and hyperbolic metamaterials observed through a structural modification of their dispersion, reported for the time for any type of metamaterial. Our findings show the possibility for realization of efficient hyperbolic media for unpolarised light.

9544-30, Session 7

Transparent conducting oxides as plasmonic component in near infrared *(Invited Paper)*

Jongbum Kim, Nathaniel Kinsey, Aveek Dutta, Purdue Univ. (United States); Marcello Ferrera, Purdue Univ. (United States) and Heriot-Watt Univ. (United Kingdom); Clayton Devault, Alexander V Kildishev, Vladimir M. Shalaev, Alexandra Boltasseva, Purdue Univ. (United States)

The development of new plasmonic materials enables novel optical devices, and they in turn assist in the progress of optical communications. As a result of the significant attention in searching for alternative materials, transparent conducting oxides (TCOs) have been proposed as promising plasmonic compounds at telecommunication wavelengths [1]. They are eminently practical materials because they are CMOS-compatible, can be grown on many different types of substrates, patterned by standard fabrication procedures, and integrated with many other standard technologies.

Due to the ability of TCO nanostructures to support strong plasmonic resonance in the NIR, metasurface devices, such as a quarter wave plate, have been demonstrated whose properties can be easily adjustable with post processing such as thermal annealing [2,3]. Additionally, TCOs can be used as epsilon near zero (ENZ) materials in the NIR. From our recent study of the behavior of nanoantennae sitting upon a TCO substrate, we found that TCOs serve as an optical insulating media due to the high impedance of TCOs at the ENZ frequency, enabling emission shaping.

Finally, the optical properties of TCOs can be varied by optical or electrical means. Current research is focused on studying the ultrafast carrier dynamics in doped zinc oxide films using pump-probe spectroscopy. We have shown that aluminum doped zinc oxide films can achieve a 40% change in reflection with ultrafast dynamics (<1ps) under a small fluence of 3mJ/cm2. Consequently, TCOs are shown to be extremely flexible materials, enabling fascinating physics and unique devices for applications in the NIR regime.

Towards low-loss, infrared and THz nanophotonics and metamaterials: surface phonon polariton modes in polar dielectric crystals *(Invited Paper)*

Joshua D. Caldwell, U.S. Naval Research Lab. (United States); Lucas Lindsey, Oak Ridge National Lab. (United States); Vincenzo Giannini, Imperial College London (United Kingdom); Igor Vurgaftman, Thomas L. Reinecke, U.S. Naval Research Lab. (United States); Stefan A. Maier, Imperial College London (United Kingdom); Orest J. Glembocki, Oak Ridge National Lab. (United States) and U.S. Naval Research Lab. (United States)

The field of nanophotonics is based on the ability to confine light to sub-diffractional dimensions. Up until recently, research in this field has been primarily focused on the use of plasmonic metals. However, the high optical losses inherent in such metal-based surface plasmon materials has led to an ever-expanding effort to identify, low-loss alternative materials capable of supporting sub-diffractional confinement. One highly promising alternative are polar dielectric crystals whereby sub-diffraction confinement of light can be achieved through the stimulation of surface phonon polaritons within an all-dielectric, and thus low loss material system. Both SiC and hexagonal BN are two exemplary SPhP systems, which along with a whole host of alternative materials promise to transform nanophotonics and metamaterials in the mid-IR to THz spectral range. In addition to the lower losses, these materials offer novel opportunities not available with traditional plasmonics, for instance hyperbolic optical behavior in natural materials such as hBN, enabling super-resolution imaging without the need for complex fabrication. This talk will provide an overview of the SPhP phenomenon, a discussion of what makes a 'good' SPhP material and recent results from SiC and the naturally hyperbolic material, hBN from our research group.

Spectroscopy of semiconductor meta-device building blocks

Nikita A. Butakov, Jon A. Schuller, Univ. of California, Santa Barbara (United States)

Inspired by the potential of designing highly efficient nanophotonic optical elements, numerous researchers are currently exploring the use of dielectric resonators in constructing meta-devices. A wide range of optical components have been demonstrated, including metasurfaces that act as two-dimensional lenses, gratings, and axicons. At the core of these devices is a dielectric building block, typically a Silicon nano-disk or nano-rod, that supports Mie-like leaky mode excitations with a geometrically tunable amplitude and phase response. Here we present a comprehensive experimental characterization of these building blocks. We elucidate their multipolar mode structure, and explain the dependence on the underlying substrate. We find that fundamentally new buried magnetic modes emerge in high-index substrates, and that Fabry-Perot effects in silicon-on-insulator platforms can be utilized to enhance or suppress specific modes. When individual resonators are arranged into arrays with sub-wavelength periodicities, inter-particle coupling leads to a shift in the resonant response. When the periodicities are on the same order as the operating wavelength, the localized resonances may couple with the global diffraction modes, leading to the possible formation of distinct high-quality-factor surface-lattice-resonant modes, similar to those encountered in plasmonic gratings. We conclude by exploring the behavior of resonators constructed out of active materials, such as polar materials that support phonon-polariton excitations, and phase-change materials with tunable dielectric constants.

Properties of infrared doped semiconductor Mie resonators

Tomer Lewi, Univ. of California Santa Barbara (United States); Prasad P. Iyer, Nikita A. Butakov, Jon A. Schuller, Univ. of California, Santa Barbara (United States)

Dielectric optical antenna resonators have recently emerged as a viable alternative to plasmonic resonators for metamaterials and nanophotonic devices, due to their ability to support multipolar Mie resonances with low losses. In this work, we experimentally investigate the mid-infrared Mie resonances in Si and Ge subwavelength spherical particles. In particular, we leverage the electronic and optical properties of these semiconductors in the mid-infrared range to design and tune Mie resonators through free-carrier refraction.

Si and Ge semiconductor spheres of varying sizes of 0.5-4 ?m were fabricated using femtosecond laser ablation. Using single particle infrared spectroscopy, we first demonstrate size-dependent Si and Ge Mie resonances spanning the entire mid-infrared (2-16 ?m) spectral range. Subsequently we show that the Mie resonances can be tuned by varying material properties rather than size or geometry. We experimentally demonstrate doping-dependent resonance frequency shifts that follow simple Drude models of free-carrier refraction. We show that Ge particles exhibit a stronger doping dependence than Si due to the smaller effective mass of the free carriers. Using the unique size and doping dispersion of the electric and magnetic dipole modes, we identify and demonstrate a size regime where these modes are spectrally overlapping. We also demonstrate the emergence of plasmonic resonances for high doping levels and long wavelengths. These findings demonstrate the potential for tuning infrared semiconductor Mie resonances by optically or electrically modulating charge carrier densities, thus providing an excellent platform for tunable electromagnetic metamaterials.

All dielectric near-field transducers for optical field concentration at the nanometer scale and heat assisted magnetic recording *(Invited Paper)*

Andrey K. Sarychev, Institute for Theoretical and Applied Electrodynamics (Russian Federation); Sergey Vergeles, L.D. Landau Institute for Theoretical Physics (Russian Federation) and Moscow Institute of Physics and Technology (Russian Federation); Alexei L. Bogdanov, Stanley Burgos, HGST (United States)

Concentration of light into nanospots is greatly beneficial for applications such as heat assisted magnetic recording (HAMR), biomedical imaging and sensing, optical microscopy with single-molecule resolution, quantum plasmonics, nanolasing, etc. We propose novel, all-dielectric near field transducers (NFT), which allow focusing light into a hot spot, much smaller than the wavelength. In existing HAMR heads with metal plasmonic NFT, light is typically concentrated at a metallic tip, which appears to be one of the hottest spots of the whole head and, thus, is most severely affected by thermal stress, dramatically shortening usable lifetime of the head. However, if the NFT optical components are fully dielectric and optically lossless, the hottest temperature spot is at the surface of the targeted media in the vicinity of the tip, but not within the NFT itself. Thus, the aforementioned detrimental thermal effects can be significantly reduced and head life time is greatly increased opening new venue in the magnetic recording.

We propose the dielectric NFT in the form of the pumped dielectric resonator.

The electric field concentrates at the tip of the prolate dielectric beak attached to the resonator. For a sufficiently elongated beak, the intensity of the field just outside the tip of the beak is Eps times larger than the resonator field, where Eps is the permittivity of the resonator+beak. A cascade enhancement of the electric field is being achieved: first, there is a resonance in the dielectric resonator, and then the resonant field is further amplified due to the dipole polarization of the beak.

9544-110, Session 7

Nonlinear optical metamaterials *(Invited Paper)*

Xiang Zhang, Univ. of California, Berkeley (United States)

Nonlinear metamaterials, manmade structures in which the electromagnetic fields can change material properties, have potential for frequency conversion, amplification, and switching. Phase-matching is critical for coherent nonlinear optical processes, allowing nonlinear sources to combine constructively, resulting in more efficient emission. We discuss phase matching in zero index optical metamaterials, single plasmonic nanostructures, and others.

Nonlinearities in hyperbolic plasmonic metamaterials *(Invited Paper)*

Andres D. Barbosa Neira, Silvia Peruh, Giuseppe Marini, Mazhar Nasir, Alexey V. Krasavin, Nicolas Olivier, Wayne Dickson, Gregory A. Wurtz, Anatoly V. Zayats, King's College London (United Kingdom)

We will present experimental studies and numerical modeling of nonlinear optical processes in plasmonic metamaterials based on assemblies of metallic nanorods and other complex geometries. Second- and third-order nonlinear optical response originating from a plasmonic component of the metamaterial will be discussed. Such plasmonic metamaterials can be used for engineering enhanced nonlinear optical properties with the required spectral and temporal response. We will also discuss a novel concept of an on-chip ultrafast all-optical modulator based on a hyperbolic metamaterial integrated in a silicon waveguide.

9544-36, Session 8

Mid-infrared hyperbolic metamaterial based on graphene-dielectric multilayers *(Invited Paper)*

Theodore B. Norris, You-Chia Chang, Che-Hung Liu, Chang-Hua Liu, Univ. of Michigan (United States); Siyuan Zhang, Seth R. Marder, Georgia Institute of Technology (United States); Zhaohui Zhong, Univ. of Michigan (United States)

Graphene is an interesting building block for metamaterials due to its atomic thickness and the ability to modify the optical properties by chemical doping or electrical gating. We have designed and fabricated a hyperbolic metamaterial composed of alternating Al2O3 and chemical-vapor-deposited (CVD) graphene. This hyperbolic metamaterial operates in the mid-infrared range, where CVD graphene has minimal loss. The effective medium approximation can accurately describe the metamaterial due to large wavelength-to-periodicity ratio. Fabrication is done by repeated graphene transfer and atomic layer deposition. Using an infrared ellipsometer, the anisotropic effective permittivities is measured, showing a transition from elliptical to hyperbolic dispersion.

9544-37, Session 8

LCR model for the design of hyberbolic metamaterials

Christopher Rosenbury, Daniel B. Fullager, Michael A. Fiddy, The Univ. of North Carolina at Charlotte (United States)

In an HMM, we assumed layer thicknesses are small on the scale of the wavelength and alternate layers can have positive and negative permittivity. Surface plasma waves are generated on the boundaries. These plasma waves create image charge distributions in neighboring conducting layers due to the small separation between sheets. These image charge distributions have a phase lag due to the interaction of the inductance and the capacitance. As the image charge distributions propagate through the layers, the lag increases. This effect gives a volume distribution of modes for any single frequency of generated plasma waves. One can physically interpret this as what gives rise to the hyperbolic density of states in a HMM. By treating the HMM as an LCR circuit, the density of states and the dispersion relation can be engineered to fit any desired parameters since such changes can be directly tied to alterations in the physical parameters of the structure. As the number of layers increases and hence the number of occupied modes increases, the transfer of energy into increasing high k-modes occurs and this can also be understood using the LCR model. Finite feature sizes in the HMM will limit the maximum k vector by diffraction. This makes the LCR model a valuable tool in the design of HMM's.

9544-39, Session 8

Optical mode confinement in three-dimensional Al/SiO2 nano-cavities with hyperbolic dispersion

Carla M. Bacco, Priscilla N. Kelly, Lyuba Kuznetsova, San Diego State Univ. (United States)

Today's technological needs are demanding for faster and smaller optical components. Optical microcavities offer a high confinement of electromagnetic field in a small volume, with dimensions comparable to the wavelength of light, which provides a unique system for the enhancement of light-matter interactions on the nanoscale. However, further reducing the size of the optical cavity (from microcavity to nanocavity) is limited to the fundamental diffraction limit. In hyperbolic metamaterials, large wavevectors can be achieved [1]. Therefore, optical cavities, created from hyperbolic metamaterials, allow the confinement of the electromagnetic field to an extremely small volume with dimensions significantly smaller than the wavelength of light.

This paper presents the results of numerical study of the optical mode confinement in nanocavities with hyperbolic dispersion using nanolayered Al/SiO2 hyperbolic metamaterial [2] with different Al fill fractions. The fundamental properties of the optical modes and resonance frequencies for the nanocavities are studied using the finite-difference time-domain numerical technique. Numerical simulations show that the light can be adequately confined to a space 22 times smaller than a silicon oxide disk. Reducing the cavity size further doubled the Purcell factor for the disk with aluminum doping.

Beyond this point, the cavities exhibited antenna-like properties. This paper will also focus on other variables of mode confinement such as quality factor, loss, and fill fraction. Potential future applications for three-dimensional nanocavities with hyperbolic dispersion include: silicon photonics optical communications networks, ultrafast LEDs and biological nanoparticles sensing.

Thermal radiation of metallic surfaces and hyperbolic metamaterials

Mikhail A. Noginov, A. Mozafari, Thejaswi U. Tumkur, John K. Kitur, Norfolk State Univ. (United States); Evgenii E. Narimanov, Purdue Univ. (United States)

We studied angular distributions and spectra of thermal radiation of lamellar metal/dielectric metamaterials with hyperbolic dispersion and compared them with the corresponding characteristics of simple metallic films and pairs of metallic and dielectric layers. The spectra of thermal radiation, in the mid-infrared part of the spectrum, were nearly flat and featureless, in a good agreement with the model predictions. The angular distributions of thermal emission closely followed the Lambert's law, ?cos?. The thermal radiation properties of hyperbolic metamaterials were not much different from those of simpler metallic structures.

Rare-Earth frequency converters for thermophotovoltaics-revisiting century old claims

Ekembu K. Tanyi, Brandi T. Burton, Norfolk State Univ. (United States); Evgenii E. Narimanov, Purdue Univ. (United States); Mikhail A. Noginov, Norfolk State Univ. (United States)

Harnessing more energy from the sun has led to the development of materials which can efficiently trap the sun radiation in the whole spectrum and re-emit it into a narrow spectral band corresponding to the band gap of a photovoltaic device. The field of metamaterials is largely aimed at designing nanostructured surfaces with tailored absorption (emission) spectra. Many rare-earth doped crystals and glasses can efficiently absorb light throughout the whole visible and near-infrared range of the spectrum and emit radiation at longer wavelengths (1.5 to 3 microns). We report studies of absorption and thermal emission of several rare-earth doped crystals.

9544-42, Session 9

Energy conversion and photo-thermal effect within plasmonic absorption metamaterials in infrared region

Yongqian Li, Chenglin Zhang, Lei Su, Xiaoying Li, Northwestern Polytechnical Univ. (China); Zili Zhou, Science and Technology on Metrology and Calibration Lab. (China)

The energy-conversion process and photo-thermal effect within a plasmonic absorber metamaterials (PAM) were investigated theoretically using the Poynting theorem. The Ohmic loss and dielectric loss were calculated to estimate the amount of heat energy produced. The heat-generation within the PAM was studied numerically. From the microscopic details, the heat-generation owing to the electric current accounts for the majority of the energy conversion, while the magnetic resonance plays a negligible role. The distinct resonant peaks of the PAMs are attributed to the polarization sensitive excitation of plasmonic resonance. The strong field confinement and redistribution inside the structure of the PAM were investigated for use in a subsequent thermal-detection design. Field redistribution and enhancement associated with multiplex resonant electromagnetic wave passing through the PAM medium provided insight into the energy conversion processes inside the nanostructure.

9544-43, Session 9

Design and analysis of chevrons shaped split ring resonator in the mid-infrared region

Neerad Nandan, Than Singh Saini, Ajeet Kumar, Ravindra K. Sinha, Delhi Technological Univ. (India)

The terahertz region of the electromagnetic spectrum is relatively new area of interest and incorporates a wide range of applications from image sensing to spectroscopy and many more yet to be discovered. In the area of metamaterials many new designs have been discovered, but "chevrons" shaped split ring resonators (ch-SRRs) in the mid-infrared region has not been studied to the best of our knowledge. This paper presents the analysis and simulation of ch-SRRs in the mid infrared region. Tunability of SRRs is important for various industrial and scientific applications and hence this paper analyzes the tunability of the ch-SRRs by variation of angle. The device is simulated in two configurations i.e., one with two chevrons shaped SRRs on the same plane of the dielectric substrate and the other with each of the two chevron shaped SRRs on the opposite plane of the substrate. Standard polarization method for SRR has been used. Gold SRRs is used, since we are working in the terahertz region Lorentz-Drude model is employed. The ch-SRRs have been embedded upon the silicon substrate. The numerical simulation software uses finite element method (FEM) method to simulate the results. The results obtained for reflectance and transmittance are of particular interest. The effective medium parameters viz. Impendence, permittivity, permeability and refractive index obtained for the split ring resonator are also evaluated. This design is improvement over single chevron design with respect to the sharpness of reflectance as well as transmittance curves which may be of specific interest.

9544-44, Session 9

Colossal optical transmission through buried metal gratings

Christopher M. Roberts, Univ. of Massachusetts Lowell (United States); Runyu Liu, Xiang Zhao, Lan Yu, Xiuling Li, Daniel M. Wasserman, Univ. of Illinois at Urbana-Champaign (United States); Viktor A. Podolskiy, Univ. of Massachusetts Lowell (United States)

In Extraordinary Optical Transmission (EOT), a metallic film perforated with an array of [periodic] apertures exhibits transmission over 100% normalized to the total aperture area, at selected frequencies. EOT devices have potential applications as optical filters and as couplers in hybrid electro-optic contacts/devices. Traditional passive extraordinary optical transmission structures, typically demonstrate un-normalized transmission well below 50%, and are typically outperformed by simpler thin-film techniques. To overcome these limitations, we demonstrate a new breed of extraordinary optical transmission devices, by "burying" an extraordinary optical transmission grating in a dielectric matrix via a metal-assisted-chemical etching process. The resulting structure is an extraordinary optical transmission grating on top of a dielectric substrate with dielectric nano-pillars extruded through the grating apertures. These structures not only show significantly enhanced peak transmission when normalized to the open area of the metal film, but more importantly, peak transmission greater than that observed from the bare semiconductor surface. The structures were modeled using three-dimensional rigorous coupled wave analysis and characterized experimentally by Fourier transform infrared reflection and transmission spectroscopy, and the good agreement between the two has been demonstrated. The drastic enhancement of light transmission in our structures originates from structuring of high-index dielectric substrate, with pillars effectively guiding light through metal apertures.

9544-45, Session 9

Experimental verification of classical electromagnetically induced transparency in conductors

Adil-Gerai Kussow, Yassine Ait-Ei Aoud, Alkim Akyurtlu, Univ. of Massachusetts Lowell (United States)

The effect of electromagnetically induced transparency in non-Ohmic conductors, being based on the concepts of classical nonlinear optics was discussed recently. We report an experimental demonstration of this effect within the mid-IR wavelength range. A low-dispersion semiconductor, i.e. ZnTe, and a highly dispersive Au were subjected to bichromatic parametric irradiation with a certain frequencies, amplitudes, phases, and polarizations of a constituent waves. When a specific phase matching conditions are satisfied, experimental evidence for strong signature of EIT was found. The optical losses were considerably reduced in both materials. This effect can be utilized to improve the optical quality of metamaterials.

9544-46, Session 10

Guiding electromagnetic waves around sharp corners: topologically protected photonic transport in meta-waveguides *(Invited Paper)*

Gennady B. Shvets, The Univ. of Texas at Austin (United States); Alexander B. Khanikaev, Queens College (United States); Tzuhsuan Ma, Kueifu Lai, The Univ. of Texas at Austin (United States)

Science thrives on analogies, and a considerable number of inventions and discoveries have been made by pursuing an unexpected connection to a very different field of inquiry. For example, photonic crystals have been referred to as “semiconductors of light” because of the far-reaching analogies between electron propagation in a crystal lattice and light propagation in a periodically modulated photonic environment. However, two aspects of electron behavior, its spin and helicity, escaped emulation by photonic systems until recent invention of photonic topological insulators (PTIs). The impetus for these developments in photonics came from the discovery of topologically nontrivial phases in condensed matter physics enabling edge states immune to scattering. The realization of topologically protected transport in photonics would circumvent a fundamental limitation imposed by the wave equation: inability of reflections-free light propagation along sharply bent pathway. Topologically protected electromagnetic states could be used for transporting photons without any scattering, potentially underpinning new revolutionary concepts in applied science and engineering.

I will demonstrate that a PTI can be constructed by applying three types of perturbations: (a) finite bianisotropy, (b) gyromagnetic inclusion breaking the time-reversal (T) symmetry, and (c) asymmetric rods breaking the parity (P) symmetry. We will experimentally demonstrate (i) the existence of the full topological bandgap in a bianisotropic, and (ii) the reflectionless nature of wave propagation along the interface between two PTIs with opposite signs of the bianisotropy.

9544-47, Session 10

Light emission in nonlocal plasmonic metamaterials *(Invited Paper)*

Viktor A. Podolskiy, Brian Wells, Univ. of Massachusetts Lowell (United States); Pavel Ginzburg, Anatoly V. Zayats, King’s College London (United Kingdom)

Plasmonic metamaterial composites are often considered to be promising building blocks for a number of applications that include subwavelength light manipulation, imaging, and quantum optics engineering. These applications often rely on effective medium response of metamaterial composites and require metamaterial to operate in exotic (hyperbolic, or epsilon-near-zero) regimes. However, the behaviour of metamaterials is often different from the predictions of effective medium. In this work we aim to understand the implications of composite nature of metamaterials on their optical properties. Plasmonic nanowire metamaterials are a convenient metamaterial platform that is capable of realization of ENZ, hyperbolic, and elliptic responses depending on light frequency and metamaterial geometry. In this work we show that the response of metamaterial in elliptical regime may be strongly affected by the additional electromagnetic wave that represents collective excitation of cylindrical surface plasmons in nanowire arrays. We present an analytical description of optical properties of additional wave and analyse the effect of this mode on quantum emitters inside nanorod metamaterials.

9544-48, Session 10

Metamaterials for group-velocity dispersion compensation

Philippe Tassin, Chalmers Univ. of Technology (Sweden); Babak Dastmalchi, Thomas Koschny, Costas M. Soukoulis, Ames Lab. (United States) and U.S. Dept. of Energy (United States) and Iowa State Univ. of Science and Technology (United States)

In this contribution, we present our results concerning metamaterials for group-velocity dispersion compensation. Resonant metamaterials usually exhibit substantial dispersion, which is considered a shortcoming for many applications. But we can also take advantage of the ability to tailor the dispersive response of a metamaterial, introducing a new method of group-velocity dispersion compensation. The method consists of stacking a number of highly dispersive sheet metamaterials and is capable of compensating the dispersion of optical fibers with either negative or positive group-velocity dispersion coefficients. We demonstrate that the phase-engineered metamaterial, essentially consisting of a metasurface exhibiting the classical analogue of electromagnetically induced transparency, can provide strong group-velocity dispersion management without being adversely affected by large transmission loss, while at the same time offering high customizability and a small footprint.

9544-49, Session 10

Multi-foci metalens for spin and orbital angular momentum interaction

Shengtao Mei, Cheng-Wei Qiu, Muhammad Qasim Mehmood, Kun Huang, National Univ. of Singapore (Singapore)

The emergence of two-dimensional version of Metamaterial, named metasurface, provides an intriguing methodology for designing miniaturized and integrated optical devices owing to their ultrathin merit. Here we theoretically propose and experimentally demonstrate a multi-foci metalens for spin-orbital angular momentum interaction (SOI). The designed metasurface consists of a monolayer of metallic nano-void antenna with spatially varying orientation. Compared with traditional lens, such flat lens takes advantage of its ultrathin trait to multi orbital angular momentum (OAM) focal points, namely, OAM with different topological charge are focused onto different focal planes. Meanwhile, due to the dual-polarity feature brought by the Pancharatnam–Berry phase based metasurface, we observe several pairs of OAM focal points with opposite topological charges on both sides of the metalens. These pairs correspond to different parts of the multiple ring-shape lens, in which real and virtual OAM foci are achieved by opposite helical incident light. It is also observed that only linearly polarized lights can produce both real and virtual OAM foci simultaneously. The designed metalens may find potential applications in multi-particle manipulation, angular-momentum-based quantum information processing and integrated nano-optoelectronics.

9544-50, Session 10

Birefringence modulation of thermally-driven metal nanograting

Takashi Shimura, Miho Ishii, Kentaro Iwami, Hideaki Nagasaki, Norihiro Umeda, Tokyo Univ. of Agriculture and Technology (Japan)

Subwavelength metallic grating has been known to have giant birefringence for visible light. The authors have been produced Au nanograting half wave plate for visible light. Recently, reconfigurable photonic metamaterial fabricated on Au/Si3N4 bimorph beams have been reported that modulate transmittance of near-infrared light by thermal deflection of beams. In this paper, nanograting of thermally-driven bimorph beams was developed that modulate birefringence for at the wavelength of 650 nm. The nanoslits are consisted of Au/SiO2 bimorph beams, and actuated by Joule heating. The width and length of the beam is 300 nm and 20 ?m, respectively. The thickness of Au and SiO2 is 200 nm, respectively. From FDTD simulation, the phase difference at 650 nm is calculated to be modulated from 0 to 45 degree by actuating bimorph beams. The phase modulator is fabricated on the glass substrate using EB lithography, lift-off process and sacrificial layer etching. The phase difference of fabricated modulator was measured at the wavelength range of from 500 to 800 nm with a driving voltage of 10 V. Phase modulation is obtained on the broad wavelength range, and the maximum variation is -3.3 degree at 646 nm. The drive current is 100 mA. Measured modulation was relatively small to simulation. As it is considered to be due to small displacement of beams and it can be improved by refining fabrication process. Because of the modulating characteristics and ultra-small scale, this modulator is expected to be applied as a new display module.

9544-51, Session 10

Building novel nanophotonics devices using symmetry considerations

Boubacar Kante, Univ. of California, San Diego (United States)

Symmetries play a fundamental role in engineering. In this talk, I will show how symmetry considerations can enable novel nanophotonics devices with advanced functionalities. Novel electromagnetic cavities that can hold light for an infinite amount of time will be introduced as well as the design of novel metamaterials built solely from symmetry considerations. I will present a realized closed ring negative index metamaterial and a self-assembled symmetry breaking metamaterials with controllable optical response.

9544-52, Session 11

Laser processing of metamaterial structures *(Invited Paper)*

Alberto Piqué, Nicholas A. Charipar, Heungsoo Kim, Eric Breckenfeld, Scott A. Mathews, U.S. Naval Research Lab. (United States)

The use of metamaterials structures has been the subject of extensive discussions given their wide range of applications. However, a large fraction of the work available to date has been limited to simulations and proof-of-principle demonstrations. One reason for the limited success inserting these structures into functioning systems and real-world applications is the high level of complexity involved in their fabrication. Direct-write processes are ideally suited for the fabrication of arbitrary periodic and aperiodic structures found in most metamaterial and plasmonic designs. For these applications, laser-based processes offer numerous advantages since they can be applied to virtually any surface over a wide range of scales. Furthermore, laser direct-write or LDW allows the precise deposition and/or removal of material thus enabling the fabrication of novel metamaterial designs. This presentation will show examples of metamaterial and plasmonic structures developed at the Naval Research Lab using LDW, and discuss the benefits of laser processing for these applications.

This work was sponsored by The Office of Naval Research.

9544-53, Session 11

Large-area, low-cost plasmonic perfect absorber sensor fabricated by laser interference lithography *(Invited Paper)*

Shahin Bagheri, Nikolai Strohfeldt, Andreas Tittl, Harald Giessen, Univ. Stuttgart (Germany)

We employ laser interference lithography as a reliable method to create nanowire and nanorod arrays in photopolymers for manufacturing plasmonic perfect absorber sensors over a homogeneous area as large as 2 cm2. Subsequently we transfer the fabricated pattern into a metal layer by using argon ion beam etching techniques. Geometry and periodicity of our large-area metallic nanostructures are precisely controlled by adjusting the interference conditions during single- and double-exposure processes, resulting in structures with spectrally selective perfect absorption of light from the visible to the mid-infrared wavelength range. We also demonstrate the applicability of our large-area structures for hydrogen detection schemes by measuring the hydrogen sensing performance of a palladium-based perfect absorber operating in the visible wavelength range. Since palladium changes its optical properties upon hydrogenation, exposure of the sample to hydrogen gas causes fast and reversible changes in the absorption of light which is easily measured by an FTIR microscope. Our large-area perfect absorber sensor provides nearly perfect absorption of light at 730 nm, and the reflectance changes from 1 % to 5 % in the presence of hydrogen. The large-area and fast fabrication process makes our approach highly attractive for simple and low-cost sensor fabrication, which is suitable for industrial production of plasmonic devices in the near future.

9544-54, Session 11

Design and analysis of near-perfect metamaterial reflector in visible range

Ravindra K. Sinha, Nishant Shankhwar, Delhi Technological Univ. (India)

A unit cell was simulated in frequency domain using COMSOL Multiphysics and s parameters were obtained. Reflection and transmission coefficients were analysed to optimize the Aspect ratio (height/base diameter) of cone in order to achieve highest reflectivity. Using s-parameters, material properties-effective refractive index (neff), permittivity (?), permeability (μ) and impedance (?) were calculated. The underlying principle for this property is Mie Resonance in dielectric. Reflectivity is high when either electric or magnetic (but not both) resonance exists and real part of impedance is close to zero. These conditioned are satisfied and the structure shows high reflectivity in the range 650nm-730nm leading to ~99.99% reflectivity at wavelengths 660nm and 720nm.

9544-55, Session 11

The Silicon photomultiplier as a metasystem with designed electronics as metadevice for a new receiver-emitter in visible light communications

Rafael M. Gutierrez, Luis Castañeda, Javier Castaño, Univ. Antonio Nariño (Colombia)

A Silicon Photomultiplier, SiPM, can be considered a metasystem of microscopic Avalanche Photodiodes, APDs, which embedded in a specific purpose electronic, becomes a metadevice with unique and useful advanced

functionalities by transforming microscopic quantum processes of the radiation-matter interaction into macroscopic detectable classical electronic signals. This metadevice provides new capacities to capture, transmit and analyze information with increased efficiency and security. The SiPM is a very small state of the art photo-detector made of a matrix arrangement of many APDs (thousands by mm2), with very high efficiency and sensitivity, it has a well define frequency response, is unaffected by magnetic fields and has very high photo-electric gain. New results of R&D, some of them performed at the "Laboratorio de Detectores" of the Universidad Antonio Nariño, demonstrate that the metadevice constituted by the SiPM and an appropriated designed electronics, has a very good response to controlled light pulses in the presence of background light without presenting saturation. In this work we present some results of this metadevice to understand and profit its advanced functionalities in transforming photo-detection into electronic signals to propose a new receiver-emitter device for Visible Light Communication, VLC. This metadevice is highly sensitive to fast and low intensity pulses and does not show saturation, therefore, it does not need filters; both are challenges of the receiver-emitter devices presently used in VLC. This new VLC receiver-emitter metadevise, could facilitate new and diverse applications by introducing and developing state of the art high energy physics photo-detectors into VLC.

9544-58, Session 11

Metamaterial-based single pixel imaging system *(Invited Paper)*

Willie Padilla, Duke Univ. (United States); Claire M. Watts, Boston College (United States); Christian Nadell, Duke Univ. (United States); John A. Montoya, Sanjay Krishna, The Univ. of New Mexico (United States)

Single pixel cameras are useful imaging devices where it is difficult or infeasible to fashion focal plan arrays. For example in the Far Infrared (FIR) it is difficult to perform imaging by conventional detector arrays, owing to the cost and size of such an array. The typical single pixel camera uses a spatial light modulator (SLM) - placed in the conjugate image plane – and is used to sample various portions of the image. The spatially modulated light emerging from the SLM is then sent to a single detector where the light is condensed with suitable optics for detection. Conventional SLMs are either based on liquid crystals or digital mirror devices. As such these devices are limited in modulation speeds of order 30 kHz. Further there is little control over the type of light that is modulated.

We present metamaterial based spatial light modulators which provide the ability to digitally encode images – with various measurement matrix coefficients – thus permitting high speed and fidelity imaging capability. In particular we use the Hadamard matrix and related S-matrix to encode images for single pixel imaging. Metamaterials thus permit imaging in regimes of the electromagnetic spectrum where conventional SLMs are not available. Additionally, metamaterials offer several salient features that are not available with commercial SLMs. For example, metamaterials may be used to enable hyperspectral, polarimetric, and phase sensitive imaging. We present the theory and experimental results of single pixel imaging with digital metamaterials in the far infrared and highlight the future of this exciting field.

9544-56, Session 12

Device applications of metafilms and metasurfaces *(Invited Paper)*

Mark L. Brongersma, Geballe Lab. for Advanced Materials (GLAM) (United States)

Many conventional optoelectronic devices consist of thin, stacked films of metals and semiconductors. In this presentation, I will demonstrate how one can improve the performance of such devices by nano-patterning the constituent layers at length scales below the wavelength of light. The resulting metafilms and metasurfaces offer opportunities to dramatically modify the optical transmission, absorption, reflection, and refraction properties of devices. This is accomplished by encoding the optical response of nanoscale resonant building blocks into the effective properties of the films and surfaces. To illustrate these points, I will show how nanopatterned metal and semiconductor layers can be used to enhance the performance of solar cells, photodetectors, and enable new imaging technologies. I will also demonstrate how the use of active building blocks can facilitate the creation of active metafilm devices.

9544-57, Session 12

Mechanics meets plasmonics: new devices and sensors *(Invited Paper)*

Ertugrul Cubukcu, Univ. of Pennsylvania (United States)

In this talk, we will discuss our recent result on new types of devices and sensors enabled by on chip integration of plasmonic resonators and mechanical microresonators. In the first part, we will talk about low noise infrared thermal optomechanical detectors based on nanoantenna light absorbers. In the second part, we will present our work on hybrid multimode optomechanical biosensors with an ultra large dynamic sensing range. In the last part, voltage tunable Fano resonances arising from the coupling of Fabry-Perot and nanoantenna resonances in a metamaterial perfect absorber that supports strong optomechanical coupling will be introduced.

9544-59, Session 12

Design theory of thin film hyperbolic metamaterial collimators

Daniel B. Fullager, Michael A. Fiddy, The Univ. of North Carolina at Charlotte (United States)

Hyperbolic metamaterial (HMM) research has led to the fabrication of devices which have unbounded k-space ellipsoids. Alternating layers of films with alternating signs of relative permittivity or permeability in a given direction enable multi-layer surfaces that are, in theory, either perfectly reflective or transmissive at an angle dependent upon the free space wave vector and ratios of the permittivity or permeability in the normal and transverse directions. By having knowledge of the electromagnetic properties of the constituent materials of a multi-layer HMM over a given bandwidth, the functionality of these structures can be altered by changing the fill fraction of the constituents. One potential device design that results is that of a flat electromagnetic wave collimator. The degree to which a multi-layer HMM collimates comes from the contrast in the magnitudes of the relative permeability or permittivity in the normal and transverse directions. With large material parameter contrast at a given frequency, the transverse wave vectors that allow for successful EM wave propagation at the HMM/atmosphere interface approach zero. This leads to propagation of a narrow angular cone of waves relative to the surface normal of the HMM. Herein we show that the transfer matrix method is in relatively good agreement with finite element method electromagnetic simulations performed in COMSOL's RF module and compare dispersion relations of known materials to the resulting collimation generated in a corresponding HMM. We thereby use existing material data and predictive theories show how to tailor the frequency response of HMMs.

9544-60, Session 12

Engineering optical systems using transformation optics

Saul Wiggin, Queen Mary, Univ. of London (United Kingdom)

This paper presents a method for calculating theZernike aberrations in a lens design using transformation opticsin FDTD. Currently there is no literature on calculating imageaberrations in FDTD. In this paper I divulge the methods tocalculate the Zernike aberration using a polynomial fitting fora wavefront.

The results are shown to match very well with theZernike aberrations in an equivalent lens in ZEMAX

9544-61, Session 12

Plasmonic photocathodes

Rosa A. Lukaszew, Zhaozhu Li, Kaida Yang, Jose Riso, The College of William & Mary (United States)

Surface Plasmon polaritons (SPPs) on patterned surfaces have drawn attention since this approach enables enhancement of the electric field intensity near the patterned surface, which may be important for specific applications,such as photoemission. Due to interaction of the incident light with the nanopatterm, SPPs can exhibit a different response as consequence of the choice of the pattern parameters. This may offer improved performance in certain applications, for example increased quantum efficiency in metallic photocathodes exploiting this phenomenon. In the present case we utilized conformal growth of metallic layers onto optical gratings but applying oblique shadow thin film deposition to modify the conformal growth compared to normal incidence, leading to an increase of the grating amplitude while also reducing emittance compared to other designs. We have carried out measurements and simulations of the surface plasmon resonance (SPR) response of such sample and compared it with that of a film grown at normal incidence. The comparison of the SPR dip in reflectivity for each type of sample shows a significant change, with a narrower and deeper response for the obliquely deposited one compared to the normal deposition. The observed results are attributed to lower radiative damping of the SPP in the latter. Previous reports associate lower damping with enhanced electric fields in SPR excitations, thus, the observed narrower SPR feature in the obliquely deposited sample measurements and simulations reported is also correlated with enhancement of the SPPs localized electric field. Measurements of the photocurrent in the two types of samples will also be presented and discussed in this context.

This project is funded under Department of Energy (DOE) and the award # is DE-SC0008546

9544-62, Session 12

Stripe-teeth metamaterial Al- and Nb-based rectennas

Richard M. Osgood III, Stephen A. Giardini, Joel B. Carlson, U.S. Army Natick Soldier Research, Development and Engineering Ctr. (United States); Prabhuram Joghee, Ryan P. O'Hayre, Colorado School of Mines (United States); Kenneth Diest, Mordechai Rothschild, MIT Lincoln Lab. (United States)

Unlike a semiconductor, where the absorption is limited by the band gap, a "microrectenna array" could theoretically very efficiently rectify any desired portion of the infrared frequency spectrum (25 – 400 THz). We investigated vertical metal-insulator-metal (MIM) diodes that rectify vertical high-frequency fields produced by a metamaterial planar stripe-teeth Al or Au array (above the diodes), similar to stripe arrays that have demonstrated near-perfect absorption in the infrared due to critical coupling [1]. Using our design rules that maximize asymmetry (and therefore the component of the electric field pointed into the substrate, analogous to Second Harmonic Generation), we designed, fabricated, and analyzed these metamaterial-based microrectenna arrays. NbOx and Al2O3 were produced by anodization and ALD, respectively. Smaller visible-light Pt-NbOx-Nb rectennas have produced output power when illuminated by visible (514 nm) light [2].

The resonances of these new Au/NbOx/Nb and Al/Al2O3/Al microrectenna arrays, with larger dimensions and more complex nanostructures than in Ref. 1, were characterized by microscopic FTIR microscopy and agreed well with FDTD models, once the experimental refractive index values were entered into the model. Current-voltage measurements were carried out, showed that the Al/Al2O3/Al diodes have very large barrier heights and breakdown voltages, and were compared to our model of the MIM diode. We calculate expected THz-rectification using classical [3] and quantum [4] rectification models, and compare to measurements of direct current output, under infrared illumination.

Understanding of increased diffuse scattering in regular arrays of fluctuating resonant particles *(Invited Paper)*

Andrei Andryieuski, DTU Fotonik (Denmark); Mihail Petrov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Andrei Lavrinenko, DTU Fotonik (Denmark); Sergei Tretyakov, Aalto Univ. School of Science and Technology (Finland)

In this presentation we will discuss the analytical and numerical approaches to modeling electromagnetic properties of geometrically regular subwavelength 2D arrays of random resonant plasmonic particles.

Amorphous metamaterials and metasurfaces attract interest of the scientific community due to promising technological implementations with cost-efficient methods of large-scale chemical nanoparticles synthesis as well as their self-organization. Random fluctuations of the particles size, shape, and/or composition are inevitable not only in the bottom-up synthesis, but also in conventional electron beam and photolithography fabrication. Despite the significant progress in large-scale fabrication, modeling and effective properties prediction of random/amorphous metamaterials and metasurfaces is still a challenge, which we address here. We present our results on analytical modelling of metasurfaces with regular periodic arrangements of resonant nanoparticles of random polarizability/size/material at normal plane-wave incidence. We show that randomness of the polarizability is related to increase in diffused scattering and we relate this phenomenon to a modification of the dipoles' interaction constant. As a result, we obtain a simple analytical formula which describes diffuse scattering in such amorphous metasurfaces. Employing the supercell approach we numerically confirm the analytical results.

The proposed approach can be easily extended from electrical dipole arrays and normal wave incidence to more general cases of electric and magnetic resonant particles and oblique incidence.

9544-64, Session 13

Giant field fluctuations in dielectric metamaterials and SERS sensors

Andrey K. Sarychev, Konstantin N. Afanasiev, Irina A. Boginskaya, Institute for Theoretical and Applied Electrodynamics (Russian Federation); Igor A. Budashov, N.M. Emanuel Institute of Biochemical Physics (Russian Federation); Igor V. Bykov, Institute for Theoretical and Applied Electrodynamics (Russian Federation); Ilya N. Kurochkin, N.M. Emanuel Institute of Biochemical Physics (Russian Federation); Andrey N. Lagarkov, Institute for Theoretical and Applied Electromagnetics (Russian Federation); Ilya A. Ryzhikov, Andrey V. Ivanov, Alexander V. Vaskin, Institute for Theoretical and Applied Electrodynamics (Russian Federation)

Sensor for the detecting and analyzing bio and chemical substances is the important practical application for the modern metamaterials. We suggest the new dielectric metamaterials with special structure, where the local

electromagnetic field is much enhanced in comparison with the amplitude of the incident light. The metamaterial has facet structure, where each elementary cell separate by the gaps from the rest of the material. Each facet operates as a micro resonator of Fabry-Perot type. The incident light excites these micro resonators that have various resonance frequencies. The em field oscillations in the facets interact and form the collective modes. In spite of the collective nature, the modes are spatially localized in so called hot spots, where local field has maxima. The incident light pumps energy in the localized mode increasing the local em field. The local field enhancement is mainly restricted by the radiation loss. The scale of the local field localization is about few microns in the proposed metamaterials. The metal nanoparticles, being placed at the surface of the dielectric metamaterial, are excited by the giant local field. The strong local electric field in the metamaterial excites surface plasmon in the metal nanoparticle, placed at the surface of the metamaterial. The enhancement factor of the local field is multiplied by the enhancement factor of the plasmon resonance. The cascade enhancement results in the strong SERS in the analyte molecules adsorbed at the surface of the metal nanoparticles.

9544-65, Session 13

Opto-mechanical interactions in split ball resonators

Yue Sun, Sergey V. Suchkov, Andrey E. Miroshnichenko, Andrey A. Sukhorukov, The Australian National Univ. (Australia)

We demonstrate that a gold split-ball resonator (SBR) in the form of a spherical nanoparticle with a cut supports both optical magnetic and acoustic modes, which have strong field confinement around the cut. Such localization away from the bottom is expected to lead to an immunity to anchor loss and thus potentially high quality factors of acoustic oscillations when positioned on a substrate. As a result, when a planewave pulse excites the optical resonance, it can then efficiently drive the acoustic vibration through laser heating and/or optical forces. We estimate the overall heat variation by modelling the optical energy dissipation inside the SBR due to the dispersive and absorbing nature of gold at optical wavelengths. The optically induced force is given by the time averaged Lorentz force density. We simulate the mechanical vibrations under the optical excitation through time-dependent simulations using solid mechanics module of COMSOL software. Assuming a moderate quality factor of 10, under a plane wave pulsed laser pump which gives 100K temperature change to the SBR, both the laser heating and optical forces lead to the excitation of the acoustic mode at the same frequency with different magnitudes of 200pm and 10pm, resulting 10% and 0.5% modification of the total optical scattering, respectively. These results show that the SBRs support strong opto-mechanical coupling and are promising in applications such as surface-enhanced Raman spectroscopy and detection of localised strain.

9544-66, Session 13

Ultrahigh-capacity non-periodic photon sieves operating in visible light

Cheng-Wei Qiu, Shengtao Mei, National Univ. of Singapore (Singapore); Hong Liu, A*STAR Institute of Materials Research and Engineering (Singapore); Kun Huang, National Univ. of Singapore (Singapore); Jinghua Teng, A*STAR Institute of Materials Research and Engineering (Singapore)

Miniaturization of optical structures makes it possible to control light at the nanoscale, but on the other hand imposes a challenge of accurately handling numerous unit elements in the miniaturized devices. Up to date, photonic structures of periodic or quasi-periodic arrangement have been predominantly developed and investigated. Breaking such a convention by engineering aperiodic and random nanophotonics to govern complex optical responses, we can go for technological innovations in light manipulation, optical microscopy, and nanolithography. Here, we report both the new analytical model and experimental demonstration of the photon sieves made of ultrahigh capacity of subwavelength holes (over 34 thousands) arranged in two different structural orders of randomness and aperiodicity. The random photon sieve produces uniform optical hologram with high diffraction efficiency and free from twin-images usually seen in conventional holography while the aperiodic photon sieve manifests far-field sub-diffraction limit focusing in air. A hybrid approach resulting in an analytical solution is developed to make the design of random and aperiodic photon sieve viable for high-accuracy control of the amplitude, phase and polarization of visible light beyond the evanescent range. The polarization independence of the photon sieve will also greatly benefit its applications in optical imaging and spectroscopy.

9544-67, Session 13

A non-Monte Carlo approach to analyzing 1D Anderson localization in dispersive metamaterials

Glen J. Kissel, Univ. of Southern Indiana (United States)

Monte Carlo simulations have been used to study Anderson localization in models of one-dimensional random stacks. Because such simulations can use substantial computational resources and because the randomness of random number generators used in such simulations has been called into question, a non-Monte Carlo approach is of interest. This paper makes use of a non-Monte Carlo methodology, limited to discrete random variables, to determine the Lyapunov exponent, or its reciprocal, frequently known as the localization length, for a one-dimensional random stack model, proposed by Asatryan, et al., consisting of alternating and non-alternating layers of positive and negative index materials that include the effects of dispersion and absorption, as well as previously studied off-axis incidence and polarization effects. In the paper, Furstenberg's integral formula is used to calculate the Lyapunov exponent of an infinite product of random matrices modeling the one-dimensional stack. The integral formula requires integration with respect to the probability distribution of the randomized layer parameters, as well integration with respect to the so-called invariant probability measure of the direction of the vector propagated by the long chain of random matrices. The non-Monte Carlo approach is made possible by a numerical procedure of Froyland and Aihara which calculates the invariant measure as the left eigenvector of a certain sparse row-stochastic matrix, thus avoiding the use of any random number generator. The results show excellent agreement with the Monte Carlo generated simulations which made use of continuous random variables, while also frequently providing dramatic reductions in computation time.

9544-68, Session 14

Tunable metasurfaces *(Invited Paper)*

Harry A. Atwater Jr., California Institute of Technology (United States)

Metasurfaces composed of sub-wavelength artificial structures show promise for extraordinary light-manipulation and development of ultrathin optical components such as lenses, wave plates, orbital angular detection, and holograms over a broad range of the electromagnetic spectrum. However structures developed to date do not allow for post-fabrication control of antenna properties. We have investigated the integration of the transparent conductor indium tin oxide (ITO) active elements to realize gate-tunable phased arrays of subwavelength patch antenna in a metasurface configuration to enable gate tunable permittivity. The magnetic dipole resonance of each patch antenna interacts with the carrier density-dependent permittivity resonance of the ITO to enable phase and amplitude tunability. Operation of patch antennas and beam steering phased arrays will be discussed.

9544-69, Session 14

Vertical split-ring resonators for plasmon coupling, sensing, and metasurface *(Invited Paper)*

Din Ping Tsai, Academia Sinica (Taiwan) and National Taiwan Univ. (Taiwan); Pin Chieh Wu, Wei-Lun Hsu, Wei Ting Chen, Yao-Wei Huang, Chun Yen Liao, Wei-Yi Tsai, National Taiwan Univ. (Taiwan); Ai Qun Liu, Nanyang Technological Univ. (Singapore); Nikolay I. Zheludev, Optoelectronics Research Ctr. (United Kingdom); Greg Sun, Univ. of Massachusetts Boston (United States)

Plasmonic metamaterials composed of artificial structures in subwavelength scale exhibit many unconventional properties for light manipulation, and it is also very promising for photonic devices, high-sensitivity optical sensor, etc. Split-ring resonator (SRR), one kind of building block of metamaterials, has attracted wide attentions due to the resonance excitation of electric and magnetic dipolar response. Here, the fundamental plasmon properties and potential applications in novel three dimensional vertical split-ring resonators (VSRRs) are designed and discussed.

The resonant properties arose from the electric and magnetic interactions between the VSRR and light are theoretically and experimentally studied. Tuning the configuration of VSRR unit cells is able to generate various novel coupling phenomena in VSRRs, such as plasmon hybridization and Fano resonance. The magnetic resonance plays a key role in plasmon coupling in VSRRs. The VSRR-based refractive-index sensor will be demonstrated. Due to the unique structural configuration, the enhanced plasmon fields localized in VSRR gaps can be lifted off from the dielectric substrate, allowing for the increase of sensing volume and enhancing the sensitivity. We perform a VSRR based metasurface for light manipulation in optical communication frequency. By varying the prong heights, the 2ϖ phase modulation can be achieved in VSRR for the design of metasurface. Because the phase shift is changed via the upright configuration rather than the one parallel to the substrate, it can be used for high area density integration of metal nanostructures and opto-electronic devices.

9544-70, Session 14

Cascaded meta-surfaces for broadband antenna isolation

Joseph A. Miragliotta, David Shrekenhamer, Robert Scott, Allan Jablon, Jerry Friedman, Derek Harshbarger, Johns Hopkins Univ. Applied Physics Lab., LLC (United States); Daniel F. Sievenpiper, Univ. of California, San Diego (United States)

We report a computational and experimental study using meta-surfaces to enhance isolation between antennas that share a common ground plane. Our current emphasis is on the development of a high-impedance surface (HIS) that enables broadband isolation between transmit and receive antennas. The unit cell geometry in each of the arrays is the Sievenpiper mushroom, which contains a band gap that inhibits the propagation of surface waves within a very specific frequency region. In addition to its ease of fabrication, this simple unit cell structure is quite amenable to tailoring the frequency of the band gap through subtle changes to the geometric parameters such as via radius. For our specific HIS, we have formed a cascade of HIS unit cells and have thus expanded the isolation bandwidth to provide greater than 1 octave isolation relative to the bare ground plane. In addition to bandwidth, the HIS was designed to exhibit a 10 dB enhancement to isolation relative to an uncoated ground plane for operation between the X- through Ku-band (~ 8 to 18 GHz). Computational optimization was performed on the cascaded structure when selecting the unit cell and array parameters to assure maximum isolation amplitude and bandwidth.

9544-71, Session 14

Anisotropic meta-surfaces for enhanced antenna isolation

Joseph A. Miragliotta, David Shrekenhamer, Johns Hopkins Univ. Applied Physics Lab., LLC (United States); Daniel F. Sievenpiper, Univ. of California, San Diego (United States)

Electromagnetic band gap structures, also referred to as high impedance surfaces (HIS), inhibit the propagation of surface electromagnetic waves within a given frequency range and are an effective means to enhance the isolation between antenna that share a common ground plane. To date, the majority of HIS structures that have been designed, fabricated and tested for antenna isolation applications have relied on an isotropic distribution of unit cells within the overall surface structure, which results in a corresponding isotropic impedance profile. Although this type of impedance profile is sufficient for antenna systems on flat ground plane surfaces, they have limited performance when incorporated onto surfaces that have significant curvature. In this report, we discuss results from our computational and experimental investigation associated with enhanced antenna isolation on a non-planar ground plane via an anisotropic HIS. Unit cell anisotropy within the array was created by a number of approaches, including a variation in the aspect ratios of both rectangular and diamond shape profiles. Data associated with the isolation performance of the anisotropic impedance surface is compared to the corresponding results from an isotropic HIS in the 8 to 18 GHz microwave region.

9544-72, Session 14

Plasmon drag effect in plasmonic metasurfaces

Vincent Rono, Norfolk State Univ. (United States); Matthew LePain, Georgia Southern Univ. (United States); Rabia Hussain, Norfolk State Univ. (United States); David Keene, Maxim Durach, Georgia Southern Univ. (United States); Natalia Noginova, Norfolk State Univ. (United States)

Plasmon drag effect (PLDE) is the generation of dc electric currents associated with the excitation and propagation of surface plasmon polaritons in metal nanostructured systems. In order to better understand the mechanism of the effect and explore its properties, we experimentally study PLDE in the dependence on light intensity, wavelength and angle of incidence in hyperbolic metasurfaces of different periodicity and surfaces with random roughness. The results are discussed theoretically in a frame of the hydrodynamic loss approach.

9544-73, Session 14

Cramér-Rao bounds for metasurfaces susceptibilities

Thomas Lepetit, Boubacar Kante, Univ. of California, San Diego (United States)

Over the past fifteen years, a lot of efforts have been focused on understanding the effective properties of metamaterials [1]. In the last few years, metasurfaces in particular have been widely investigated [2]. Several homogenization methods dedicated to them have been proposed but, due to the topic's complexity, none have yet to be widely accepted.

We considered a specific homogenization method dedicated to metasurfaces, namely Generalized Sheet Transition Conditions (GSTC, [3]). This method was chosen because it is compatible with retrieval from reflection and transmission coefficients. In this method, metasurfaces are characterized by electric and magnetic susceptibilities. In the literature, retrieved effective parameters have been shown to violate causality around resonances and this has been attributed to spatial dispersion [4]. In order to determine if spatial dispersion is the only source of this phenomenon,

we have investigated the statistical properties of estimators that have been put forward for these susceptibilities. We have thus computed the Cramér-Rao lower bounds on the variance of these estimators. We have shown that this bound increases substantially around resonances making retrieval possible only for very high Signal-to-Noise Ratio (SNR, [5]). Therefore, in experiments, issues arising from spatial dispersion and noise compound and result in non-physical effective parameters. To mitigate this, we have proposed a least-squares estimator for susceptibilities that has a better performance with respect to noise.

Sensitivity to noise is particularly acute for low-loss metasurfaces. It often results in required SNRs that are unachievable in practice. The present work is thus relevant to the development of loss-compensated metasurfaces for which the issues posed by retrieval will have to be closely considered for accurate and robust device characterization.

Hybrid plasmonic nanosandwich structures

Soad Alsheheri, Marjan Saboktakin, Mohammed Matin, Univ. of Denver (United States)

Plasmonic properties of gold and silver nanoparticles has several applications in the last decade. Of the several shapes of nanoparticles, triangular nanoprisms are of significant interest to us. In this study, Ag and Au nanoprisms with different edge length and thicknesses were simulated by using Finite- difference time-domain (FDTD) simulation technique. The edge length are varied between 90 to 150 nm and thicknesses are between 10 to 50 nm of Ag and Au nanoprisms. The increase in edge length and thicknesses were found red shift to the plasmonic peak of the nanostructures. The dipole resonance peak occurs at ~700 nm for an Au nanoprism with an edge length of 90 nm and a thickness of 10 nm while it occurs at ~800 nm for an Ag nanoprism of the same size and shape. The plasmonic dipole resonance of these Ag nanoparticles varied between 725 nm and 913 nm with varying nanoprism thickness from 10 nm to 50 nm. Similarly, the dipole resonance peak for Au nanoparticles have experienced a blue shift from 721 nm corresponding to the thickness of 10 nm to 636 nm corresponding to the thickness of 50 nm. After studying the plasmonic resonance of individual Au and Ag nanoprisms, we constructed hybrid plasmonic nanoprisms in the form of gold (Au)-dielectric- silver (Ag) sandwich structures. Moreover, by creating the sandwich structure (Au/ dielectric/ Ag), the ability to tune the plasmonic resonance will be by having two peaks that can control the strength of each of them depending on the application.

Adjustment characteristics in terahertz transmission through a split ring resonator-based metamaterial

Jun Luo, Yehua Bie, Xinyu Zhang, Hongshi Sang, Changsheng Xie, Huazhong Univ. of Science and Technology (China)

The artificially structured metamaterials has led to many potential applications in terahertz regime, but the role in adjusting the terahertz transmission still needs to be carefully investigated. Currently, designs with split ring resonator (SRR) based metamaterials can provide a promising approach for understanding the terahertz transmission characteristics. In the experiments, a SRR-based metamaterial is proposed for presenting terahertz transmission characteristics. The substrate of the metamaterial is an n-type gallium arsenide (n-GaAs) film grown over a semi-insulating GaAs wafer. Then, the metallic film, fabricated on n-GaAs, is patterned into an arrayed four-gap microstructure according to traditional ultraviolet photolithography methods. The metal film and n-GaAs film form a Schottky contact. In the experiments, the transmission frequency spectrum of the metamaterial has an obvious fluctuation with a frequency interval of f = 0.15 THz in the 0.6–1.23 THz and 1.52–2.4 THz range, and the experimental results show that the frequency region of the intensive oscillatory signal essentially agrees with that of the metamaterial characteristic transmission spectrum in the 0.5–2.5 THz range. The terahertz characteristic transmission spectrum of the fabricated metamaterial are measured at the central frequency of ~1.0 THz and ~1.5 THz, this oscillation characteristics can be explained by dipole resonance. The measured time-domain transmission signals and corresponding frequency responses based on the metamaterial agree well with simulation results, including resonance frequency, surface current and electric field. Therefore, our research shows a potential application of the transmission adjusting roles in terahertz regime.

Plasmon coupling in vertical split-ring resonator magnetic metamolecules

Mu Ku Chen, Pin Chieh Wu, Wei-Lun Hsu, Wei Ting Chen, National Taiwan Univ. (Taiwan); Din Ping Tsai, Academia Sinica (Taiwan); Yi-Teng Huang, Yao-Wei Huang, Chun Yen Liao, National Taiwan Univ. (Taiwan)

Vertical split-ring resonators (VSRRs) were fabricated which behave as magnetic metamolecules sensitive to both incident electric and magnetic fields with the stronger induced magnetic dipole moments upon excitation in comparison to planar SRRs. Using these metamolecules with different spacing in VSRR dimers, we investigate the hybridization of the magnetic plasmon modes associated with each constituent VSRRs. We found that plasmon coupling can be precisely controlled by varying the gap separation between VSRRs. The resulting wide tuning range of these hybrid modes offers the possibility of developing frequency selective functional devices such as sensors and filters based on plasmon coupling with high sensitivity.

Active metasurface grating for broadband electronic modulation of free space terahertz waves

Muhammad Tayyab Nouman, Jae Hyung Jang, Sungbae J. Lee, Gwangju Institute of Science and Technology (Korea, Republic of)

Terahertz frequency band promises applications in vast number of areas. To actively control and manipulate terahertz waves, various devices based on active metasurfaces have been demonstrated. However, they all exhibit narrowband nature. In this paper, design of a broadband electronic terahertz modulator, using an active metasurface, is proposed and numerically evaluated. The proposed design exploits the small slits in a metallic plate that modify its Drude like response to a Lorentzian response. The design consists of a metallic grating on a doped gallium arsenide substrate, where the grating bars form a Schottky contact with the substrate. Application of voltage bias across Schottky contact permits control of the carrier concentration in the slits. Under zero bias the carrier concentration in the slits is large so that whole surface acts as a metal plate exhibiting a Drude like response. Upon application of a large negative voltage to the Schottky contact, the charge carriers in the slits are depleted and the metasurface

exhibits a Lorentzian response, thus achieving the modulation. Grating dimensions are optimized for maximum modulation depth and bandwidth using an electromagnetic simulation tool. Simulation results promise superior performance in terms of modulation depth and insertion loss, compared to the previously demonstrated broadband electronic modulators. This work is supported by National Research Foundation of Korea through a grant (No. 20110017603).

Shaping the light distribution of strongly focused systems for efficient excitation of optical nano-circuits

Boris Okorn, Jordi Sancho-Parramon, Institut Ruder Bo?kovic (Croatia); Silvio Hrabar, Univ. of Zagreb (Croatia)

Optical nano-circuits and metatronics have emerged as a promising alternative to classical electronic circuits that could enable operations at higher frequencies. Large efforts have been devoted to investigation of optical nano-circuits but so far all studies either bypass the problem of excitation of the metatronic system. In the present study we theoretically investigate how shaping the light distribution that illuminates a high numerical aperture lens can be used to efficiently couple light to given elements of optical nano-circuits located at the focal plane of the lens. In addition to standard plane waves, we consider illumination schemes that provide peculiar light distributions at focus, such as cylindrical vector beams. These results show that light excitation may be included as an additional degree of freedom in the optimization of optical nano-circuits and metatronics designs.

Quantum toroidal moments of nanohelix eigenstates

Johnny Williamson, Mario R. Encinosa, Florida Agricultural and Mechanical Univ. (United States)

Developments in the area of metamaterial research have generated interest in toroidal moments and their treatment in the quantum regime. A quantum mechanical method of determining toroidal moments due to current circulating on a toroidal helix is presented. The Laplacian of the toroidal helix manifold is determined and used to develop the Hamiltonian of a negatively charged spinless particle constrained to motion in the vicinity of a toroidal helix having loops of arbitrary eccentricity. In the limit that the particle is constrained to the toroidal helix, the particle's wave function is assumed to decouple into components tangential and normal to the toroidal helix. Once confined to the toroidal helix, only the motion along the manifold is nontrivial. An additional term arises in the Hamiltonian that depends on the curvature of the toroidal helix. Using this resulting Hamiltonian, the three dimensional Schrodinger equation is effectively reduced to a one dimensional form inclusive of curvature effects. The curvature term that arises from the dimensional reduction procedure is periodic over the azimuthal angle of the system. Thus a Bloch-type formalism is utilized to define a basis set which is used to find the Hamiltonian matrix. This Hamiltonian matrix is diagonalized and the energies and low-lying eigenfunctions of the toroidal helix system are calculated. The eigenfunctions are used to calculate probability currents which in turn are used to calculate corresponding toroidal moments. A disagreement, not predicted by a classical treatment, arises between toroidal moments of elliptic toroidal helix systems when vertical and horizontal eccentricity are transposed.

Mie resonance in the arrays of dielectric rods in air

Ravindra K. Sinha, Reena Dalal, Yogita Kalra, Delhi Technological Univ. (India)

Mie resonance in square arrays of dielectric rods has been reported. Arrays in square lattice of dielectric rods with very high permittivity in air have been considered. Light of transverse electric mode has been launched on the square arrays of cylindrical dielectric rods. Mie resonance of first two orders has been observed in the dielectric rods, due to which electric and magnetic dipoles are generated in the rods. At optimized parameters the electric field is confined in the dielectric rods and magnetic field is rotating around the dielectric rods. Simulations are done for different values of permittivity from 40 to 100. Materials like titanium dioxide and strontium titanate have very high permittivity. We observe better results at the permittivity ?r= 60 in our design. Negative value of effective permittivity and effective permeability at different frequencies in the range of 0.1 THz to 2.5 THz has been obtained. Thus, electric resonance and magnetic resonance at different frequencies has been observed.

Taming microwave propagation with hyperbolic and chiral metal-dielectric metamaterials

Brittany Bates, Brandon Allison, Nicole Greene, Vincent Rono, Natalia Noginova, Norfolk State Univ. (United States)

Bulk lamellar metal-dielectric structures as well as layers of wires arranged in aligned or chiral manner have been fabricated and studied in microwave free space propagation experiments. We have shown that a ~ 10 cm x 10 cm x 10 cm cube of a planar metamaterial has properties of a focusing lens and a polarizer. Rotation of polarization (optical activity) has been demonstrated in chiral structures. We have further explored use of natural magnetic materials as constituent ingredients of metamaterials as well as the possibility to tune material parameters at microwave range with external magnetic fields.

Simulation of space-time cloaking using FDTD for terahertz frequency range

Egor A Gurvitz, Mikhail V Sharaevsky, ITMO University (Russian Federation); Mikhail K. Khodzitky, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

Recently, investigation of metamaterials gave new turn of scientific development. Their unique properties design devices which can control wave in space and time. Metamaterials already have been applied in the field of antennas, cloaking, high resolution imaging, etc [1]. Generally these applications require spatial distribution of constitutive parameters. This work is based on the theory of transformation optics [2] and field theory [3] and these theories extend the mathematical apparatus of object concealment for time applications [4]. Using FDTD numerical simulation of the electromagnetic fields distribution in the cloaking medium with non ordinary constitutive parameters for two space dimensions and time was shown. The work is focused on magneto-electric interactions of incident wave and the medium, which possesses constitutive parameters tensors with non diagonal components.

Temperature-controlled infrared broadband cloaking with the bilayer of semiconductor and superconductor

Xiaohua Wang, Nanjing Univ of Aeronautics and Astronautics (China); Youwen Liu, Nanjing Univ. of Aeronautics and Astronautics (China)

From the beginning of this century, metamaterial has attracted more and more attention owing to its unique properties and many potential applications. Among these applications, electromagnetic cloaking is undoubtedly paid more attention. Up to now, many research groups have investigated electromagnetic cloaking using the following approaches: transformation optics and scattering cancellation. Usually, the latter is relatively easy to realize, because the cloaking is obtained by using isotropic and homogeneous plasmonic materials, whilst the former may achieve perfect cloaking with the use of the anisotropic and inhomogeneous metamaterials.

Superconductor is a good plasmonic material because of low loss and temperature-tunability in THz and infrared band. In this contribution, we design the invisibility cloak made of the two materials of semiconductor (n-type germanium) and high-temperature superconductor ($YBa_2Cu_3O_7$). Based on the Mie theory, we derive the formula of total scattering cross-section and the cloaking condition of the composite structure under the long-wavelength approximation. This invisibility cloak may reduce the total scattering cross-section of the composite structure of 90% over a broadband frequency of near 20 THz and the cloaking frequency may be tuned by the applied temperature. Further, we discuss numerically the effect of the structure parameters on the cloaking performance of the composite structure. The results show that the cloaking frequency may be tuned by changing the thickness of the outer semiconductor layer, and the tuning range of this bilayer structure is wider than that of single superconductor layer. It can provide a feasible way to design a broadband tunable cloak.

A new type of metamaterial panel for invisible using

Hongwei Sun, Fei Yan, Jari Tooling Technology Co. (China)

This paper presents modeling, analysis techniques and experiment of metamaterial panel for Broadband Vibration Absorption. For a unit cell of an infinite fmetamaterial panel, governing equations are derived using the extended Hamilton principle. The concepts of negative effective mass and stiffness and how the spring-mass-damper subsystems create a stopband are explained in detail. Numerical simulations reveal that the actual working mechanism of the proposed metamaterial panel is based on the concept of conventional mechanical vibration absorbers. It uses the incoming elastic wave in the panel to resonate the integrated membrane-mass-damper absorbers to vibrate in their optical mode at frequencies close to but above their local resonance frequencies to create shear forces and bending moments to straighten the panel and stop the wave propagation. Moreover, a two-dimension acoustic metamaterial panel consisting of lumped mass and elastic membrane is proposed in the lab. We do experiments on the model and The results validate the concept and show that, for two-dimension acoustic foam metal metamaterial panel do exist two vibration modes. For the wave absorption, the mass of each cell should be considered in the design. With appropriate design calculations, the proposed two-dimension acoustic foam metal metamaterial panel can be used for absorption of low-frequency waves and hence expensive micro-manufacturing techniques are not needed for design and manufacturing of such foam metal metamaterial panel for low-frequency waves absorption/isolation.

Controlling the bandwidth of metamaterial properties

Morteza Karami, Michael A. Fiddy, The Univ. of North Carolina at Charlotte (United States)

We have studied meandering wire or S-shaped resonators which are well known for exhibiting overlapping negative permittivity and permeability to achieve negative and zero index bulk metamaterials. The resonators are continuously connected in one direction and their dimensions are readily chosen so that resonant frequencies lie in the frequency range of choice, e.g. 5-10 GHz. Two sets of S-elements are placed on either side of a substrate (FR4). The bulk properties of this metamaterial are determined from scattering parameters and the retrieval method assumes an infinite array of meta-atoms in the plane perpendicular to the plane of incidence and periodic boundary conditions in the other two dimensions. The retrieved refractive index values are consistent with expectations, do not arise from diffraction phenomena, and their dependence on the collective resonant properties of the metamaterial is clear. Moreover, predictable properties are found when the S elements, originally made from copper, are made from a high permittivity dielectric such as barium strontium titanate. Inserting rod-like structures in the FR4 substrate has the effect of shifting and broadening/smearing the electrical resonance, with little change to the magnetic resonance. Addition of more rods can eventually shift and suppress the magnetic resonance while shift the bulk plasma frequency to higher frequencies. This combination of effects, now understood, allows one to design an index value with a prescribed bandwidth, to some extent. By replacing the metal with a high permittivity dielectric, the associated losses are reduces as we will show.

Full control of light using plasmonic metasurfaces

jianxiong li, Nankai university (China); Shuqi Chen, Nankai Univ. (China); Jianguo Tian, Nankai university (China)

Harnessing light for modern photonic applications often involves the control and manipulation of light polarization and phase. The polarization and phase are among the basic properties of light, and their manipulation enables many optical applications and plays an increasingly important role in investigating light-matter interactions. However, so far it is still challenging to simultaneously manipulate the polarization state into an arbitrary direction and a phase variation spanning over the entire 2π range.

Here, we propose and validate dual-layer plasmonic metasurfaces that can provide simultaneous manipulation of the phase and polarization of the transmitted light. An arbitrary spatial field distribution of the optical phase is obtained by using plasmonic metasurfaces consisting of six sub-units, where the orientation of these sub-units can be tuned to further control the polarization. We have proposed and experimentally validated plasmonic metasurfaces achieving simultaneous control of the phase and polarization direction of light. For linearly polarized incident light, the metasurface enables near-perfect anomalous refraction without converting the polarization to its cross-direction; while for circularly polarized incident light, the out-coupling polarization can be further controlled by the orientation of the nano-apertures. This capability also allowed us to create arbitrary vector optical fields, and as an example we generated a radially polarized beam from the circularly polarized incident light. The demonstration is in the near-infrared wavelength range, which indicates that the approach can be easily translated to mid-infrared, terahertz, and microwave frequency regimes. The new degrees of freedom of metasurfaces facilitate arbitrary manipulation of light and will profoundly affect a wide range of photonic applications.

Paraxial cloaking: ray optics and full-field

Joseph S. Choi, John C. Howell, Univ. of Rochester (United States)

We complete a paraxial cloaking formalism to include full-field (phase + amplitude) matching of light fields. Omnidirectionality is the only remaining property of what may be considered an “ideal” invisibility cloak that is broadband for the visible spectrum. Interestingly, our design remains isotropic, though some instances require metamaterials or anomalous dispersion. This suggests that anisotropy may be a characteristic of cloaking for all directions in three-dimensions. Our work also confirms the growing literature on the exclusiveness between broadband versus zero scattering cross-section.

9544-74, Session 15

Visible-frequency metasurfaces for broadband anomalous reflection and high-efficiency spectrum splitting

Zhongyang Li, Edgar Palacios, Serkan Bütün, Koray Aydin, Northwestern Univ. (United States)

Metasurfaces offer new degrees of freedom in moulding the optical wavefronts by introducing abrupt and drastic changes in the amplitude, phase and/or polarization of electromagnetic radiation at the wavelength scale. By carefully arranging multiple subwavelength anisotropic or gradient optical resonators, metasurfaces have been shown to enable anomalous transmission, anomalous reflection, optical holograms and spin-orbit interaction. However, experimental realization of high-performance metasurfaces that can operate at visible frequency range has been a significant challenge due to high optical losses of plasmonic materials and difficulties in fabricating several subwavelength plasmonic resonators with high uniformity. Here, we propose a highly-efficient yet a simple metasurface design comprising of a single, anisotropic trapezoid-shape antenna in its unit cell. We demonstrate broadband (450 - 850 nm) anomalous reflection and spectrum splitting at visible and near-IR frequencies with 85% conversion efficiency. Average power ratio of anomalous reflection to the strongest diffraction mode was calculated to be on the order of 1000 and measured to be on the order of 10. The anomalous reflected photons have been visualized using a CCD camera, and broadband spectrum splitting performance has been confirmed experimentally using a free space, angle-resolved reflection measurement setup. Metasurface design proposed in this study is a clear departure from conventional metasurfaces utilizing multiple, anisotropic and/or gradient optical resonators, and could enable high-efficiency, broadband metasurfaces for achieving flat high SNR optical spectrometers, polarization beam splitters, directional emitters and spectrum splitting surfaces for photovoltaics.

9544-75, Session 15

Metasurfaces for amplitude, phase, and polarization control *(Invited Paper)*

Uriel Levy, Boris Desiatov, Meir Grajower, Jonathan Bar David, The Hebrew Univ. of Jerusalem (Israel)

In this talk we present our recent work on dielectric metasurfaces for phase, amplitude and polarization control. We show new results in the near IR and the mid IR regime, in which the control over the properties of light can be achieve by controlling the retardation of a subwavelength periodic structure or by controlling the resonances of nano beams in semiconductors. We discuss approaches for achieving broadband retardation of light by tailoring the dispersion properties of the metasurface. Both guided mode and free space configurations are considered. The effect of introducing metals is also analyzed and demonstrated. Finally, we also discuss and demonstrate tunable metasurfaces.

9544-76, Session 15

Light manipulation by resonant dielectric nanostructures and metasurfaces *(Invited Paper)*

Arseniy I. Kuznetsov, A*STAR - Data Storage Institute (Singapore)

Resonant nanostructures made of high-refractive index dielectric materials offer a new way for manipulation of light at nanoscale. Due to their inherently high magnetic and electric resonant response and low losses at optical frequencies these nanostructures offers unique functionalities, which are not achievable with conventional nanoscale plasmonics. Simple examples are strong magnetic near-field enhancement and directional scattering by nanoparticles of spherical shape, also known as a Kerker’s effect. In this talk, I will review this new rapidly developing research direction and present several new results of our team, which demonstrate a huge potential of dielectric nanoantennas for various applications. Fist will be experimental demonstration of highly localized magnetic and electric fields in silicon nanodimer antennas, which can be excited at any polarization of incoming light. Second will show low-loss light propagation in silicon nanoparticle waveguides, which can be much longer than in plasmonic waveguide of similar dimensions. Finally I will present how the light can be manipulated with almost fully transparent resonant dielectric metasurfaces having a full 2ϖ control over the phase of incoming light at visible and near-IR wavelengths.

9544-77, Session 15

Metasurface-enabled quantum vacuum effects over macroscopic distances

Pankaj K. Jha, Xingjie Ni, Chihhui Wu, Yuan Wang, Xiang Zhang, Univ. of California, Berkeley (United States)

Quantum vacuum engineering is an active field of research. Here we use recent advances in the field of metasurface (2D-array of sub-wavelength scale nano-antennas) to construct an anisotropic quantum vacuum (AQV) in the vicinity of a quantum emitter located at some macroscopic distance from the metasurface. Such AQV can induce quantum interference among several atomic transitions, even when the transition dipole moment corresponding to the decay channels are orthogonal.

Recently, there have been few theoretical proposal to use metamaterials to engineer the back-action. All these approaches, which works in the near

field (few tens of nanometers from the surface), suffers from trapping an atom at these distance, surface interactions like quenching, Casimir force etc. Hence it's pivotal to construct the back-action over macroscopic distance. We harness the polarization dependent response of a metasurface to engineer the back-action of the spontaneous emission from the atom to itself. We show strong anisotropy in the decay rate of a quantum emitter which is a manifestation of AQV.

Engineering light-matter interaction over macroscopic distances opens new possibilities for long-range interaction between quantum emitters for quantum information processing, spin-optics/spintronics etc.

9544-78, Session 15

All-dielectric metasurfaces for structured light generation

Mikhail Shalaev, Jingbo Sun, Univ. at Buffalo (United States); Apra Pandey, CST of America, Inc. (United States); Kirill Nikolsky, M.V. Lomonosov Moscow State Univ. (Russian Federation); Natalia M. Litchinitser, Univ. at Buffalo (United States)

Recent progress in nanostructured optical materials has enabled new ways of manipulating intensity, polarization and phase distribution of light beams. Metamaterials and metasurfaces facilitate a new class of ultra-compact optical elements. In particular, optical metasurfaces allow precise control of phase and wave-front properties of light beams. To date, most work has been focused on metal-dielectric structures relying on resonant response of metallic nanoantennas. There are several challenges associated with this approach, including anisotropic and polarization-dependent properties of the structures and ohmic losses introduced by metals. These problems can be addressed using all-dielectric metasurfaces instead of more conventional metal-dielectric counterparts. Here, we demonstrate subwavelength-thick efficient all-dielectric matasurfaces enabling generation/conversion of light beams with orbital angular momentum (OAM) operating in transmission mode. We utilize the strong resonant response of high-permittivity dielectric meta-atoms in the near-IR spectral range. Such nanostructures support both electric and magnetic dipolar Mie-type resonances and possess very low intrinsic losses. Such all-dielectric metasurfaces having both electric and magnetic responses can be designed to be polarization independent, enable high transmission and are compatible with existing complementary metal–oxide–semiconductor (CMOS) processes, which makes them attractive for practical applications in optoelectronics and communication industries.

9544-79, Session 15

Dynamically reconfigurable metasurfaces

Prasad P. Iyer, Nikita A. Butakov, Jon A. Schuller, Univ. of California, Santa Barbara (United States)

Recently, the use of phased array metasurfaces to control the phase and amplitude of electromagnetic waves at subwavelength dimensions have led to large number of devices ranging from flat optical elements to holographic projections. Here we analytically (& numerically using FDTD techniques) develop a design principle to form reconfigurable metasurfaces that control the phase of transmitted beam between 0 and 2ϖ in a lossless manner. For a linearly polarized plane wave incident on a sub-wavelength array of dielectric resonators, we engineer the size of the individual resonators and the array periodicity such that the fundamental Electric and Magnetic dipole resonances of the device cross each other. This mode crossing caused by coupling of individual resonator modes with the surface lattice resonances, constructively interferes with the incident plane wave enabling us to form lossless metasurfaces. By optically pumping charge carriers into the resonators, we can tune the refractive index of the individual resonators leading to arbitrary control over the phase of the transmitted beam between 0 and 2ϖ with less than 3dB loss in intensity. Further, we extend these strategies by redesigning the resonator elements by forming core-shell (metal-dielectric) resonators to cause the resonance matching within each resonator. This enables the mode crossing to be independent of the periodicity of the resonator elements while preserving the arbitrary control over the phase through charge carrier modulation. Such metasurfaces with spectrally overlapping electric and magnetic dipole modes may form the basis for a range of metadevices with unprecedented control over the Electromagnetic wave front.

9544-80, Session 16

Metagratings for tunable unidirectional steering and focusing of surface plasmons *(Invited Paper)*

Federico Capasso, Daniel Wintz, Harvard School of Engineering and Applied Sciences (United States); Patrice Genevet, Singapore Institute of Manufacturing Technology (Singapore) and Harvard School of Engineering and Applied Sciences (United States); Antonio Ambrosio, Harvard School of Engineering and Applied Sciences (United States) and Univ. degli Studi di Napoli Federico II (Italy); Alex Woolf, Harvard School of Engineering and Applied Sciences (United States)

In this paper, we present new results on the controlled directional steering and focusing of surface plasmon polaritons (SPPs) via 1D and 2 D metagratings by changing the angle of incidence, the incident wavelength and polarization. These findings build on previous work of our group on polarization controlled steering of SPPS using fishbone meta gratings and greatly expand on the functionality of the latter using novel designs.

First we show that by creating a running wave of polarization along a one dimensional metallic metagrating consisting of subwavelength spaced rotated apertures that propagates faster than the SPP phase velocity, we can generate surface plasmon wakes, which are the two-dimensional analogue of Cherenkov radiation. The running wave of polarization travels with a speed determined by the angle of incidence and the photon spin angular momentum. We utilize this running wave of polarization to demonstrate controlled steering of the wakes by changing both the angle of incidence and the polarization of light, which we measure through near-field scanning optical microscopy.

Next we report a simple 2D metagrating design strategy that can be used for focusing, polarization beam splitting, waveguide coupling, and even phase control at the focus of an SPP beam. We experimentally verify our 2D metasurface by creating a four wavelength plasmonic demultiplexer, which also has polarization selectivity (on/off). The wavelength demultiplexer is designed such that each of the four wavelengths is focused to a different spot outside of the structure. Coupling of free space light to SPPs is achieved by milling subwavelength apertures into a thin gold film. This methodology can be easily extended to any wavelength where SPPs exist, for an arbitrary number of wavelengths, and with polarization selectivity and phase control at the focus as well.

9544-81, Session 16

Metasurfaces and epsilon-near-zero modes in semiconductors *(Invited Paper)*

Igal Brener, Salvatore Campione, Sandia National Labs. (United States); Francois Marquier, Institut d'Optique (France)

Thin layers of semiconductors where the permittivity crosses zero, support a particular polariton mode called epsilon-near-zero (ENZ) mode. This zero crossing can be obtained near optical phonon resonances in dielectrics or the plasma frequency in doped semiconductors. The coupling of metamaterial resonators to these ENZ modes leads to particularly large Rabi splittings. ENZ layers can be added to metamaterial-based strongly coupled systems to increase this coupling even further. I will discuss several examples of these coupled systems that include metasurfaces, phonons, intersubband transitions and ENZ modes.

9544-82, Session 16

Carpet cloak with graded dielectric metasurface

LiYi Hsu, Thomas Lepetit, Boubacar Kante, Univ. of California, San Diego (United States)

We demonstrate a method to hide a Gaussian-shaped bump on a ground plane from an incoming plane wave. In essence, we use a graded metasurface to shape the wavefronts like those of a flat ground plane[1,2]. The metasurface provides additional phase to the electromagnetic field to control the reflection angle. To mimic a flat ground plane, the reflection angle is chosen to be equal to the incident angle. The desired phase distribution is calculated based on generalized Snell's laws[3]. We design our metasurface in the microwave range using sub-wavelength dielectric resonators. We verify the design by full-wave time-domain simulations and show that the result matches our theory well. This approach can be applied to hide any object on a ground plane not only at microwave frequencies but also at higher frequencies up to the infrared.

Ultra-thin metasurface carpet cloak

Xingjie Ni, Zi Jing Wong, Michael Mrejen, Yuan Wang, Univ. of California, Berkeley (United States); Xiang Zhang, Univ. of California, Berkeley (United States) and Lawrence Berkeley National Lab. (United States)

We experimentally demonstrate a three-dimensional ultra-thin metasurface carpet cloak can cover on an arbitrary-shaped object and make it undetectable by the visible light. Our metasurface cloak consists of subwavelength-scale nanoantennas which provide a distinct phase shift to the reflected electromagnetic waves. Based on this phase control capability, we design a metasurface so that at each local point on the interface of the cloaked region the phase of the light scattered by the interface is the same as that reflected from a flat mirror. One of the most significant problem of the plasmonic metasurface designs resides in their poor overall efficiency. In our carpet cloak case, we adapt an ultrathin dielectric space layer to create a gap plasmon resonance. The overall reflectivity can be close to 90% with proper optimization.

9544-84, Session 16

Flat optical beam shapers based on all-dielectric Huygens' metasurfaces

Katie E. Chong, Isabelle Staude, The Australian National Univ. (Australia); Anthony James, Jason Dominguez, Sheng Liu, Salvatore Campione, Ganapathi S. Subramania, Ting S. Luk, Sandia National Labs. (United States); Manuel Decker, Dragomir N. Neshev, The Australian National Univ. (Australia); Igal Brener, Sandia National Labs. (United States); Yuri S. Kivshar, The Australian National Univ. (Australia)

Functional optical metasurfaces have gained a lot of attention in the last couple of years for their potential in ultra-thin flat optics; however their practicality has been restricted by their low efficiencies caused by reflection losses, undesired polarization conversion or the intrinsic loss of metals at optical frequencies, for example. Here, we study highly efficient polarization-independent beam shapers based on all-dielectric Huygens' metasurfaces [1]. Our beam shapers consist of subwavelength arrays of silicon nanodisks fabricated using electron-beam lithography and reactive-ion etching on silicon-on-insulator wafers. Each nanodisk radiates as a pair of crossed electric and magnetic dipoles in the forward direction into the farfield [2], thereby emulating the behavior of a Huygens' source. As a result, they can impose local phase shifts on the arbitrarily polarized incident light field and allows for wavefront control of the incident wave. By systematically varying the geometry of the nanodisks in the arrays and arranging them in four quadrants, a phase shift of 0, $\varpi/2$, ϖ or $3\varpi/2$ radians is imposed onto the incident light in each quadrant. Therefore a spatial phase gradient in the azimuthal direction is produced, covering the full 2ϖ range and leading to the generation of a vortex beam. Our beam shapers can achieve transmittance efficiencies close to the theoretical limit of 100%, thereby paving a way to practical lossless flat optics that are compatible with standard and well-established nanofabrication procedures, making mass production of such meta-devices achievable.

9544-85, Session 17

An atom/metamaterial hybrid system *(Invited Paper)*

David Wilkowski, Nanyang Technological Univ. (Singapore); Eng Aik Chan, Syed Abdullah Aljunid, Giorgio Adamo, Centre for Disruptive Photonic Technologies (Singapore); Martial Ducloy, Centre for Disruptive Photonic Technologies (Singapore) and Laboratoire de physiques des Lasers (France); Nikolay Zheludev, Centre for Disruptive Photonic Technologies (Singapore) and Optoelectronics Research Centre & Centre for Photonic Metamaterials (United Kingdom)

We report recent studies on an atom/surface Metamaterial Hybrid device. The plasmonic resonance of the Metamaterial is designed to cover a transition of Caesium atom. We use the selective reflection spectroscopy to probe the system. This technic reveals the sub-Doppler structure of the atomic line. Thus we succeed to couple two systems, where those resonance linewidths differ by more than 6 orders of magnitude. As a consequence we observe Fano-like resonance shapes which we interpret as a mixing of the reactive and the dissipative response of the atomic dipole operator. On top of it, the selective reflection spectroscopy probes atoms which are located at the vicinity of metamaterial. Hence Casimir-Polder interaction can observe and tune through the surface plasmonic resonance of the metamaterial.

Several interesting applications of this new type of hybrid system are envisioned. First, taking advantage of the strong nonlinearity of the atom response, efficient nanophotonic devices like optical switch at few photons level could be in principle implemented. Second, surface metamaterials may provide a new platform to cool and manipulate atoms for nano sensing devices.

9544-86, Session 17

Metamaterial models of curved spacetime

Tom G. Mackay, The Univ. of Edinburgh (United Kingdom); Akhlesh Lakhtakia, The Pennsylvania State Univ. (United States)

In the early 20th century, Igor Tamm established a formal equivalence between the electromagnetic properties of vacuous curved spacetime and a certain fictitious material in flat spacetime. This fictitious medium - known as the Tamm medium - is generally bianisotropic and nonhomogeneous. The Tamm medium offers the possibility of exploring the electromagnetic properties of certain curved spacetime scenarios that may be impractical

to explore by direct methods. The realization of various Tamm mediums as metamaterials is considered here. The approach taken is based on the homogenization of relatively simple component materials, with the inverse Bruggeman formalism exploited to determine appropriate constitutive parameters. The bianisotropic nature of Tamm mediums can be accommodated via the homogenization of chiral (or otherwise magnetoelectric) component materials. Typically, Tamm mediums are highly anisotropic in regions corresponding to relatively large spacetime curvature (e.g., in the vicinity of spacetime singularities). In principle at least, such high degrees of anisotropy may be achieved by homogenizing component particles that are highly elongated. The nonhomogeneous nature of Tamm mediums can be accommodated by adopting a piecewise homogeneous approach, which is valid for sufficiently-long wavelength regimes. The spacetime scenarios considered include those of gravitational plane waves, Schwarzschild-(anti-)de Sitter, and cosmic strings.

9544-87, Session 17

Electron beam excitation of CSRR loaded waveguide for Cherenkov radiation

Emmy Sharples, The Cockcroft Institute (United Kingdom) and Lancaster Univ. (United Kingdom); Rosa Letizia, Lancaster Univ. (United Kingdom) and The Cockcroft Institute (United Kingdom)

An electron beam is used to excite a unique electromagnetic response from a complementary split ring resonator (CSRR) metasurface loaded waveguide and investigate it as a backward propagating Cherenkov radiation source. This novel structure comprises of a metallic WR-284 waveguide loaded with four layers of CSRR-metasurface 1 mm thick, with sufficient spacing between the metasurface layers for electron beam propagation. The loaded waveguide exhibits left handed behaviour around 5.86 GHz where a TM-like mode exists. The transverse confinement of this mode between the closely lying metasurface layers and the strong electrical response of the CSRRs leads permeability and permittivity to be simultaneously negative. The structure has been optimised to reduce the surface current on the metasurface, improve the fabrication suitability and minimise the effect of hybrid modes.

The structure is suitable for beam-based applications as it exhibits strong beam coupling parameters and excitation of longitudinal wake impedance at the frequency of the TM-like mode. The beam coupling parameters exhibited are high with R/Q of 36 ? and shunt impedance of 177 k?. Strong excitation of the longitudinal wake impedance of 10 k?, with minimal transverse wake impedance and minimal beam disruption, has been observed for this mode. Results from particle-in-cell simulations will be shown to verify that backward propagating Cherenkov is radiated when a suitable electron beam propagates between the central layers of the waveguide. This investigation can lead to new solutions for non-destructive beam detection and wakefield acceleration which can potentially be scaled to higher frequency ranges.

9544-88, Session 17

Synchrotron infra-red spectral microscopy of metal-dielectric-metal cavity metamaterial absorbers

Janardan Nath, Deep Panjwani, Mehmet Yesiltas, Univ. of Central Florida (United States); Carol J. Hirschmugl, Univ. of Wisconsin-Milwaukee (United States); Farnood K. Rezaie, Robert E. Peale, Univ. of Central Florida (United States)

Metamaterial absorbers typically comprise a periodically-structured metal surface, a dielectric spacer, and a metal ground plane, which together give rise to strong absorption resonances. Using diffraction-limited synchrotron-based infrared spectral microscopy in the 2-8 micron wavelength range, we succeeded in measuring the spatial distribution of absorption for a single unit cell of such an absorber, for which the surface structure comprised a single isolated 2 micron x 2 micron square of 100 nm thick gold on a 100 nm thick electron-beam evaporated layer of SiO2. The ground-plane was an optically thick Au film on a Si substrate. The reflectance spectrum revealed a fundamental absorption band at 6.4 micron wavelength and a higher-order resonance at 2.5 microns. For comparison, a reflectance spectrum for a device comprising a 2D 3-micron-period array of such squares on similar layers revealed similar resonances, which differed only by being about twice stronger and red shifted by less than 2%. These experiments confirm a waveguide standing wave resonance model, which is independent of the periodicity of the 2D array, where resonances and their harmonics depend on the lateral dimension of the squares and the thickness of the dielectric and on no other geometrical parameters. Specifically, interaction among the neighboring cavities is unimportant. Devices of the type considered have application to infrared bolometers and potentially for localization of heat in medical therapy.

9544-89, Session 17

Double Fano resonances in a composite metamaterial possessing tripod plasmonic resonances

Jeong-Weon Wu, Y. U. Lee, E. Y. Choi, E. S. Kim, J. H. Woo, B. Kang, J. Kim, Ewha Womans Univ. (Korea, Republic of); Byung Cheol Park, T. Y. Hong, Jae Hoon Kim, Yonsei Univ. (Korea, Republic of)

We experimentally demonstrate a classical analogue of double Fano resonances in a planar composite metamaterial possessing tripod plasmonic resonances, where a common subradiant dipole corresponding to the dark mode is coupled with two superradient dipoles corresponding to two bright modes. The composite metamaterial is structured such that four-rod resonators (FRR) are embedded inside double-split ring resonators (DSRR) superlattice. Two dipole resonances of DSRR are superradiant modes and one dipole resonance of FRR is subradiant mode. Proximity of the inner diameter of DSRR and the rod-length of FRR permits near field coherent couplings, and the composite metamaterial is a tripod metamaterial system possessing two superradiant dipole resonances of DSRR coupled coherently with one common subradiant dipole resonance of FRR in near field, similar to a tripod atomic system with four atomic levels coupled coherently by coherent optical fields. Important finding is that double Fano resonances in the composite metamaterial are correlated, showing up as a transfer of the absorbed power from one superradiant dipole to the other superradient dipole in DSRR. The general feature of plasmonic Fano resonance is examined where both superradiant and subradiant oscillators are externally driven. Analysis based on two coupled oscillators model leads to the fact that the characteristic asymmetric Fano resonance formula of plasmonic structure is kept the same with a modication in the asymmetry parameter q.

9544-92, Session 18

Polarization and angle dependent electromagnetic response of microwave metamaterials

David A. Lee, The MITRE Corp. (United States); James L. Vedral, Univ. of Colorado at Colorado Springs (United States); Randall Musselman, U.S. Air Force Academy (United States); Anatoliy O. Pinchuk, Univ. of Colorado at Colorado Springs (United States)

Microwave metamaterials are of interest for antenna applications, such as Radome shielding. In this work we present experimental and theoretical results on angle dependent transmission through a slab of microwave negative index metamaterials. We used S-shaped Split Ring Resonator (SSRR) as a unit cell to design, fabricate, and test a negative index metamaterial slabs in the X-Ku and K microwave bands. We tested the negative index of refraction by cutting the slabs into prisms and measuring the refraction of a plane electromagnetic wave in an anechoic chamber.

Angle dependent transmission through a uniform slab of microwave metamaterial was measured for a linear polarized incident electromagnetic wave. Theoretical simulations by using the HFSS package showed a good agreement between the theory and experiments. We then fabricated a set of single axis boards (1 D metamaterial) and a set of two-dimensional interlocked metamaterial slabs (2D metamaterial), and tested them in the anechoic chamber. The transmission spectra S21 were measured as a function of the orientation of the metamaterial slabs within the incoming linearly polarized electromagnetic waves. The single axis board (1 D metamaterial) exhibited a strong anisotropic response with respect to the incoming linearly polarized electromagnetic wave. The dual interlocked metamaterial slab, however, did not exhibit this response. We conclude that the dual axis 2D metamaterial slab is isotropic with respect to the linearly polarized incoming electromagnetic wave.

9544-93, Session 18

Extraordinary terahertz transmission through electrically small particles

Mohammed R. AlShareef, King Abdulaziz City for Science and Technology (Saudi Arabia); Omar M. Ramahi, Univ. of Waterloo (Canada)

An array composed of six electrically small resonators and a transmission line is proposed to enhance terahertz (THz) waves' transmittance. Silver is the metal of choice for the proposed array. 3000 of the proposed array are fabrication on an intrinsic double-side polished silicon wafer using nano-technology tools, followed by a THz time-domain spectroscopy (THZ-TDS) measurement, to validate the numerical findings experimentally.

In detail, Transmission mode THz-TDS experimental setup was applied. This setup mainly consisted of Ti:sapphire femtosecond laser, transmitter and receiver photoconductive antennas and four off-axis mirrors. First, the femtosecond laser pulses excite the THz emitter (transmitter antenna) which in turns generates THz pulses. The THz pulses are then collimated by the first off-axis mirror followed by focusing the beam on the sample with aid of the second off-axis mirror. The transmitted THz beam that passes through the sample is collimated again by the third off-axis mirror and then focused by the fourth off-axis mirror on the THz detector.

The silicon wafer with and without the metallic structure were at the focus of THz beam. The measured THz temporal pulses, in transient mode, of the sample and the reference (pure silicon) were Fourier transformed to THz spectrums. Next, the transmission was obtained from the ratio between the sample and reference spectrums.

At the resonance frequency of the structures (around 0.4 THz), an extra-ordinary transmission was observed. This phenomenon is attributed mainly to the periodic structure composed of the sub-wavelength unit cells.

9544-94, Session 18

Two layer metamaterials for selective frequency transmission in the terahertz region

Mayer A. Landau, Air Force Research Lab. (United States)

We have fabricated a metamaterial tunable filter for dynamic frequency selection in the terahertz region. The metamaterial consists of a sandwich of two meta-surfaces grown on high resistivity silicon wafers. The first meta-surface consists of a two-dimensional array of gold double split ring resonators and the second meta-surface consisits of an array of gold cut rods. Both meta-surfaces are fabricated for a response in the terahertz region. Our terahertz pulses are produced using the standard Austin switch technique. The terahertz pulse is focused onto the two meta-surfaces which are sandwiched together to produce a transmission window. Together, with the right orientation, translation, and parallelism of the two meta-surfaces, we achieve filtering of terahertz pulses. Since the unit cells for the inclusions are on the order of 100 microns, control of the translation, orientation, and parallelism of the two meta-surfaces with respect to each other and with respect to the orientation and direction of the impinging terahertz field is a challenge. We describe our technique for doing this and present data on our frequency filtering in the terahertz.

9545-2, Session 1

Surface functionalized spherical nanoparticles: an optical assessment of local chirality

Jamie M. Leeder, David L. Andrews, Henryk T. Haniewicz, Univ. of East Anglia (United Kingdom)

Electromagnetic radiation propagating through any molecular system typically experiences a characteristic change in its polarization state as a result of light-matter interaction. Circularly polarized light is commonly absorbed or scattered to an extent that is sensitive to the incident circularity, when it traverses a medium whose constituents are chiral. This research assesses specific modifications to the properties of circularly polarized light that arise on passage through a system of surface-functionalized spherical nanoparticles, through the influence of chiral molecules on their surfaces. Non-functionalized nanospheres of atomic constitution are usually inherently achiral, but can exhibit local chirality associated with such surface-bound chromophores. The principal result of this investigation is the quantification of functionally conferred nanoparticle chirality, manifest through optical measurements such as circularly polarized scattering and emission.

The relative position of chiral chromophores fixed to a nanoparticle sphere are first determined by means of spherical coverage co-ordinate analysis. For both emission and scattering, the total electromagnetic field received by a spatially fixed, remote detector is determined. It is shown that bound chromophores will accommodate both electric and magnetic dipole transition moments, whose scalar product represents the physical and mathematical origin of chiral properties identified in the detected signal. Results are reported for both oriented and isotropically averaged systems, the latter accounting for solutions (or randomly oriented) cases where the associated transition moments are uncorrelated with the detector. The analysis concludes with discussion of the magnitude of circular differential optical effects, and their potential significance for the characterization of surface-functionalized nanoparticles.

9545-3, Session 1

Semiconductor nanoplatelets: a new colloidal system for low-threshold, high-gain stimulated emission

Matthew A. Pelton, Univ. of Maryland, Baltimore County (United States) and Argonne National Lab. (United States); Chunxing She, Univ. of Chicago (United States); Igor Fedin, Dmitriy Dolzhnikov, Sandrine Ithurria, The Univ. of Chicago (United States); Erfan Baghani, Stephen K. O'Leary, The Univ. of British Columbia (Canada); Arnaud Demortiere, Illinois Institute of Technology (United States); Richard D. Schaller, Argonne National Lab. (United States); Dmitri V. Talapin, The Univ. of Chicago (United States) and Argonne National Lab. (United States)

Quantum wells (QWs) are thin semiconductor layers than confine electrons and holes in one dimension. They are widely used for optoelectronic devices, particularly semiconductor lasers, but have so far been produced using expensive epitaxial crystal-growth techniques. This has motivated research into the use of colloidal semiconductor nanocrystals, which can be synthesized chemically at low cost, and can be processed in the solution phase. However, initial demonstrations of optical gain from colloidal nanocrystals involved high thresholds.

Recently, colloidal synthesis methods have been developed for the production of thin, atomically flat semiconductor nanocrystals, known as nanoplatelets (NPLs). We investigated relaxation of high-energy carriers in colloidal CdSe NPLs, and found that the relaxation is characteristic of a QW system. Carrier cooling and relaxation on time scales from picoseconds to hundreds of picoseconds are dominated by Auger-type exciton-exciton interactions. The picosecond-scale cooling of hot carriers is much faster than the exciton recombination rate, as required for use of these NPLs as optical gain and lasing materials.

We therefore investigated amplified spontaneous emission using close-packed films of NPLs. We observed thresholds that were more than 4 times lower than the best reported value for colloidal nanocrystals. Moreover, gain in these films is 4 times higher than gain reported for other colloidal nanocrystals, and saturates at pump fluences more than two orders of magnitude above the ASE threshold. We attribute this exceptional performance to large optical cross-sections, relatively slow Auger recombination rates, and narrow ensemble emission linewidths.

9545-5, Session 1

Manipulating the spatial extent of the exciton diffusion through QDs assembly by controlling dimensionality, energy landscape, and exciton density *(Invited Paper)*

Keiko Munechika, Jiye Lee, Dimitrios Simatos, Mauro Melli, Steve Whitelam, Alexander Weber-Bargioni, The Molecular Foundry (United States)

Semiconductor quantum dots are considered a promising material class with the potential of highly tunable and novel optoelectronic properties. Recent research efforts have shown that quantum dots, assembled in well-ordered 1D, 2D and 3D geometries have the potential to funnel excitons via Förster Resonance Energy Transfer (FRET) through the nanocrystal composite. Understanding the inter quantum dot coupling and the spatial extend of exciton diffusion is key to design material for the deliberate control of energy transport through them. In this regard, we study Förster Resonance Energy Transfer (FRET) between CdSe quantum dots in a well-defined 2D assembly with different interparticle distances. We then examine the spatial extent of FRET coupling between quantum dots using confocal fluorescence hyperspectral imaging. We spatially map out the degree of the coupling between the neighboring quantum dots by exciting the quantum dots at a known location and collect fluorescence signals at various distances relative to the excitation. We show that by varying the dimensionality, energy landscape, and exciton density, we are able to manipulate the spatial extent of exciton diffusion through the QDs assembly. Modeling was done in conjunction the experiments and well described our observations in each case. The results provide in-depth understanding into the spatial extent of exciton diffusion via FRET through ordered quantum dot assemblies and provide useful insights in engineering nano-building structures to direct and enhance the direction of the exciton transport to a preferred sites.

9545-6, Session 2

Nitride semiconductor nanostructures for classical and quantum light generation *(Invited Paper)*

Yong-Hoon Cho, KAIST (Korea, Republic of)

9545-7, Session 2

Carrier localization in In-rich InGaN/GaN multiple quantum wells for green light-emitting

Hyun Jeong, Univ. de Technologie Troyes (France); Mun Seok Jeong, Sungkyunkwan Univ. (Korea, Republic of); Gilles Lerondel, Univ. de Technologie Troyes (France)

Carrier localization of In-rich InGaN/GaN MQWs was investigated via spatially resolved optical characterization using NSOM and confocal TRPL. To assess the correlation between carrier localization and crystal quality, sapphire and GaN have been used as substrates for the growth of InGaN/GaN MQWs. We found a strong correlation between the carrier localization and the crystal quality based on temperature dependent PL results. The distribution of luminescent clusters on both samples was shown to be quite different as revealed by the NSOM analysis. The clear relation between the luminescent clusters and the longer PL decay time regions strongly support the claim that carrier localization is strongly affected by the crystal quality. Accurate understanding of the optical characteristics of In-rich InGaN/GaN MQWs is the way to overcome the "green gap" issue, which would ultimately lead to pure white LEDs.

9545-8, Session 2

CdTe quantum dots fluorescent probes for determination of 2,4-dichlorophenol compounds based on the Fe(III)PcTs-BuOOH catalysis system

Tong Yilin, Hongqi Li, Haiqing Chen, Hankou Univ. (China)

A new fluorescent probe based on the fluorescence of CdTe quantum dot was established and studied for the determination of contaminant 2,4-dichlorophenol(DCP) compounds. In the presence of 4-AAP, DCP was catalyzed by iron(II) phthalocyanine (Fe(II)Pc), the reaction product dye was generated, which quenched the fluorescence of CdTe quantum dots. t-BuOOH was added in the system to be as oxidizing agent, greatly accelerated the oxidation effect of DCP. The water soluble CdTe quantum dot was prepared. The effects of reaction conditions on the fluorescence and catalysis oxidation of DCP were studied and the optimal reaction conditions were obtained. In the concentration range of 1.0?10-6mol/L-9.0?10-6mol/L and 1.0?10-5mol/L ~1.3?10-4mol/L, there is a good linear relationship between the change value of CdTe quantum dot Fluorescence intensity P0/P and DCP concentration. This method has good repeatability and ability of resisting disturbance.

9545-9, Session 2

Nanostructured organosilicon luminophores as a new concept of nanomaterials for highly efficient down-conversion of light

Sergey A. Ponomarenko, Institute of Synthetic Polymeric Materials (Russian Federation) and Moscow State Univ. (Russian Federation) and LumInnoTech LLC (Russian Federation); Nikolay M. Surin, Oleg V. Borshchev, Maxim S. Skoroteckiy, Institute of Synthetic Polymeric Materials (Russian Federation) and LumInnoTech LLC (Russian Federation); Aziz M. Muzafarov, Institute of Synthetic Polymeric Materials (Russian Federation) and A.N. Nesmeyanov Institute of Organoelement Compounds (Russian Federation)

Organic luminophores are widely used in various optoelectronic devices, which serve for photonics, nuclear and particle physics, quantum electronics, medical diagnostics and many other fields of science and technology. Improving their spectral-luminescent characteristics for particular technical requirements of the devices is a challenging task. In this work we report on a new concept to universal solution of this problem by creation of nanostructured organosilicon luminophores (NOLs), which are a particular type of dendritic molecular antennas. A NOL consists of two types of covalently bonded via silicon atoms organic luminophores with efficient Förster energy transfer between them (Sci. Rep. 2014, 4, 6549). They combine the best properties of organic luminophores and inorganic quantum dots: high absorption cross-section, excellent photoluminescence quantum yield, fast luminescence decay time, good processability and low toxicity. A smart choice of organic luminophores allowed us to design and synthesize a library of NOLs, absorbing from VUV to visible region and emitting at the desired wavelengths having maxima varying from 390 to 650 nm. Using NOLs in plastic scintillators, widely utilized for radiation detection and in elementary particles discoveries, led to a breakthrough in their efficiency, which combines both high light output and fast decay time. Moreover, for the first time plastic scintillators, which emit light in the desired wavelength region ranging from 370 to 700 nm, have been created. Thin films of NOLs themselves or their composites with optical plastics are transparent, which leads to efficient down-conversion of light useful for different types of optical detectors.

9545-10, Session 3

Terahertz devices based on carbon nanomaterials *(Invited Paper)*

Junichiro Kono, Rice Univ. (United States)

Carbon nanomaterials attract much attention due to novel electronic, photonic, and mechanical properties that can find application in a variety of devices. In particular, they have promising properties for developing optoelec-tronic devices at long wavelengths, i.e., in the mid-infrared (MIR) and terahertz (THz) ranges, including polarizers, modulators, detectors, and sources. It has been predicted that they have superior performance over existing devices in these ranges. In this talk, after reviewing the past, current, and future of the THz science and technology of gra-phene and carbon nanotubes, we will present some of our latest results on THz dynamic conductivity and ultrafast carrier dynamic as well as THz devices including polarizers, modulators, and detectors.

9545-11, Session 3

Theoretical design of nano-layered Al/SiO2 metamaterial with hyperbolic dispersion with minimum losses

Priscilla N. Kelly, Daniel White, Lyuba Kuznetsova, San Diego State Univ. (United States)

Motivated by a greater need for increased performance in modern-day technology, this paper will show the results of theoretical calculations for the optical properties of Al/SiO2 nanolayered metamaterial with hyperbolic dispersion. Our main focus is on finding the conditions for low losses since losses might outweigh any increase in speed for use of metamaterial devices today. Using the Effective Medium approximation (EMA) with non-local corrections, we have investigated effect of three major variables (number and thickness of the Al layers and Al fill fraction) on inherent losses and hyperbolic dispersion. Our model predicts a variation of the dielectric permittivity only in the perpendicular direction as the number of Al layers changes. This is an important factor to consider when reducing losses. The first of the trends is to find the saturation limit of non-local corrections in Al/SiO2 layers. This will tell us when the number of layers reaches the EMA, therefore the full range of optical effects Al/SiO2 layers is capable of. The second and third effects, Al fill fraction with a fixed layer height and thickness of a single layer in a sample of 20 layers, will be investigated to minimize losses. Both of these effects determine the transition wavelength

to hyperbolic dispersion which allows for fine tuning of this dispersion for future applications. The paper will also discuss the repercussions these properties will have on the manufacturing techniques and future applications of Al/SiO2 devices.

9545-12, Session 3

Spectral tunability of the spacer layer in metasurface absorbers

Kai Liu, Nan Zhang, Dengxin Ji, Haomin Song, Xie Zeng, Qiaoqiang Gan, Univ. at Buffalo (United States)

Potential solar energy applications of metamaterial absorbers require spectrally tunable resonance to ensure the overlap with intrinsic absorption profiles of active materials. Although those resonance peaks of metamaterial absorbers can be tuned precisely by lithography-fabricated nanopatterns with different lateral dimensions, they are too expensive for practical large-area applications. In this work, we will report another freedom to tune the spectral position of the super absorbing resonance, i.e. the spacer thickness. The structure was fabricated by evaporating an optically opaque metallic ground plate, a dielectric spacer layer, and a top metallic thin film followed by thermal annealing processes to form discrete nanoparticles. As the spacer thickness increases from 10-90 nm, two distinct shifts of the absorption peak can be observed [i.e. a blue-shift for thinner (10-30 nm) and a red-shift for thicker spacer layers (30-90 nm)]. To understand the physical mechanism, we characterized effective optical constants of top nanopattern layer and loaded them into numerical simulation models. A good agreement with experimental data was only observed in the thick spacer region (i.e. 30-90 nm). The optical behavior for thinner spacers cannot be explained by effective medium theory and interference mechanism. Therefore, a microscopic study has to be performed to reveal strongly coupled modes under metallic nanopatterns, which can be interpreted as separate antennas strongly coupled with the ground plate. Since the resonant position is sensitive to the spacer thickness, a tunable super absorbing metasurface is realizable by introducing spatial tunable materials like stretchable chemical/biomolecules.

9545-13, Session 3

Highly efficient excitonic emission of CBD grown ZnO micropods

Roy Aad, Anisha Gokarna, Komla Nomenyo, Univ. de Technologie Troyes (France); Patrice Miska, Univ. de Lorraine (France); Wei Geng, Christophe Couteau, Gilles Lérondel, Univ. de Technologie Troyes (France)

Due to its wide direct band gap and large exciton binding energy allowing for efficient excitonic emission at room temperature, ZnO has attracted attention as a luminescent material in various applications such as UV-light emitting diodes, chemical sensors and solar cells. While low-cost growth techniques, such as chemical bath deposition (CBD), of ZnO thin films and nanostructures have been already reported; nevertheless, ZnO thin films and nanostructures grown by costly techniques, such as metalorganic vapour phase epitaxy, still present the most interesting properties in terms of crystallinity and internal quantum efficiency.

In this work, we report on highly efficient and highly crystalline ZnO micropods grown by CBD at a low temperature (< 90°C). XRD and low-temperature photoluminescence (PL) investigations on as-grown ZnO micropods revealed a highly crystalline ZnO structure and a strong UV excitonic emission with internal quantum efficiency (IQE) of 10% at room temperature. Thermal annealing at 900°C of the as-grown ZnO micropods leads to further enhancement in their structural and optical properties. Low-temperature PL measurements on annealed ZnO micropods showed the presence of phonon replicas, which was not the case for as-grown samples. The appearance of phonon replicas provides a strong proof of the improved crystal quality of annealed ZnO micropods. Most importantly, low-temperature PL reveals an improved IQE of 15% in the excitonic emission of ZnO micropods. The ZnO micropods IQE reported here are comparable to IQEs reported on ZnO structures obtained by costly and more complex growth techniques. These results are of great interest demonstrating that high quality ZnO microstructures can be obtained at low temperatures using a low-cost CBD growth technique.

9545-14, Session 3

High-speed tip-enhanced Raman imaging *(Invited Paper)*

Marc Chaigneau, HORIBA Jobin Yvon S.A.S. (France); Andrey V. Krayev, AIST-NT Inc. (United States); Ophélie Lancry, HORIBA Jobin Yvon S.A.S. (France); Sergey A. Saunin, AIST-NT Inc. (United States)

Tip Enhanced Raman Scattering (TERS), a technique that provides molecular information on the nanometer scale, has been a subject of great scientific interest for 15 years. But regardless of the recent achievements and applications of TERS, ranging from material science and nanotechnology, strain measurement in semiconductors, to cell biological applications, the TERS technique has been hampered by extremely long acquisition times, measured in hours, required for collection of reasonably high pixel density TERS maps.

In this talk, specifics of the TERS setup that enable fast, high pixel density nano-Raman imaging will be discussed: The innovative integration of technologies brings high-throughput optics and high-resolution scanning for high-speed imaging without interferences between the techniques. The latest developments in near-field optical probes also provide reliable solutions for academic and industrial researchers alike to easily get started with nanoscale Raman spectroscopy. Thanks to those latest instrumental developments, we will present the nanoscale imaging of chemical and physical properties of graphene, carbone nanotubes and self-assembled monolayers of organic molecules, with a spatial resolution routinely obtained in TERS maps in the 15 - 20 nm range and a best resolution achieved being of 7 nm

Design of metal/dielectric/nanocrystals core/shell/shell nano-structures for the fluorescence enhancement of cadmium-free semiconductor nanocrystals *(Invited Paper)*

Théo Chevallier, Gilles Le Blevennec, Frederic Chandezon, Commissariat à l'Énergie Atomique (France)

AgInS2-ZnS (ZAIS) quaternary semiconductors nanocrystals are versatile cadmium-free luminescent nanomaterials that are ideal for the development of innovative white-LED devices. By grafting ZAIS nanocrystals to carefully chosen metal@dielectric core@shell nanoparticles, both the absorption and emission processes can be tuned and enhanced. A simulation was used to predict the nano-optical behavior of a silver@oxide@nanocrystals structures and find the most efficient structures before synthesizing and testing them.

This study shows the potential of silver@oxide@ZAIS nanocrystals nanostructures and highlights the use of simulation as a guiding tool for the design of efficient photonic nanostructures targeting specific applications.

Adiabatic mode coupler on ion-exchanged waveguides for the efficient excitation of surface plasmon modes

Josslyn Beltran Madrigal, Univ. de Technologie Troyes (France); Martin Berthel, Institut NÉEL (France); Florent

Gardillou, Teem Photonics S.A. (France); Ricardo Tellez Limon, Christophe Couteau, Univ. de Technologie Troyes (France); Denis Barbier, Teem Photonics S.A. (France); Aurelien Drezet, Institut NÉEL (France); Rafael Salas-Montiel, Univ. de Technologie Troyes (France); Serge Huant, Institut NÉEL (France); Sylvain Blaize, Wei Geng, Univ. de Technologie Troyes (France)

Several works have already shown that the excitation of plasmonic structures through waveguides enables a strong light confinement and low propagation losses [1]. This kind of excitation is currently exploited in areas such as biosensing [2], nanocircuits[3] and spectroscopy[4].

The efficient excitation of surface plasmon modes (SPP) with guided modes supported by high-index-contrast waveguides, such as silicon-on-insulator waveguides, had already been shown [1,5]. However, the use of weak-confined guided modes of a glass ion exchanged waveguide as a SPP excitation source represents a technological challenge, because the mismatch between the size of their respective electromagnetic modes is so high that the resultant coupling loss is unacceptable for practical applications.

In this work, we describe how an adiabatic taper structure formed by an intermediate high-index-contrast layer placed between a plasmonic structure and an ion-exchanged waveguide decreases the mismatch between effective indices, size, and shape of the guided modes. This hybrid structure concentrates the electromagnetic energy from the micrometer to the nanometer scale with low coupling losses to radiative modes. The electromagnetic mode confined to the high-index-contrast waveguide then works as an efficient source of SPP supported by metallic nanostructures placed on its surface.

We theoretically studied the modal properties and field distribution along the adiabatic coupler structure. In addition, we fabricated a high-index-contrast waveguide by electron beam lithography and thermal evaporation on top of an ion-exchanged waveguide on glass. This structure was characterized with the use of near field scanning optical microscopy (NSOM). Numerical simulations were compared with the experimental results.

Multiscale modeling of the plasmonic and light trapping response of random nanostructured TiO2-photoelectrodes

Ivonne Carvajal, George P. Demopoulos, Raynald Gauvin, McGill Univ. (Canada)

Random nanostructured materials possess electromagnetic properties that greatly differ from those of ordinary bulk materials. The capacity to control the optical response of the material by tuning its internal structure has rendered these architectures into a promising light trapping technology for solar energy conversion and photocatalytic applications. However, a rigorous electromagnetic computation of these structures in large-scale systems is computationally demanding and impractical. Here, we present a multiscale optical model approach to study random nanostructured TiO2-photoelectrodes for solar cell applications. In this approach, Maxwell's electromagnetic equations are solved with the generalized-multiparticle-Mie theory for a system of aggregated TiO2 nanoparticles in a subwavelength volume. The results are then implemented in a Monte Carlo algorithm to simulate the propagation of light within the photoelectrode. We investigate the influence of the TiO2 crystal phase, porosity, and pore and particle size distributions on the photoelectrode transmitted, reflected and absorbed spectra. Results of the simulations agree with the observed experimental data. We show that careful engineering of the internal structure and of the photoelectrode gives accurate control on the coupling of incident light with the nanostructured film over the UV to near-IR spectrum range that can lead to enhanced solar energy conversion efficiency. Our approach provides for the first time insight into the spatial distribution of electron generation within the photoelectrode that is of great importance for the design and optimization of the photoelectrode. Finally, we show the potential of this model to investigate randomly structured materials composed of nanowires.

New design of photonic band gap filter: the random dimer effect

Brezini Abderrahmane, Univ. d'Oran (Algeria); Fares Kanouni, Ctr. de Recherche (Algeria); Qin Zou, Institut Telecom Sud Paris (France)

A new type of optical filter using photonic band gap materials is suggested. We consider photonic superlattices composed of two alternating photonic crystals. The structure is denoted as A/B/A/B.....A/B, where photonic crystals A and B act as photonic wells and barriers, respectively. The propagation of electromagnetic waves in such one dimensional disordered photonic crystal is investigated by means the transfer matrix formalism. In particular the presence of short range correlation in disorder into the sample induces the suppression of localization. By introducing a short range intentionally binary disorder provides predicted resonance breaking down the Anderson localization. By properly adjusting the intrinsic dimer unit cell parameter i.e. dimer dielectric constants ?d, light can be transmitted over the whole sample with a very large localization length ? through a ballistic canal. Such findings open up possibilities in performing new design optical filter. Moreover with increasing the degree of disorder, by means the dimer concentration cd and the period number N, the quality in transmitting light around the resonance is significantly improved with the smoother corresponding allowed mini band.

9545-19, Session 4

Optical properties of polyaniline-coated silica spheres: aging effect in acetone

Byeong-Wu Kim, Sang-Jo Kim, So-Yeon Kang, Sang-Hyeon Moon, Eun-Hye Park, Kwang-Sun Kang, Kyungil Univ. (Korea, Republic of)

Polyaniline (PAn)-coated silica spheres have been synthesized by attaching various amounts of N-[3-(trimethoxysilyl)propyl]aniline (TMSPA) and polymerizing with ammonium persulfate. The ratios of tetraethoxy orthosilicate and TMSPA were 10:1 (PAn-A), 5:1 (PAn-B), and 3:1 (PAn-C). After polymerization of the aniline moieties the –OH absorption peak drastically reduced and the new sharp peaks appeared at 1398 cm-1 and 617 cm-1 representing C-N and C-S stretching vibrations, respectively. The polymerized spheres were soaked into the acetone for three months. New absorption peak at 1712 cm-1 representing C=O stretching vibration of an ester appears after three months storage in acetone and becomes stronger with the smaller amount of PAn. Although the sphere film color is gray when it is dried, the color turned to dark when it was wetted with methanol. Complicated solvatochromic behavior was observed for whole UV-visible range depending on the solvent. The solution color changed from clear to dark brown, brown, and yellow for the PAnA, PAnB and PAnC, respectively. The absorption peaks of the dried solution for PAn-A and PAn-B at 3230, 2972, 2926, 1712, 1434/1377, and 1051 cm-1 represent C-OH, R-CH3, R2-CH2, -C=O, C-H, and Si-O-Si absorption, respectively. Photoluminescence peak of the solution shifted toward longer wavelength with the decrease the amount of PAn. The sequence of the amount of new material formation is PAn-A > PAn-B > PAn-C.

Investigation of Ta nanoparticles characteristics produced by laser ablation method

Fariba Azadi Kenari, Mohammad Reza Hantehzadeh, Islamic Azad Univ. (Iran, Islamic Republic of)

In this paper the characteristics of Tantalum nano particles produced by laser ablation method is investigated experimentally with a first harmonic of a Q-switched Nd:YAG laser of 1064 nm wavelengths at 6 ns pulse. Spherical nano particles of Ta have been produced successfully by using a 1?cm?^2 Ta bulk plate in Ethanol.The fluency of laser is 105 j/?cm?^(-2) .By using some molecular-scale devices such as transmission Electron Microscopy (TEM),photo luminescence (PL), X-ray diffraction (XRD) and absorption spectroscopy we determined the optical characteristic, size, band gap energy,crystlline characteristics and size of nano particles.And at the end, some applications of Ta have been noticed.

Resonant tunneling in 2D-photonic superlattices

Fares Kanouni, Ctr. de Développement des Téchnologies Avancées (Algeria); abderrahmane Brezini, Thin films and nanostructures Laboratory LaMiN, Polytechnic School, Oran, 31000, Algeria (Algeria); fahima arab, radouane graine, Ctr. de Développement des Téchnologies Avancées/ research unit in optics and photonics (Algeria)

Transmissions and resonant tunneling of two-dimensional (2D) photonic superlattices (PhSLs) are discussed. We consider PhSL composed of two alternating 2D-photonic crystals. The structure is denoted as A/B/A/B..... A/B, where photonic crystals A and B act as photonic wells and barriers, respectively. The transmission coefficient is calculated using the Transfer Matrix Method (TMM) in combination with Bloch theorem. The transmission spectra of the PhSLs indicate that the formation of photonic minibands and minigaps inside the wells. The positions and number of the minibands can be artificially tuned by varying the well width. By appropriately choosing the structure parameters, these interesting results can be used to develop new photonic devices.

Broadband ENZ metamaterials based on metal-polymer composite films

Pavlo Pinchuk, Ke Jiang, Univ. of Colorado at Colorado Springs (United States)

Epsilon-near-zero metamaterials are of interest for a broad range of potential applications in photonics, photovoltaics, and communications. In this work we present the experimental and theoretical results on a broadband ENZ metamaterial composite film based on gold metal nanoparticles of different sizes embedded in a polymer thin film. Gold metal nanoparticles of the sizes ranges 10 - 50 nm were synthesized using chemical reduction of gold chloride with borohydride. The solutions of the nanoparticles were characterized by using the UV-VIS spectroscopy, DLS, and SEM microscopy. The nanoparticles were then mixed and embedded into composite thin polymer films. The thin films were characterized by UV-VIS spectroscopy. The optical absorption spectra were then used to retrieve the complex dielectric permittivity of the solutions of the nanoparticles and the composite thin films by using Kramers-Kronig integrals. The Maxwell-Garnett effective medium theory was then used to calculate the effective complex dielectric permittivity of the composite polymer films.

Using of radiation intensity dependence on excitation level for the analysis of surface plasmon resonance effect on ZnO luminescence

Stepan I. Rumyantsev, Mikhail V. Ryzhkov, Charus M. Briskina, Valery M. Markushev, Institute of Radio Engineering and Electronics (Russian Federation); Andrey P. Tarasov, Moscow Institute of Physics and Technology (Russian Federation) and Institute of Radio Engineering and Electronics (Russian Federation); Andrey A. Lotin, Institute on Laser and Information Technologies (Russian Federation)

For the analysis of surface plasmon (SP) resonance effect on ZnO luminescence the system of rate equations (SRE) is proposed. It contains a set of parameters that characterizes processes participating in luminescence: zone-zone excitation, excitons formation and recombination, formation and disappearance of photons and SP. It is shown that utilizing SRE experimental ZnO microstructure radiation intensity dependence on photoexcitation level can be approximated. Thus the values of these parameters can be estimated and used for luminescence analysis.

This approach was tested on ZnO microfilms with different thickness of Ag island film covering. It was revealed that the increase of cover thickness leads to the increase of losses and probability of photons to SP conversion decrease.

Based on SRE parameters dependence of luminescence intensity of ZnO microstructures covered by Ag with MgO spacer on its thickness was simulated. It turns out that it is possible to obtain the result near to the experimental one if we assume exponential decrease of probability of photons hit in Ag-cover with the increase of spacer thickness.

In order to take into account visible emission rate equations for levels populations in energy gap and for corresponding photons and SP were added to SRE. Using such SRE it is shown that the form of visible luminescence intensity dependence on excitation level (P) like (P) raised to the power of 1/3 as obtained elsewhere (Studenikin et al., J.Appl.Phys.91, 5060, 2002) is possible only for emission of donor-acceptor pairs.

Visible-light response of TiO2 photocatalysts introduced by annealing

Fangzhou Liu, The Univ. of Hong Kong (Hong Kong, China); Mu Yao Guo, Alan Man Ching Ng, South Univ. of Science and Technology of China (China) and The Univ. of Hong Kong (Hong Kong, China); Aleksandra B. Djuri?i?, Wai Kin Chan, The Univ. of Hong Kong (Hong Kong, China)

TiO2 has been one of the most investigated photocatalysts for its high effectiveness and efficiency for degradation of various organic compounds. Several major crystal phases of TiO2, such as anatase and rutile, as well as the commercially available form with mixed phases, all exhibit considerable photocatalytic activities. However, due to their large band-gaps, these TiO2 forms are primarily active under UV illumination which only accounts for a very small portion of solar energy.1 To overcome this restriction, efforts have been made by doping TiO2 with metal or non-metal atoms, coupling with narrow band-gap materials, oxygen deficiency, as well as the investigation of carbon-titania composites.1 Oxygen deficient TiO2 has been reported as a visible-light-active photocatalyst due to the midgap states below the conduction band introduced by oxygen vacancies.2 Based on this understanding, various techniques can be utilized to enable visible-light photoactivity of TiO2 materials.

In this work, we proposed a simple approach to obtain visible-light-responsive TiO2 photocatalysts. TiO2 nanoparticles with different crystal

phases (anatase, rutile, and anatase-rutile mixture) were annealed together with Cu foil in vacuum at specified temperatures. The as-fabricated samples exhibited enhanced photocatalytic activities under solar illumination with UV block filter compared to initial materials. Other characterizations were performed to detect the changes of the materials corresponding to visible-light activation. Possible mechanisms were explained in detail.

Photovoltaic study of dye sensitized solar cells based on TiO2, ZnO:Al3+ nanoparticles

Ruben A. Rodríguez-Rojas, Humberto E. Sanchez, Jesus Castañeda-Contreras, Virginia F. Marañon-Ruiz, Héctor Pérez Ladrón de Guevara, Univ. de Guadalajara (Mexico); Tzarara López-Luke, Elder De la Rosa-Cruz, Ctr. de Investigaciones en Óptica, A.C. (Mexico)

A technique to fabricate dye (rhodamine B) sensitized solar cells based on titania oxide and zinc oxide nanoparticles is reported. The TiO2 was synthesized using the sol-gel method and the ZnO was synthesized by hydrolysis method to obtain nanoparticles of ~ 5 nm and 150 nm respectively. ZnO was doped with Al3+ in order to enhance the photovoltaic efficiency in order to promote the electrons mobility. The photovoltaic conversion characterization of films of TiO2, ZnO and ZnO:Al3+ nanoparticles is also reported. The generated photocurrent was measured by two methods; one of those uses a three electrode electrochemical cell and the other use an electronic array where the cells were exposed to UV lamp and the sun light. The role of the TiO2, ZnO and Al3+ doped ZnO nanoparticles is discussed to obtain a better efficiency in the generation of photocurrent (PC). The results exhibited by the electrochemical cell method, efficiencies of 0.55 (PC=187 μA/cm2) and 0.22 (PC=149 μA/cm2) for TiO2 and undoped ZnO respectively. However, when ZnO is doped with Al3+ at the higher concentration the efficiency was 0.44. While using the electronic array the results exhibited efficiencies of 0.31 (PC=45 μA/cm2) and 0.09 (PC=16 μA/cm2) for TiO2 and undoped ZnO respectively. However, when ZnO is doped with Al3+ at the higher concentration the efficiency was 0.44 and 0.48 for electrochemical cell and electronic array respectively. This shows that Al3+ enhances the photogenerated charge carriers increasing the mobility of electrons.

Photodisaggregation of silver nanoparticles suspended in ethanol

Gabriel J. Ortega, Alfonso Padilla-Vivanco, Carina Toxqui-Quitl, Univ. Politécnica de Tulancingo (Mexico); Placido Zaca, Fernando Chávez, Benemérita Univ. Autónoma de Puebla (Mexico); O. Goiz, Instituto Politécnico Nacional (Mexico)

An experimental study about of aggregation and disaggregation of silver nanoparticles suspended in ethanol is presented. Disaggregate process is implemented when a non-colloidal solution of silver nanoparticles whose size are less than 100 nm is irradiated with a pulsed laser via an optical fiber. Results show that, it is possible to disaggregate and aggregate nanoparticles with certain sizes only by controlling the laser energy. A colloidal solution with a spectrum extinction characteristic and particular color is obtained when a non-colloidal solution is irradiated with a laser energy greater than 100 nJ. Furthermore, we also show that, the laser light also provokes aggregation of silver nanoparticles with certain sizes when a colloidal solution is irradiated with an energy laser greater than 100 nJ. Experimental results are presented.

Suppressing spontaneous polarization of p-GaN by graphene oxide passivation: augmented light output of GaN UV-LED

Hyun Jeong, Univ. de Technologie Troyes (France); Mun Seok Jeong, Sungkyunkwan Univ. (Korea, Republic of)

GaN-based ultraviolet (UV) LEDs are widely used in numerous applications, including white light pump sources and high-density optical data storage. However, one notorious issue is low hole injection rate in p-type transport layer due to poorly activated holes and spontaneous polarization, giving rise to insufficient light emission efficiency. Therefore, improving hole injection rate is a key step towards high performance UV-LEDs. Here, we report a new method of suppressing spontaneous polarization in p-type region to augment light output of UV-LEDs. This was achieved by simply passivating graphene oxide (GO) on top of the fully fabricated LED. The dipole layer formed by the passivated GO enhanced hole injection rate by suppressing spontaneous polarization in p-type region. The homogeneity of electroluminescence intensity in active layers was improved due to band filling effect. As a consequence, the light output was enhanced by 60% in linear current region. Our simple approach of suppressing spontaneous polarization of p-GaN using GO passivation disrupts the current state of the art technology and will be useful for high-efficiency UV-LED technology.

9545-38, Session PWed

A simple method for p-type doping of monolayer MoS2 using graphene oxide

Hye Min Oh, Young Hee Lee, Mun Seok Jeong, Sungkyunkwan Univ. (Korea, Republic of)

We propose a novel and simple method for p-type doping of monolayer MoS2 by spin-casting of graphene oxide sheet (GO). The GO sheets act as a p-type dopant because of their large number of functional groups, which exhibit electron-withdrawing characteristics. Increased PL intensity and shifted peak positions in the PL and Raman spectra, which served as evidence of the p-type doping of the MoS2, were clearly observed. Moreover, the current versus voltage curves recorded for backward and forward bias also confirmed the rectifying behavior of a MoS2 p-n junction diode. The observed p-type doping effect can be explained by the numerous electron-withdrawing groups present on GO sheets. Moreover, using confocal PL/Raman spectroscopic analysis, we observed that the p-type doping of MoS2 is extremely sensitive to the thickness of the coated GO sheets. Our technique for the p-type doping of MoS2 through contact with GO sheets offers remarkable advantages for optoelectronic applications; the process is simple and low in cost, and it allows the large-scale fabrication and the modulation of doping concentration by controlling the thickness of the coated GO sheets.

Determination of refractive index and absorbance modulation amplitudes from angular selectivity of holograms in polymer material with phenanthrenequinone

Vladimir N Borisov, Andrey N Veniaminov, ITMO University (Russian Federation)

Amplitude and phase contributions to mixed volume holographic gratings were extracted from measured contours of angular selectivity. Holograms for the investigation were recorded in the glassy polymer material with phenanthrenequinone (PQ) using the DPSS CW laser (532 nm) and then self-developed due to molecular diffusion of PQ, reaching diffraction

efficiency about 40%. Refractive index and absorbance modulation amplitudes of those holograms were obtained as adjustable parameters from theoretical equations by fitting angular dependences of zeros and 1st orders diffraction efficiency measured at 450, 473, 532, and 633 nm at the different stages of hologram development. Mixed gratings manifest themselves in asymmetrical transmittance selectivity contours with one minimum and one maximum shifted with respect to the Bragg angle, while symmetrical contours with a minimum or a maximum are characteristic of pure phase and amplitude gratings, respectively. In the course of hologram development, it converts from a predominantly amplitude-mixed to almost purely phase one in the case of readout using a light within the absorption band of PQ and maintains the phase nature besides it. The value of refractive index amplitude is ranging from 5?10-6 to 10-4 and the value of absorbance amplitude is up to 140 m-1.

9545-40, Session PWed

Synthesis, characterization, and electrical properties of Pd doped ZnO nanoparticles with enhanced visible light phtocaralytic activity

Omar Abdullah Al-Hartomy, Mohammad Mujahid, Univ. of Tabuk (Saudi Arabia)

Synthesis of pure and Pd doped ZnO has been carried out using easy hydrothermal method which is less time-consuming, inexpensive and give high yields. The synthesized materials are characterized by standard analytical techniques, such as X- ray Diffraction analysis (XRD), Scanning Electron Microscopy (SEM), Transmission Electron Microscopy (TEM) and UV-Visible Spectroscopy. The XRD analysis shows no change in crystal structure of ZnO after doping with different concentration of Pd indicating single phase polycrystalline material. The SEM images confirm that Pd are well incorporated on the surface of ZnO. The UV-Visible absorption analysis technique indicate that the doping of Pd into the ZnO lattice shift the absorption band towards the visible region. The electrical properties of the synthesized particle have been performed by monitoring the dielectric constant (?), dielectric loss (tan ?) and ac conductivity with respect to frequency. The dielectric constant and dielectric loss decreases with the increase in frequency upto certain limit, after then on further increase in frequency, they became independent. The a.c. conductivity increases with the increase of frequency. The dielectric property also decreases by increase of the dopant concentration.

9545-20, Session 5

Rh6G released from solid and nanoporous SiO2 spheres prepared by sol-gel route

Jorge A. Garcia-Macedo, Pedro Francisco-Santiago, Alfredo Franco, Univ. Nacional Autónoma de México (Mexico)

Porous silica nanoparticles are considering good systems for drug cargo and liquid separation. In this work we studied the release of rhodamine 6G from solid and porous silica nanoparticles. Solid SiO2 spheres were prepared by sol-gel method. Nanoporous channels were produced by using a surfactant that was removed by chemical procedure. Rh6G was incorporated into the channels by impregnation. The hexagonal structure of the pores was detected by XRD and confirmed by HRTEM micrographs. N2 adsorption-desorption isotherm Type V, was obtained by BET in the nanoporous particles. Surface area was bigger in the nanoporous spheres than in the solid ones. Rh6G released from the particles by stirring them in water at controlled speed was studied as function of time by photoluminescence. Released ratio was faster in the solid nanoparticles than in the porous ones. In the last case, a second release mechanism was observed. It was related with rhodamine coming out from the porous.

9545-21, Session 5

Fabrication and characterization of p-ZnO:(P,N)/n-ZnO:Al homojunction ultra-violet (UV) light emitting diodes

Amiruddin Rafiudeen, T. Srinivasa Reddy, Shaheer Cheemadan, M.C. Santhosh Kumar, National Institute of Technology, Tiruchirappalli (India)

ZnO possess distinctive characteristics such as low cost, wide band gap (3.36 eV) and large exciton binding energy (60meV). As the band gap lies in ultra violet (UV) region, ZnO is considered as a novel material for the fabrication of ultra violet light emitting diodes (UV-LEDs). However, ZnO being intrinsic n-type semiconductor the key challenge lies in realization of stable and reproducible p-type ZnO. In the present research dual acceptor group-V elements such as P and N are simultaneously doped in ZnO films to obtain the p-type characteristics. The deposition is made by programmable spray pyrolysis technique upon glass substrates at 697K. The optimum doping concentration of P and N were found to be 0.75 at% which exhibits hole concentration of 4.48 x 10^18 cm-3 and resistivity value of 9.6 Ω.cm. The deposited p-ZnO were found to be stable for a period over six months. Highly conducting n-type ZnO films is made by doping aluminum (3 at%) which exhibits higher electron concentration of 1.52 x 10^19 cm-3 with lower electrical resistivity of 3.51 x 10-2 Ω.cm. The structural, morphological, optical and electrical properties of the deposited n-ZnO and p-ZnO thin films are investigated. An efficient p-n homojunction has been fabricated using the optimum p-ZnO:(P,N) and n-ZnO:Al layers. The current–voltage (I–V) characteristics show typical rectifying characteristics of p-n junction with a low turn on voltage. Electroluminescence (EL) studies reveals the fabricated p-n homojunction diodes exhibits strong emission features in ultra-violet (UV) region around 378 nm.

9545-22, Session 5

Control of photoinduced fluorescence enhancement of colloidal quantum dots using metal oxides

Seyed M. Sadeghi, Waylin J. Wing, Kira Patty, The Univ. of Alabama in Huntsville (United States)

It is well known that irradiation of colloidal quantum dots can dramatically enhance their emission efficiencies, leading to so-called photoinduced fluorescence enhancement (PFE). This process is the result of the photochemical and photophysical properties of quantum dots and the way they interact with the environment in the presence of light. In this contribution we will discuss the results of our recent investigations regarding the impact of metal oxides on PFE of quantum dots. For this, using spectroscopic techniques, we investigated emission of different types of quantum dots (with and without shell) in the presence of various types of metal oxides while being irradiated with a laser field. We observed significant increase of PFE when quantum dots are deposited on about one nanometer of aluminum oxides, suggesting such oxide can profoundly increase quantum yield of such quantum dots. On the other hand, copper oxide can lead to significant suppression of emission of quantum dots, making them nearly completely dark. We discovered for certain types of quantum dots, aluminum oxide can be used to reduce the adverse impact of photo-oxidation, allowing reduction of quantum dot core sizes without significant increase of their non-radiative decay rates. We discuss these results in terms of impact of aluminum oxide on coulomb blockade caused by photo-ionization in quantum dots and the way laser intensity influence this process. The results of this study show how metal oxides can be used to induce or accelerate certain types of photo-induced processes in quantum dots, providing us unique tools to explore and utilize their photophysics and photochemistry.

9545-23, Session 5

Optical thin film materials and devices for harsh environment, high temperature sensing applications

Paul R. Ohodnicki Jr., Zsolt Poole, Thomas Brown, John Baltrus, National Energy Technology Lab. (United States); Kevin Chen, Aidong Yan, Univ. of Pittsburgh (United States)

Optical sensors display a number of advantages for extreme temperature, harsh environment sensing applications. A research program has therefore been established at the National Energy Technology Laboratory in the area of functional optical sensor materials for harsh environment sensing applications. The presentation will provide an overview of research technical developments in the specific area of optical nanocomposite based sensing layers consisting of metal oxides integrated with noble metal nanoparticles for optical H2 sensing applications at ambient and elevated temperatures.

Two different types of functional sensor layers will be investigated, namely (1) Pd and AuPd-alloy nanoparticle incorporated silica based sensing layers as well as (2) Pd / nanostructured TiO2 based sensing layers. Film characterization results will be presented for films deposited on planar substrates and characteristic elevated temperature sensing responses for fabricated prototype sensors will be presented at temperatures that are relevant for typical fuel gas streams in solid oxide fuel cell applications, for example. The results demonstrate that in the presence of oxidizing gas species at elevated temperatures, oxidation and reduction reactions of Pd-based nanoparticles can play a significant or even dominant role in the measured sensing response. In the absence of oxidizing gas species, responses are likely to be dictated by a combination of characteristic absorption of the oxide matrix and/or the direct interaction of H2 with the Pd-based nanoparticles. Theoretical modeling results that help to explain the reported observations will also be discussed.

9545-24, Session 5

Enhanced luminescence excitation via efficient optical energy transfer *(Invited Paper)*

Roy Aad, Komla D. Nomenyo, Univ. de Technologie Troyes (France); Bogdan Bercu, Univ. de Reims Champagne-Ardenne (France); Christophe Couteau, Univ. de Technologie Troyes (France); Vincent Sallet, Univ. de Versailles Saint-Quentin-en Yvelines (France); David J. Rogers, Nanovation (France); Michael Molinari, Univ. de Reims Champagne-Ardenne (France); Gilles Lérondel, Univ. de Technologie Troyes (France)

Luminescent nanoscale materials (LNMs) have received widespread interest in sensing and lighting applications due to their enhanced emissive properties. For sensing applications, LNMs offer improved sensitivity and fast response time which allow for lower limits of detection. Meanwhile, for lighting applications, LNMs, such as quantum dots, offer an improved internal quantum efficiency and controlled color rendering which allow for better lighting performances. Nevertheless, due to their nanometric dimensions, nanoscale materials suffer from extremely weak luminescence excitation (i.e. optical absorption) limiting their luminescence intensity, which in turn results in a downgrade in the limits of detection and external quantum efficiencies. Therefore, enhancing the luminescence excitation is a major issue for sensing and lighting applications.

In this work, we report on a novel photonic approach to increase the luminescence excitation of nanoscale materials. Efficient luminescence excitation increase is achieved via a gain-assisted waveguided energy transfer (G-WET). The G-WET concept consists on placing nanoscale materials atop of a waveguiding active (i.e. luminescent) layer with optical gain. Efficient energy transfer is thus achieved by exciting the nanoscale material via the tail of the waveguided mode of the active layer emission. The G-WET concept is demonstrated on both a nanothin layer of fluorescent sensitive polymer and on CdSe/ZnS quantum dots coated on ZnO thin film, experimentally proving up to an 8-fold increase in the fluorescence of the polymer and a 3-fold increase in the luminescence of the CdSe/ZnS depending of the active layer emission regime (stimulated vs spontaneous emission). Furthermore, we will discuss on the extended G-WET concept which consists on coating nanoscale materials on a nanostructured active layer. The nanostructured active layer offers the necessary photonic modulation and a high specific surface which can presumably lead to a more efficient G-WET concept. Finally, the efficiency as well as the observation conditions of the GWET will be discussed and compared with more conventional charge transfer or dipole-dipole energy transfer.

9545-25, Session 6

Optical property tuning of bismuth chalcogenides using chemical intercalation *(Invited Paper)*

Jie Yao, Univ. of California, Berkeley (United States)

Two-dimensional (2D) materials with natural layer structures have been proven to provide extraordinary physical and chemical properties. Bismuth chalcogenides are examples of such two-dimensional materials. They are strongly bonded within layers and weak van der Waals interaction ties those layers together. Such naturally layered structure allows chemical intercalation of foreign atoms into the van der Waals gaps. Here, we show that by adding large number of copper atoms into van der Waals gaps of bismuth chalcogenides, we observed counter-intuitive enhancement of optical transparency together with improved electrical conductivity, which is on the contrary to most bulk materials in which doping reduces the light transmission. This surprising behavior is caused by substantial tuning of material optical property and nanophotonic anti-reflection effect unique to ultra-thin nanoplates. With the intercalation of copper atoms, large number of electrons have been added into the semiconducting material system and effectively lift the Fermi level of the resulting material to its conduction band, as proved by our density-functional-theory computations. Occupied lower states in the conduction band do not allow the optical excitation of electrons in the valence band to the bottom of the conduction band, leading to an effective widening of optical band gap. Optical transmission is further enhanced by constructive interference of reflected beams as bismuth chalcogenides have large permittivity than the environment. The synergy of these two effects in two-dimensional nanostructures can be exploited for various optoelectronic applications including transparent electrode. The reversible intercalation process allows potential dynamic tuning capability.

9545-26, Session 6

Utilizing homogenous FRET to extend molecular photonic wires beyond 30 nm

Sebastian A. Diaz, Susan Buckhout-White, Mario G. Ancona, Joseph S. Melinger, Igor L. Medintz, U.S. Naval Research Lab. (United States)

Molecular photonic wires (MPWs) present interesting applications in energy harvesting, artificial photosynthesis, and nano-circuitry. MPWs allow the directed movement of energy at the nanoscopic level. Extending the length of the energy transfer with a minimal loss in efficiency would overcome an important hurdle in allowing MPWs to reach their potential. We investigated Homogenous Förster Resonance Energy Transfer (HomoFRET) as a means to achieve this goal. We designed a simple, self-assembled DNA nanostructure with specifically placed dyes (Alexa488-Cy3-Cy3.5-Alexa647-Cy5.5) at a distance of 3.4 nm, a separation at which energy transfer should theoretically be very high. The input of the wire was at 466 nm with an output up to 697 nm. Different structures were studied where the Cy3.5 section of the MPW was extended from one to six repeats. We found that though the efficiency cost is not null, HomoFRET can be extended up to six repeat dyes with only a 22% efficiency loss when compared to a

single step system. The advantage is that these six repeats created a MPW which was 17 nm longer, almost 2.5 times the initial length. To confirm the existence of HomoFRET between the Cy3.5 repeats fluorescence lifetime and fluorescence lifetime anisotropy was measured. Under these conditions we are able to demonstrate the energy transfer over a distance of 30.4 nm, with an end-to-end efficiency of 2.0%, by utilizing a system with only five unique dyes.

9545-27, Session 6

TiO2 membranes for concurrent photocatalytic organic degradation and corrosion protection

Robert Liang, Melisa Hatat, Horatio He, Y. Norman Zhou, Univ. of Waterloo (Canada)

Organic contaminants and corrosion products in water treatment effluents are a current and emerging global problem and the development of effective methods to facilitate the removal of organic contaminants and create effective corrosion control strategies are required to mitigate this problem. TiO2 nanomaterials that are exposed to UV light can generate electron-hole pairs, which undergo redox reactions to produce hydroxyl radicals from adsorbed molecular oxygen. They hydroxyl radicals are able to oxidize organic contaminants in water. This same process can be used in conjunction to protect metals from corrosion via cathodic polarization. In this work, TiO2 nanomaterials were synthesized and deposited as films on conductive substrates via electrophoretic deposition. These films were characterized for their material and structural properties using XRD, XPS, and SEM. An illuminated TiO2 film on a conductive surface served as the photoanode and assisted in the cathodic protection of steel and the degradation of organic pollutants, in this case glucose. This proof-of-concept relied on photoelectrochemical experiments conducted using a potentiostat and a xenon lamp illumination source to mimic solar radiation. The open-circuit potential changes along with weight loss measurements was measured and determined whether a metal was protected from corrosion under illumination. The electrical characteristics of the TiO2 film or membrane under dark and arc lamp illumination conditions were analyzed using electrochemical impedance spectroscopy. Furthermore, the effect of organic contaminants on the photocathodic protection mechanism and the oxidation of glucose during this process were explored.

9545-28, Session 6

Optically active quantum dots

Yurii K. Gun'ko, Trinity College Dublin (Ireland)

The main goal of our research is to develop new types of technologically important optically active quantum dot (QD) materials, study their properties and explore their applications. For the first time chiral II-VI QDs (penicillamine stabilised) have been prepared by us using microwave induced heating with the racemic (Rac), D- and L-enantiomeric forms of penicillamine as stabilisers. Circular dichroism (CD) studies of these QDs have shown that D- and L-penicillamine stabilised particles produced mirror image CD spectra, while the particles prepared with a Rac mixture showed only a weak signal. It was also demonstrated that these QDs show very broad emission bands between 400 and 700 nm due to defects or trap states on the surfaces of the nanocrystals. These QDs have demonstrated highly specific chiral recognition of various biological species including aminoacids and DNA. The utilisation of chiral stabilisers also allowed the preparation of new water soluble white emitting CdS nano-tetrapods, which demonstrated circular dichroism in the band-edge region of the spectrum. Biological testing of chiral CdS nanotetrapods displayed a chiral bias for an uptake of the D- penicillamine stabilised nano-tetrapods by cancer cells. Then we have developed a range of ZnS and ZnSe based chiral nanostructures have doped them by various metal ions. These nanostructures have been used for in vitro photodynamic therapy studies. It is expected that this research will open new horizons in the chemistry of chiral nanomaterials and their application in nanobiotechnology, photonics, medicine and optical chemo- and bio-sensing.

9546-1, Session 1

Meta-infrared detectors for 4th generation infrared imagers *(Invited Paper)*

Sanjay Krishna, The Univ. of New Mexico (United States)

There is an increased emphasis on obtaining detectors with spectro-polarimetric functionality at the pixel level. Meta-infrared detectors in which infrared detectors are combined with metamaterials are a promising way to realize this. The infrared region is appealing due to the low metallic loss, large penetration depth of the localized field and the larger feature sizes compared to the visible region. We will discuss approaches to realize multicolor detectors using these approaches.

9546-2, Session 1

Wideband and wide angle thermal emitters for use as lightbulb filaments

Christopher H. Granier, Simon G. Lorenzo, Jonathan P. Dowling, Georgios Veronis, Louisiana State Univ. (United States)

Lighting is a field that has been widely researched. Recently this research has been focused on creating energy-efficient visible light sources. One of the most recently commercially introduced products is the light emitting diode (LED) bulb, which is highly energy efficient; however, these bulbs are extremely expensive. Compact fluorescent bulbs (CFL) are energy-efficient and less expensive. While CFL bulbs are cheaper than LED bulbs, they contain toxic mercury and are more expensive than traditional tungsten-filament based bulbs. Tungsten bulbs are extremely cheap to mass produce and contain no poisonous elements; however, they are the most energy inefficient of any bulb used today. Here, we present optimized aperiodic structures for use as broadband, broad-angle thermal emitters which are capable of drastically increasing the efficiency of tungsten lightbulbs. One-dimensional layered structures without texturing are preferable to more complex two- and three-dimensional structures because of the relative ease and low cost of fabrication. These aperiodic multilayer structures designed with alternating layers of tungsten and air or tungsten and silicon carbide on top of a tungsten substrate exhibit broadband emittance peaked around the center of the visible wavelength range. We design structures using a genetic optimization algorithm coupled to a transfer matrix code which computes thermal emittance. We investigate the properties of these genetic-algorithm-optimized aperiodic structures for use as filaments in lightbulbs, and compare their performance with conventional lightbulbs. We find that the genetic-algorithm-optimized structures greatly enhance the emittance over the visible wavelength range, while also increasing the overall efficiency of the bulb.

9546-3, Session 1

Intensity tunable mid-wavelength infrared broadband absorbers based on planar nanometric film coatings employing thermochromic phase change material

Hasan Kocer, Turkish Military Academy (Turkey); Serkan Bütün, Edgar Palacios, Zizhuo Liu, Koray Aydin, Northwestern Univ. (United States)

Spectrally selective resonant absorption can be achieved using plasmonic and metamaterial based nano/micro-structured materials, where the resonant bandwidth and absorption intensity can be engineered by controlling the size and geometry of nanostructures. Here, a simple, lithography-free approach was demonstrated for obtaining a resonant and dynamically tunable broadband absorber based on vanadium dioxide (VO_2) thermochromic phase transition. Using metal-insulator-metal planar nanometric film coatings, where top layer is chosen to be an ultrathin (20 nm) VO_2 film, broadband, angular and polarization-independent IR light absorption tuning (from ~90 % to ~30 % in measured absorption intensity) was demonstrated over the entire mid wavelength infrared spectrum. VO_2 undergoes a structural transition from an insulating phase to a metallic phase at 68 °C. This reversible phase change occurs on a sub-picosecond timescale. In order to better understand the absorption mechanism in VO_2 based absorbers for two different phases, local electric field intensities and absorbed powers were calculated for insulator VO_2 and metal VO_2 based absorbers at 4 μm wavelength using finite difference time domain simulations. The numerical and experimental results indicate that the bandwidth of the absorption bands can be controlled by changing the dielectric spacer layer thickness. Broadband tunable absorbers can find applications in absorption filters, thermal emitters, thermophotovoltaics and sensing.

9546-4, Session 1

Optimization of Er and Yb dopant concentrations and ratios for efficient high-brightness mid-infrared light sources

Behsan Behzadi, Mani Hossein-Zadeh, Ravi Jain, The Univ. of New Mexico (United States)

We will describe our experimental and theoretical studies on the optimization of the Er and Yb concentrations for high-brightness mid-infrared light sources. Although many aspects of these studies apply to numerous host crystals and glasses, our initial studies have focused on ZBLAN glasses as hosts, and the impact of this data on the design of next-generation mid-infrared fiber and microresonator lasers and luminescent sources in the 3 um spectral region. High doping densities (> 5 mol%) of Er and Yb are preferred for high pump absorption, particularly for the small dimensions of the doped 3 um microresonator lasers, but the density and ratio of these dopants have to selected carefully for optimization of the Yb-Er forward energy transfer, and appropriate optimization of the energy transfer upconversion processes and the upper and lower laser lifetimes and their ratios.

9546-5, Session 1

Phased arrays based on second harmonic generation from metamaterials coupled to semiconductor heterostrustures *(Invited Paper)*

Omri Wolf, Salvatore Campione, Alexander Benz, Sandia National Labs. (United States); Arvind P. Ravikumar, Princeton Univ. (United States); Sheng Liu, Ting S. Luk, Emil A. Kadlec, Eric A. Shaner, John F. Klem, Michael B. Sinclair, Igal Brener, Sandia National Labs. (United States)

9546-6, Session 2

Hybrid optical-thermal nanoantennas for enhanced light focusing and radiative cooling *(Invited Paper)*

Svetlana V. Boriskina, Gang Chen, Massachusetts Institute of Technology (United States)

Metallic nanoparticles supporting localized surface plasmon resonances have become an indispensable tool in sensing and nanoscale imaging applications. However, the high plasmon-enhanced electric field intensity in the visible and near-IR range that enables the above applications also causes excessive heating of metal nanoparticles, which is a major drawback in plasmonics. In my talk I will discuss the design of hybrid optical-thermal nano-antennas that simultaneously enable intensity enhancement at the operating wavelength in the visible and reduction of the operating temperature via a combination of reduced absorption and radiative cooling.

9546-7, Session 2

Broadband nonresonant funneling of light via ultrasubwavelength channels

Ganapathi S. Subramania, Sandia National Labs. (United States); Stavroula Foteinopoulou, The Univ. of New Mexico (United States); Igal Brener, Sandia National Labs. (United States)

Efficient control of light-matter interaction at deeply subwavelength scales is key to many photonics applications such as detectors, sensors and novel light sources. Enhancing and funneling light efficiently through nanoscale channels can dramatically improve the performance of such devices by making them compact and more efficient. Currently, this is accomplished by utilizing the extraordinary optical transmission phenomenon wherein structural surface plasmon resonances are excited in perforated nanostructured metal films. As a result the phenomenon is inherently narrowband with low transmission. Here, we introduce a new paradigm structure consisting of a double-grooved metallic nanostructure platform that can outperform extraordinary optical transmission structures while operating nonresonantly across broadband (Phys. Rev. Lett. 107, 163902(2011)). Our platform consists of a continuous periodic metallic nanostructure composed of an array of connected large (~100-200nm) and small (~ 15-20nm) rectangular slits. The key feature of our platform is that the optical power can be channeled through an area as small as ~ (?/500)2 associated with optical field enhancement and high transmission while operating across a broad wavelength band in the mid-infrared (~ 2- 20 ?m). We will discuss the nonresonant mechanism underlying this phenomenon based on a simple quasistatic picture that shows excellent agreement with our numerical simulations.

We will also show experimental implementations of this platform and discuss pertinent results.

Sandia National Laboratories is a multi-program laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000.

9546-8, Session 2

Mid-IR phonon-polaritonics: superabsorpion and super-steering *(Invited Paper)*

Ganga C. R. Devarapu, Univ. of St Andrews (United Kingdom); Stavroula Foteinopoulou, The Univ. of New Mexico (United States)

Plasmonics has been a growing field in the last decade, exploring strong light control by resonant coupling between light and free electron oscillations at nanostructured metal surfaces. However, metals respond only poorly to mid-IR light, as the light penetration depth, known as skin-depth, is very small at such frequencies. The exciting physics and capabilities of plasmonics is transferrable to the mid-IR regime with materials of strong phonon-resonant response to EM radiation. We discuss here judicious designs of such phonon-polaritonic microstructures that can demonstrate near-perfect absorption within a thin material layer as thick as one-thousandth the impinging lights wavelength, highly asymmetric absorption as well as super-steering of a light beam beyond 90 deg.

Photonic crystal enhanced light emission from silicon *(Invited Paper)*

Liam O'Faolain, Univ. of St. Andrews (United Kingdom)

Realising efficient light emission from silicon is a major challenge for silicon photonics due to the material's indirect band gap. Overcoming this barrier would enable a host of important applications ranging from low power optical interconnects to biosensing. In this work, we take both a material and device engineering route. We deposit the optically active ytterbium disilicate on top of a silicon photonic crystal nanocavity. We demonstrate an enhancement of the Erbium emission due to the coupling with the cavity fundamental modes and show that the concentration in the excited state is about 30%

Near thresholdless laser operation at room temperature *(Invited Paper)*

Pablo A. Postigo, Instituto de Microelectrónica de Madrid (Spain)

We report a near-thresholdless laser operating at room temperature under continuous wave excitation [1]. Our laser is based on a two-dimensional photonic crystal cavity on GaAs material [2] coupled to a single embedded layer of self-assembled InAsSb quantum dots (QDs), which provides efficient luminescence at room temperature [3]. Laser emission centered at the 1.3 ?m telecommunications window is obtained with a spontaneous coupling factor ?=0.85 and a threshold of 861 nW in net absorbed power. Our results demonstrate the feasibility to produce near thresholdless laser operation at room temperature for on-chip applications.

Transverse Anderson localization and image transport through disordered fibers *(Invited Paper)*

Arash Mafi, The Univ. of New Mexico (United States); Salman Karbasi, Univ. of California, San Diego (United States); John Ballato, Clemson Univ. (United States); Karl Koch, Corning Incorporated (United States)

Disordered optical fibers show novel waveguiding properties that can be used for various device applications, such as beam-multiplexed optical communications and endoscopic image transport. The quality of the transported image is shown to be comparable with or better than some of the best commercially available multicore image fibers with less pixelation and higher contrast. Design, fabrication, characterization, and on-going efforts on the best practices for image transport in disordered optical fibers will be discussed. Novel nonlinear behavior of these fibers will also be covered.

9546-14, Session 4

Hyperuniform photonic slabs for high-Q cavities and low-loss waveguides

Timothy Amoah, Marian Florescu, Univ. of Surrey (United Kingdom)

Hyperuniform disordered photonic structures are a new class of photonic solids, which display large, isotropic photonic band gaps (PBG) comparable in size to the ones found in photonic crystals. The existence of large band gaps in HUD structures contradicts the long-standing intuition that Bragg scattering and long-range translational order is required in PBG formation, and demonstrates that interactions between “Mie-like” local resonances and multiple scattering can induce on their own PBGs.

The HUD structures combine advantages of both statistical isotropy due to disorder character and controlled scattering properties due to hyperuniformity (due to constraints imposed on the disorder) and uniform local topology.

Using FDTD and band structure simulations, we demonstrate efficient confinement of TE radiation and high-Q optical cavities and low-loss waveguides, in a trihedrally coordinated “relaxed” network lattice obtained from a centroidal tessellation protocol. For two-dimensional structures, quality factors exceeding Q > 10^9 are achieved. We further show that for 3D finite-height photonic slab high quality factors exceeding Q > 20, 000 can be maintained. Moreover, a multitude of cavity modes can be obtained, which can be classified according to their symmetry (monopole, dipole, quadrupole, etc.) of the confined electromagnetic wave pattern.

Our results put to rest the presumption that disorder would induce significant out of plane scattering in disordered structures as compared to their periodic counterparts and demonstrate the ability of disordered HUD PBG materials to serve as a general-purpose design platform for integrated optical micro-circuitry, including active devices such as optical microcavity lasers and modulators.

9546-15, Session 4

Periodic, quasiperiodic, aperiodic, and random plasmon particle array lasers *(Invited Paper)*

9546-16, Session 4

Engineering active aperiodic nanostructures *(Invited Paper)*

Luca Dal Negro, Boston Univ. (United States)

Efficient approaches to electromagnetic field localization and enhancement are essential for optoelectronic components that leverage broadband enhancement of optical cross sections, such as optical biosensors, photodetectors, light sources and on-chip nonlinear elements. In this context, the ability to tailor light-matter interactions by aperiodic order in metal-dielectric nanostructures can provide exciting opportunities. In this talk, I will discuss recent work on the development of aperiodic structures with enhanced radiation rates over broad frequency spectra. Tuning light propagation and diffusion in aperiodic metamaterials will be discussed, and applications to solar harvesting and broadband lasers with structured emission will be presented.

High Q photonic crystal cavities realized using deep ultraviolet lithography

Liam O’Faolain, Univ. of St. Andrews (United Kingdom)

As extremely precise fabrication processes are required for the realisation of high performance PhCs, Ultra-high Q PhC cavities demonstrated to date have been patterned using electron beam lithography because not only must the etched sidewalls be vertical and smooth but positioning accuracies at the nanometre level are also. To date, tThihis combination has prevented the realisation of high Q-factor devices using Deep-UV Photolithography (DUV), a key prerequisite for the mass manufacturing of silicon based optical devices. For example, DUV photomasks typically have a 5-10nm design grid (minimum increment in feature position), which prevents the nanometer scale positioning required for most ultra-high Q cavity designs. In this work, we use a recently developed 2D PhC resonator design that shows increased tolerance to fabrication imperfections and improved compatibility with DUV patterning to realise high optical Q-factors of ~200,000.

9546-19, Session 5

3D optical metamaterials formed by holographic assembly and directed solidification of eutectics *(Invited Paper)*

Paul V. Braun, Univ. of Illinois at Urbana-Champaign (United States)

Nanoscale integration of materials in three dimensions is critical for the realization of a number of highly functional optical metamaterials. Starting with structures enabled via eutectic solidification and holographic lithography, our team is applying unique template-based and post-synthetic materials transformations in conjunction with powerful computational design tools to develop the scientific underpinnings of, and to produce, 3D metamaterials derived from directionally solidified eutectics. Our approach

involves close interactions among computational design, photonic theory, eutectic materials development, template fabrication, materials chemistry, and optical characterization.

9546-20, Session 6

Highly-nonlinear quantum-engineered polaritonic metasurfaces *(Invited Paper)*

Mikhail A. Belkin, The Univ. of Texas at Austin (United States)

Intersubband transitions in n-doped semiconductor heterostructures provide the possibility to quantum engineer one of the largest known nonlinear optical responses in condensed matter systems, limited however to electric field polarized normal to the semiconductor layers. We have recently integrated these nonlinearities into laser waveguides to produce room-temperature terahertz quantum cascade laser sources based on efficient intra-cavity difference-frequency mixing [1,2]. Here we show that by coupling of electromagnetic modes in plasmonic metasurfaces with quantum-engineered intersubband transitions in semiconductor heterostructures one can create ultra-thin highly-nonlinear polaritonic metasurfaces for normal light incidence. Experimentally, we realized mid-infrared metasurfaces with giant electro-optic effect that display ultra-fast electrical tuning of reflectivity [3] and giant nonlinearity for second harmonic generation [4]. Structures discussed here represent a novel kind of hybrid metal-semiconductor metamaterials in which exotic optical properties are produced by coupling electromagnetically-engineered modes in dielectric and plasmonic nanostructures with quantum-engineered intersubband transitions in semiconductor heterostructures.

9546-21, Session 6

Alternative materials lead to practical nanophotonic components *(Invited Paper)*

Nathaniel Kinsey, Purdue Univ. (United States); Marcello Ferrera, Purdue Univ. (United States) and Heriot-Watt Univ. (United Kingdom); Clayton DeVault, Jongbum Kim, Alexander V. Kildishev, Vladimir M. Shalaev, Alexandra Boltasseva, Purdue Univ. (United States)

Recently, there has been a flurry of research in the field of alternative plasmonic materials, but for telecommunication applications, CMOS compatible materials titanium nitride and doped zinc oxides are among the most promising materials currently available. TiN is a gold-like ceramic with a permittivity cross-over near 500nm. In addition, TiN can attain ultra-thin, ultra-smooth epitaxial films on substrates such as c-sapphire, MgO, and silicon. Partnering TiN with CMOS compatible silicon nitride enables a fully solid state waveguide which is able to achieve a propagation length greater than 1cm for a ~8?m mode size at 1.55?m.

Utilizing doped zinc oxide films as a dynamic material, high performance modulators can also be realized due to the low-loss achieved by the TiN/Si3N4 waveguide. Simply by placing a thin layer of aluminum doped zinc oxide (AZO) on top of the waveguide structure, a modulator with very low insertion loss is achieved. Our recent work has investigated optical tuning of AZO films by the pump-probe method, demonstrating a change in the refractive index of ~0.17+0.25i at 1.3?m with an ultrafast response of 1ps. Assuming this change in the refractive index for the AZO film, a modulation of ~0.7dB/?m is possible in the structure with ~0.5dB insertion loss and an operational speed of 1THz. Further optimization of the design is expected to lead to an increased modulation depth without sacrificing insertion loss or speed.

Consequently, nanophotonic technologies are reaching a critical point where many applications including telecom, medicine, and quantum science can see practical systems which provide new functionalities.

9546-22, Session 6

Understanding carrier injection effects upon the Reststrahlen band of SiC using transient infrared spectroscopy

Bryan T. Spann, Ryan Compton, Adam D. Dunkelberger, James P. Long, U.S. Naval Research Lab. (United States); Paul Klein, Sotera Defense Solutions, Inc. (United States); Daniel Ratchford, Josh D. Caldwell, Jeff C. Owrutsky, U.S. Naval Research Lab. (United States)

Sub-diffractional confinement of light has led to advancements in imaging, metamaterials, nano-manufacturing, plasmonics, and other fields. One potential route to sub-diffractional confinement is via stimulated surface phonon polaritons (SPhPs). SPhPs couple infrared photons with optical phonons and consequently their lifetimes can be longer than surface plasmon polaritons (SPPs), whose lifetimes are dominated by electron scattering events. Thus, materials capable of generating SPhPs are of general interest to study. SPhPs are activated by photons with energies near the Reststrahlen band of semiconductors such as SiC. In this work we examine aspects of carrier dynamics by photo-injecting electrons into the SiC conduction band using a pulsed 355 nm laser and probe the resulting dynamics near the Reststrahlen band using a tunable CO2 laser. The fluence of the pump laser was varied to provide photo-injection levels ranging from ~1x10^17 to 1x10^19 free carriers. Probing the excited-state dynamics near the blue-edge of the Reststrahlen band resulted in complex transient behavior, showing both positive and negative changes in transient reflectance depending on the level of photo-injected carriers and probe energy. Numerical calculations of the SiC reflectance spectra with different doping levels were done to simulate the initial photo-injection level provided by the transient experiment. The computed spectra and the experimentally measured excited spectra for different photo-injection levels were compared and resulted in qualitative agreement.

9546-23, Session 6

Ultrafast dynamics of Al-doped zinc oxide under optical excitation

Nathaniel Kinsey, Clayton T. DeVault, Jongbum Kim, Purdue Univ. (United States); Marcello Ferrera, Purdue Univ, (United States) and Heriot-Watt Univ. (United Kingdom); Alexander V. Kildishev, Vladimir M. Shalaev, Alexandra Boltasseva, Purdue Univ. (United States)

There is a continual need to explore new and promising dynamic materials to power next-generation switchable devices. In recent years, transparent conducting oxides have been shown to be vital materials for such systems, allowing for both optical and electrical tunability. Using a pump-probe technique, we investigate the optical tunability of CMOS-compatible, highly aluminum doped zinc oxide (AZO) thin films. The sample was pumped at 325 nm and probed with a weak beam at 1.3 ?m to determine the timescale and magnitude of the changes by altering the temporal delay between the pulses with a delay line.

For an incident fluence of 3.9 mJ/cm2 a change of 40% in reflection and 30% (max 6.3dB/?m modulation depth) in transmission is observed which is fully recovered within 1ps. Using a computational model, the experimental results were fitted for the given fluence allowing the recombination time and induced carrier density to be extracted. For a fluence of 3.9 mJ/cm2 the average excess carrier density within the material is 0.7?10^20cm-3 and the recombination time is 88fs. The ultrafast temporal response is the result of Auger recombination due to the extremely high carrier concentration present in our films, ~10^21 cm-3. By measuring and fitting the results at several incident fluence levels, the recombination time versus carrier density was determined and fitted with an Auger model resulting in an Auger coefficient of C = 1.03?10^20cm6/sec. Consequently, AZO is shown to be a unique, promising, and CMOS-compatible material for high performance dynamic devices in the near future.

9546-24, Session 6

Advanced electrodynamic mechanisms for the nanoscale control of light by light *(Invited Paper)*

David L. Andrews, Univ. of East Anglia (United Kingdom)

A wide range of mechanisms is available for achieving rapid optical responsivity in material components. Amongst them, some of the most promising for potential device applications are those associated with an ultrafast response and a short cycle time. These twin criteria for photoresponsive action substantially favor optical, over most other, forms of response such as those fundamentally associated with photothermal, photochemical or optomechanical processes.

The engagement of nonlinear mechanisms to actively control the characteristics of optical materials is not new. Indeed, it has been known for over fifty years that polarization effects of this nature occur in the optical Kerr effect – although in fluid media the involvement of a molecular reorientation mechanism leads to a significant response time. It has more recently emerged that there are other, less familiar forms of optical nonlinearity that can provide a means for one beam of light to instantly influence another. In particular, major material properties such as absorptivity or emissivity can be subjected to instant and highly localized control by the transmission of light with an off-resonant wavelength.

This presentation introduces and compares the key electrodynamic mechanisms, discussing the features that suggest the most attractive possibilities for exploitation. The most significant of such mechanistic features include the off-resonant activation of optical emission, the control of excited-state lifetimes, the access of dark states, the inhibition or re-direction of exciton migration, and a coupling of stimulated emission with coherent scattering. It is shown that these offer a variety of new possibilities for ultrafast optical switching and transistor action, ultimately providing all-optical control with nanoscale precision.

9546-25, Session 7

Photonic quantum technologies *(Invited Paper)*

Jeremy L. O'Brien, Univ. of Bristol (United Kingdom)

The impact of quantum technology will be profound and far-reaching: secure communication networks for consumers, corporations and government; precision sensors for biomedical technology and environmental monitoring; quantum simulators for the design of new materials, pharmaceuticals and clean energy devices; and ultra-powerful quantum computers for addressing otherwise impossibly large datasets for machine learning and artificial intelligence applications. However, engineering quantum systems and controlling them is an immense technological challenge: they are inherently fragile; and information extracted from a quantum system necessarily disturbs the system itself. Of the various approaches to quantum technologies, photons are particularly appealing for their low-noise properties and ease of manipulation at the single qubit level. We have developed an integrated waveguide approach to photonic quantum circuits for high performance, miniaturization and scalability. We will described our latest progress in generating, manipulating and interacting single photons in waveguide circuits on silicon chips.

9546-26, Session 7

Deterministic placement of fabricated InGaN quantum dots in photonic structures *(Invited Paper)*

Arthur J. Fischer, Xiaoyin Xiao, Ping Lu, Ganapathi S. Subramania, Jeffrey Y. Tsao, Daniel D. Koleske, Sandia National Labs. (United States)

InGaN quantum dots (QDs) are desired for a wide variety of applications including emitters for full-color compact projectors, solid state lighting, and single photon sources. InGaN QDs can be fabricated using a process called quantum-size-controlled photoelectrochemical (PEC) etching where quantum size effects enable a self-terminated etch process. The process starts with InGaN quantum wells (QWs) which are PEC-etched to form layers of QDs. QW emission at ~500 nm can be blue-shifted by almost 100 nm via PEC etching showing a dramatic increase in confinement when going from QWs to QDs. Photoluminescence linewidths as narrow as 6 nm FWHM have been observed at low temperature for ensembles of PEC-etched QDs showing an improved size distribution compared to Stranski-Krastanov QDs. This process can potentially produce extremely uniform QD size distributions which would be very beneficial for QD laser diodes. At the same time, this process also has the potential to allow for deterministic placement of QDs at specific locations, for example at a field maximum in a photonic structure. Through careful device design, it is possible to perform PEC etching and to leave a single InGaN QD inside a photonic crystal cavity at the optimum position for efficient emitter-cavity coupling. This has clear implications for use in single photon sources for quantum information processing applications. Sandia National Laboratories is a multiprogram laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-AC04–94AL85000.

9546-27, Session 7

Towards scalable networks of solid state quantum memories in a photonic integrated circuit *(Invited Paper)*

Dirk R. Englund, Massachusetts Institute of Technology (United States)

A central goal of quantum information science is the entanglement of multiple quantum memories that can be individually controlled. Here, we discuss progress towards photonic integrated circuits designed to enable efficient optical interactions between multiple spin qubits in nitrogen vacancy (NV) centers in diamond. We describe NV-nanocavity systems in the strong Purcell regime with optical quality factors approaching 10,000 and electron spin coherence times exceeding 200 ?s; implantation of NVs with nanometer-scale apertures, including into cavity field maxima; hybrid on-chip networks for integration of multiple functional NV-cavity systems; and scalable integration of superconducting nanowire single photon detectors on-chip.

9546-28, Session 7

Quantum optics in directional one-dimensional photonic reservoirs *(Invited Paper)*

Immo Söllner, Peter Lodahl, Niels Bohr Institute (Denmark)

We present a novel photonic crystal waveguide, engineered to support broadband modes with circular in-plane polarization. We show experimental evidence that for single-photon emitters with circular dipoles these waveguides act as near-lossless unidirectional photonic reservoirs, where the emission direction is given by the helicity of the dipole. This directional coupling has a strong effect on the scattering of single photons transmitted through the system and we discuss how counter-propagating photons acquire a relative phase of π. Combining this effect with photonic structures that can map a phase to a propagation path, we show how one can create nonreciprocal photonic elements.

9546-29, Session 7

Integrated single photon detectors for chip scale quantum key distribution *(Invited Paper)*

Paul S. Davids, Chris DeRose, Nick Martinez, Douglas Trotter, Andrew Starbuck, Andrew Pomerene, Ryan Camacho, Anthony Lentine, Sandia National Labs. (United States)

In this talk, we will present our recent progress in the development of quantum key distribution (QKD) on a chip based on our integrated Si photonics platform. An essential integrated building block in discrete variable chip-scale QKD is a waveguide coupled single photon detector. Our single photon detector is based on a compact separate absorption and multiplication avalanche photodiode device design with integrated waveguide coupling. Various device designs and experimental Geiger mode device characteristics will be presented.

9546-30, Session 7

Integrated laser-written quantum photonics *(Invited Paper)*

Markus Gräfe, René Heilmann, Armando Perez-Leija, Maxime Lebugle, Diego Guzman-Silva, Matthias Heinrich, Alexander Szameit, Friedrich-Schiller-Univ. Jena (Germany)

Whispering-gallery-mode optical resonators around an exceptional point *(Invited Paper)*

Bo Peng, Sahin K. Ozdemir, Huzeyfe Yilmaz, Washington Univ. in St. Louis (United States); M. Liertzer, Technische Univ. Wien (Austria); Faraz Monifi, C. M. Bender, Washington Univ. in St. Louis (United States); Franco Nori, RIKEN (Japan) and Univ. of Michigan (United States); Lan Yang, Washington Univ. in St. Louis (United States)

I will report our experiments on unconventional control of light flow in high-quality whispering-gallery-mode (WGM) resonators around an exceptional point (EP), which is characterized by the coalescence of the eigenvalues and eigenstates of a system. The presence of an EP affects the system significantly, leading to nontrivial physics with interesting counterintuitive features. In the experiment, we show that when the resonator system is operated in the vicinity of an EP, the effect of loss could be reversed. Specifically, we demonstrate that the lasing power increases with increasing the loss introduced to the system.

III-V GaAs based plasmonic lasers

Lucas Lafone, Ngoc Nguyen, Imperial College London (United Kingdom); Ed Clarke, Univ. of Sheffield (United Kingdom); Paul Fry, The Univ. of Sheffield (United Kingdom); Rupert F. Oulton, Imperial College London (United Kingdom)

Plasmonics is a potential route to new and improved optical devices. Many predict that sub wavelength optical systems will be essential in the development of future integrated circuits, offering the only viable way of simultaneously increasing speed and reducing power consumption. Realising this potential will be contingent on the ability to exploit plasmonic effects within the framework of the established semiconductor industry and to this end we present III-V (GaAs) based surface plasmon laser platform capable of effective laser light generation in highly focussed regions of space. Our design utilises a suspended slab of GaAs with a metallic slot printed on top. Here, hybridisation between the plasmonic mode of the slot and the photonic mode of the slab leads to the formation of a mode with confinement and loss that can be adjusted through variation of the slot width alone. As in previous designs the use of a hybrid mode provides strong confinement with relatively low losses, however the ability to print the metal slot removes the randomness associated with device fabrication and the requirement for etching that can deteriorate the semiconductor's properties. The deterministic fabrication process and the use of bulk GaAs for gain make the device prime for practical implementation.

9546-34, Session 8

Time-resolved lasing dynamics for plasmonic system with gain

Jieran Fang, Jingjing Liu, Zhuoxian Wang, Xiangeng Meng, Ludmila J. Prokopeva, Vladimir M. Shalaev, Alexander V. Kildishev, Purdue Univ. (United States)

To study the light-matter interaction between plasmonic systems and gain media, numerous theoretical and numerical methods have been proposed. Among them, because of its accurate treatment of the quantum property of gain media, the time domain (TD) multi-physics approach is viewed as the most powerful method, especially for analysis of transient dynamics. Even though the finite difference, finite-volume and finite element TD methods can be readily coupled to a multi-level atomic system through auxiliary differential equations, for each of them however there is limited information on accurate TD kinetic parameters fitted with experimental measurements. In this work, we develop a multi-physics time domain model to inspect our most recent lasing experiment with a silver nanohole array. We use a classical finite difference time-domain (FDTD) model coupled to the rate equations of a 4-level gain system. To retrieve kinetic energy parameters for accurate modeling, we first fit 1-D simulations with pump-probe experiments

studying Rhodamine-101 (R-101) dye embedded in epoxy on an indium tin oxide silica substrate. The retrieved parameters are then fed into a 3-D model to study the lasing behavior of the R-101-coated nanohole array. The simulated emission intensity shows a clear lasing effect, which is in good agreement with the experimental measurements. By tracing the population inversion and polarization dynamics, the amplification and lasing regimes inside the nanohole cavity can be clearly distinguished. With the help of our systematic approach, we can further improve understanding of the time-resolved physics of active plasmonic nanostructures with gain.

9546-35, Session 8

Single mode parity-time laser

Zi Jing Wong, Liang Feng, Renmin Ma, Yuan Wang, Xiang Zhang, Univ. of California, Berkeley (United States)

In optoelectronics, optical loss is usually undesired, as it is responsible for power dissipation and light attenuation. The concept of parity-time (PT) symmetry, however, exploits the interplay between the material loss and gain to attain novel optical phenomena such as exceptional point and unidirectional light propagation. Here we experimentally demonstrate a PT symmetry laser that allows unique control of the resonant modes. In contrast to conventional ring cavity lasers with multiple competing modes, our on-chip InGaAsP/InP based PT microring laser exhibits intrinsic single-mode lasing regardless of the gain spectral bandwidth. Thresholdless parity-time symmetry breaking due to the rotationally symmetric structure leads to stable single-mode operation with the selective whispering gallery mode order. Our chip-scale semiconductor platform provides a unique route towards fundamental exploration of PT physics and next-generation active optoelectronic devices for optical communication and computing.

9546-36, Session 8

Simultaneous unidirectional lasing and reflectionless modes in PT-symmetric cavities *(Invited Paper)*

Hamidreza Ramezani, Hao-kun Li, Yuan Wang, Univ. of California, Berkeley (United States); Xiang Zhang, Univ. of California, Berkeley (United States) and Lawrence Berkeley National Lab. (United States)

We introduce a new family of spectral singularities with highly directional response in parity-time (PT) symmetric cavities. These spectral singularities support modes with infinite reflection from one side and zero reflection from the other side of the cavity, results in simultaneous unidirectional laser and unidirectional reflectionless parity-time symmetric cavity. Such unidirectional spectral singularities emerge from resonance trapping induced by the interplay between parity-time symmetry and Fano resonances.

9546-37, Session 8

Cavity-free stopped-light nanolasing in nanoplasmonic heterostructures *(Invited Paper)*

Ortwin Hess, Imperial College London (United Kingdom)

Going beyond traditional cavity-concepts, recently conceived nanolasers employ plasmonic resonances for feedback, allowing them to concentrate light into mode volumes that are no longer limited by diffraction [1]. The use of localized surface plasmon resonances as cold-cavity modes, however, is only one route to lasing on subwavelength scales. Lasing, in fact, does not require modes predefined by geometry but merely a feedback mechanism [2].

Here we demonstrate that the concept of dispersion-less stopped-light [3] allows by combination of nanoplasmonics with quantum gain materials [4] stopped-light lasing in hybrid nanoplasmonic heterostructures. Thereby, photons are trapped and amplified in space just at the point of their emission. It will be discussed that, at the stopped-light point, a stable lasing mode can form over a finite region of gain material due to the arising local (cavity-free) feedback in the form of a sub-wavelength optical vortex. We discuss the remarkable spatio-temporal dynamics of nanoplasmonic stopped-light lasing is studied on the basis of a Maxwell-Bloch Langevin approach [4]. Moreover, a new rate-equation framework is shown to grasp the particular physics of stopped-light lasing involving [4]. The observed high-? characteristics and picosecond relaxation oscillations of cavity-free stopped-light lasing can potentially allow for the design of thresholdless plasmonic laser diodes that can be modulated with THz speeds.

9546-38, Session 9

Auger-decay engineering in quantum dots in relation to applications in LEDs and lasers *(Invited Paper)*

Victor I. Klimov, Los Alamos National Lab. (United States)

Multicarrier dynamics in colloidal quantum dots (QDs) are normally controlled by nonradiative Auger recombination wherein the energy of an electron-hole pair is converted not into a photon but instead transferred to a third carrier (an electron or a hole). Auger decay is extremely fast in QDs (time scales of tens-to-hundreds of picoseconds) due to both close proximity between interacting charges and elimination of restrictions imposed by translational momentum conservation. Photoluminescence (PL) quenching by nonradiative Auger processes complicates realization of applications that require high emissivity of multicarrier states such as light-emitting diodes (LEDs) and lasers. Therefore, the development of "Auger-recombination-free" QDs is an important current challenge in the field of colloidal nanostructures.

Previous single-dot spectroscopic studies have indicated a significant spread in Auger lifetimes across an ensemble of nominally identical QDs. It has been speculated that in addition to dot-to-dot variation in physical dimensions, this spread is contributed to by variations in the structure of the QD interface, which controls the shape of the confinement potential. Here we directly evaluate the effect of the composition of the core-shell interface on single- and multi-exciton dynamics via side-by-side measurements of individual core-shell CdSe/CdS nanocrystals with a sharp vs. smooth (graded) interface. We observe that while having essentially no effect on single-exciton decay, the interfacial alloy layer leads to a systematic increase in the biexciton lifetime indicating suppression of Auger recombination. We demonstrate that using QDs with "engineered interfaces" we can considerably improve the performance of QD LEDs and lasers.

9546-39, Session 9

Nanowire quantum dots for quantum optics *(Invited Paper)*

Valery Zwiller, Michael Reimer, Klaus Joens, Lucas Schweickert, Technische Univ. Delft (Netherlands)

We demonstrate the generation of single photons as well as pairs of entangled photons with quantum dots in semiconducting nanowires, we show applications to quantum optics including generation, manipulation and detection of light at the nanoscale.

9546-40, Session 9

Redefining giant quantum dot functionality through synthesis and integration: from multifunctionality to directed photoluminescence *(Invited Paper)*

Jennifer A. Hollingsworth, Los Alamos National Lab. (United States)

Thick-shell or "giant" core/shell nanocrystal quantum dots (gQDs) are efficient and stable emitters. Their characteristic properties of non-blinking and non-photobleaching emission, as well as suppressed non-radiative Auger recombination and minimal self-reabsorption (due to a large effective Stokes shift) make them relevant to both single-emitter and many-emitter applications, e.g., live-cell single-molecule tracking in the biosciences and down-conversion phosphors for solid-state lighting. Here, I will discuss how gQDs are also ideal "building blocks" for achieving additive functionalities through synthesis and modified emission properties through integration with fabricated photonic structures. gQDs have been synthetically incorporated into the interior of a gold shell, resulting in "plasmonic gQDs" that exhibit efficient photoluminescence combined with efficient photothermal transduction and thermometry. Furthermore, through direct patterning of gQDs into all-dielectric antennas, we show an approach for realizing emitter-antenna couples (toward controlling the motion of photons) that is both deterministic and reproducible.

9546-41, Session 9

Controlled growth of CdSe quantum dots on silica spheres

Byoung-Ju Kim, Donghyun Jo, Se-Han Lim, Do-Kyoon Kim, Jin-Young Park, Jong-Hwa Jeon, Kwang-Sun Kang, Kyungil Univ. (Korea, Republic of)

Various sizes of CdSe quantum dots have been fabricated on the surface of the monodisperse silica spheres and five different photoluminescence (PL) peaks are observed from the CdSe quantum dots. The monodisperse silica spheres were synthesized with Stöber synthetic method. The surface of the spheres was modified with 100:1 ratio of phenylpropyltrimethoxysilane (PTMS) and mercaptopropyltrimethoxysilane (MPTMS). The MPTMS works as a covalent bond formation with CdSe quantum dots, and the PTMS acts as a separating quantum dots to prevent PL quenching by neighboring quantum dots. The Fourier transform infrared (FTIR) spectrum of the surface modified spheres (SMSiO2) shows strong absorption peak at 2852 and 2953 cm-1 representing the characteristic absorption of –CH or -CH2. The FTIR absorption peak at 1741 cm-1 represents the characteristic absorption of CdSe quantum dots. The field emission scanning electron microscope image shows the average diameter of the spheres ranging approximately 418 nm. The ultraviolet-visible transmittance spectrum shows stop band at 880 nm. The PL spectrum shows five different emission bands at 434, 451, 468, 492 and 545 nm, which indicates the formation of several different sizes of CdSe quantum dots.

9546-42, Session 10

Collective properties and strong coupling in the near-field of a meta-surface *(Invited Paper)*

Didier Felbacq, Emmanuel Rousseau, Univ. Montpellier 2 (France)

Meta–surfaces are the 2D analogues of metamaterials. Meta- surfaces are generally seen as devices able to control the far-field behavior of light. However, because of their resonant properties, meta–surfaces also have interesting properties in the near-field. In the present work, we aim at initiating the study of the quantum electrodynamics of meta- surfaces. In standard cavity quantum electrodynamics, one studies the coupling between an emitter, such as an atom, or quantum dot or a superconducting qubit, and the electromagnetic modes. Depending on the ratio between the light-matter coupling and that to the irreversible mechanisms, two regimes can occur: the weak coupling and the strong coupling. In the strong coupling regime, the coupling dominates the losses, the emitter and the meta-surface can exchange photons periodically in time, which leads to hybrid excited states. From an experimental point of view, this regime leads to the onset of a double peak in the emitted spectrum, due to the anti-crossing of the dispersion curves of the light and matter modes. In the present work, the coupling of a quantum emitter with the photonic surface modes supported by a meta–surface is investigated. The meta–surface is made of a periodic set of parallel nano wires. From a theoretical point of view, the meta-surface can be described by an effective impedance model, which allows to derive the density of electromagnetic modes due to the meta- surface. Further, it allows to obtain the dressed susceptibility of the quantum emitter and to exhibit the strong coupling regime.

9546-43, Session 10

Coherent coupling between a molecular vibration and Fabry-Perot optical cavity to give hybridized states in the strong coupling limit

James P. Long, Jeff C. Owrutsky, Kenan P. Fears, Walter J. Dressick, Adam D. Dunkelberger, Ryan Compton, Bryan T. Spann, Blake S. Simpkins, U.S. Naval Research Lab. (United States)

Coherent coupling between an optical-transition and confined optical mode, when sufficiently strong, gives rise to new modes separated by the vacuum Rabi splitting. Such systems have been investigated for electronic-state transitions, however, only very recently have vibrational transitions been considered. Here, we bring strong polaritonic-coupling in cavities from the visible into the infrared where a new range of static and dynamic vibrational processes await investigation.

First, we experimentally and numerically describe coupling between a Fabry-Perot cavity and carbonyl stretch (~1730 cm 1) in poly-methylmethacrylate. As is requisite for "strong coupling", the measured vacuum Rabi splitting of 132 cm 1 is much larger than the full width of the cavity (34 cm-1) and the inhomogeneously broadened carbonyl-stretch (24 cm-1). Agreement with classical theories providea evidence that the mixed-states are relatively immune to inhomogeneous broadening. Next, we investigate strong and weak coupling regimes through examination of cavities loaded with varying concentrations of urethane. Rabi splittings increases from 0 to ~104 cm-1 with concentrations from 0-20 vol% and are in excellent agreement to an analytical description using no fitting parameters. Ultra-fast pump-probe measurements reveal transient absorption signals over a frequency range well-separated from the vibrational band as well as modifications of energy relaxation times. Finally, we demonstrate coupling to liquids using the C-O stretching band (~1985 cm-1) of Mo(CO)6 in an aqueous solution.

Opening the field of polaritonic coupling to vibrational species promises to be a rich arena amenable to a wide variety of infrared-active bonds that can be studied statically and dynamically.

9546-44, Session 10

Applications of Fano resonances to active photonic devices *(Invited Paper)*

Andrey E. Miroshnichenko, The Australian National Univ. (Australia)

The current surging interest in various applications of nanoscale light-matter interactions, including biosensing, nanoantennas, photovoltaic

devices and many others, has triggered enormous effort into the old and fundamental problem of manipulation of a particle's scattering and absorption characteristics. In the recently emerging fields of nanophotonics, various novel phenomena have been demonstrated involving interaction of nanoparticles with light, such as super-scattering, control of the direction of the scattered light by metasurface, coherent perfect absorption of light by surface plasmons, Fano resonances in plasmonic and all-dielectric oligomers . At the same time, the interest in artificial magnetic responses that was fostered by the field of metamaterials has lead to the observation of artificial magnetic modes in nanoparticles and, since then, many related novel scattering features based on the interplay of both electric and magnetic responses have been demonstrated. To make further breakthroughs in different applications based on the particles scattering, there is a fundamental challenge to overcome: polarization dependence. The polarization-independent absorption is, then, quite counter-intuitive because the near field profile of the electromagnetic field does depend on the incident polarization yet the overall absorption cross-section does not. It implies that the variation of the near field with the incident polarization does not affect the overall integral absorption cross-section. It has the main implication to the origin of the Fano resonance in oligomer-like structures. By studying the near-field and discrete dipole modes distribution we reveal the necessary conditions for the Fano resonance to occur in such structures.

9546-45, Session 10

Strong light matter coupling in two-dimensional semiconductors *(Invited Paper)*

Vinod M. Menon, The City College of New York (United States)

Transition metal dichalcogenides (TMDs) have emerged as an attractive class of two-dimensional (2D) semiconductors that show unprecedented strength in its interaction with light. Here we will discuss our recent work on embedding such a 2D TMD layer of molybdenum disulphide in a dielectric microcavity showing the forming of strongly coupled half-light half-matter quasiparticles called microcavity polaritons. Realizing strong coupling at room temperature in a disorder free landscape such as 2D materials offers a practical and attractive route to realizing devices such as switches and logic gates that exploit the benefits of the half-light half-matter composition of the polaritons.

9546-46, Session 11

Phonon-modified spontaneous emission from quantum dots in structured photonic reservoirs: breakdown of Fermi's golden rule *(Invited Paper)*

Stephen Hughes, Queen's Univ. (Canada)

The spontaneous emission rate of a two-level atom coupled to a structured photonic reservoir is determined by the local density of photonic states (LDOS) at the emitter frequency, according to Fermi's golden rule. Such a relation is also supposed to hold true for semiconductor quantum dots (QDs), which behave as artificial atoms in a solid state medium [1]. A sharp atom-like transition along with an ability to couple to microcavity structures such as photonic crystal reservoirs makes QDs promising as scalable qubits at optical frequencies. However, coupling with phonons renders a QD different compared to a simple two-level atom, as has been demonstrated in a number of recent experiments [1].

In this talk, we will describe how the spontaneous emission rate of a QD coupled to structured photonic reservoir is actually determined by the broadband frequency dependence of the LDOS, in clear violation of Fermi's golden rule [2]. A self-consistent polaron master equation approach including both a photon and a phonon reservoir is utilized in determining the phonon-modified spontaneous emission rate. The theory makes no specific assumption about the structure of the reservoirs and we will exemplify the cases of a microcavity and a coupled-cavity waveguide. In particular, we find a significant breakdown of the Fermi's golden rule when the damping rates of the phonon bath and photon bath compare [2]. We will also make a direct connection to recent experiments and show how the broadband frequency dependence of the LDOS influences the PL spectra from coherently excited QDs [3].

9546-47, Session 11

Improving emission in nanorod arrays using quasi-aperiodic inverse design

P. Duke Anderson, Michelle L. Povinelli, The Univ. of Southern California (United States)

Photonic structure plays a significant role in determining the brightness and efficiency of nanoemitter systems. Using photonic crystal slabs it is possible to affect these quantities in various ways. First, positioning a leaky mode near the emission frequency allows more light to be extracted from within the slab. Second, concentrating high electric field intensity near emitter locations significantly enhances the spontaneous emission rate. However, a large body of work has suggested these two contributing factors are in competition, making it difficult to simultaneously achieve high electric field intensity and light extraction. In previous work, we identified one mode in an array of GaN nanorods which exhibited a 25X enhancement in extracted power, relative to a uniform slab. However, the mode was uncoupled to normal radiation and, consequently, produced a sharp dip in extraction efficiency. Here, we improve upon the previous design by investigating a new class of quasi-aperiodic nanorod array structures. Using an inverse design algorithm, we identify one optimized structure which achieves maximum theoretical light extraction while maintaining a high spontaneous emission rate. Overall, the optimized structure achieves a 48% increase in extracted power and a 20-48% increase in external quantum efficiency relative to the previous periodic design.

9546-48, Session 11

Photonic and plasmonic nanoresonators: a modal approach *(Invited Paper)*

Christophe Sauvan, Jean-Paul Hugonin, Lab. Charles Fabry (France); Philippe Lalanne, Lab. Photonique Numérique et Nanosciences (France)

Photonic and plasmonic resonators are dielectric or metallic optical devices that confine light at a scale smaller than the wavelength. The eigenmodes of the system are obviously powerful and intuitive tools to describe light scattering and light-matter interactions mediated by the resonant structure. However, owing to the presence of energy dissipation (by radiation or absorption), using the eigenmodes of nanoresonators is an open issue that has been solved only recently. We have developed a modal formalism that relies on the concept of quasinormal modes with complex eigenfrequencies. The theory is capable of handling any photonic or plasmonic resonator with strong radiation leakage, absorption and material dispersion. The normalization of the quasinormal modes constitutes one of the key points of the theory that we will discuss in this presentation. We will then show that the modal formalism provides a powerful tool to calculate and understand light-matter interactions in complex photonic or plasmonic systems. In particular, it allows understanding the physical mechanisms at play in the extremely large Purcell factors observed recently for emitters coupled to plasmonic nanoantennas.

9546-49, Session 12

Novel topological states in photonics *(Invited Paper)*

Marin Soljacic, Massachusetts Institute of Technology (United States)

Topologically non-trivial states have been raising a substantial interest in the electronics community because of their novel and unique properties. Similarly, topological states in photonics display an equally diverse range of novel and surprising phenomena.

Some of our recent results in this area will be presented.

9546-50, Session 12

Gyromagnetically induced transparency of metasurfaces *(Invited Paper)*

Gennady B. Shvets, Hossein Mousavi, The Univ. of Texas at Austin (United States); Alexander Khanikaev, Queens College (United States); Jeffery W. Allen, Monica Allen, Air Force Research Lab. (United States)

The concept of symmetry pervades modern physics. Through the conservation laws derived from various symmetries, high-level restrictions and selection rules can be derived for a variety of physical systems without any need for detailed investigations of their specific properties. The spatial symmetries of electric charge distribution on the metamaterial's surface determine whether the EM resonance is "bright" (radiatively coupled to) or "dark" (radiatively de-coupled from) the EM continuum. As we demonstrate in this talk, other (non-spatial) symmetries and their breaking can also be crucial to determine the properties of EM resonances and enable their mutual coupling, which in turn can give rise to EM Fano interferences.

I will consider a meta-surface formed by a two-dimensional array of double-antenna meta-molecules resting on a gyromagnetic ferrite substrate. In conclusion, I will use simple symmetry considerations to predict and numerically demonstrate two phenomena that occur in meta-surfaces when symmetry of the system is reduced by a gyromagnetic substrate: gyromagnetically induced transparency and nonreciprocal Fano interference. These phenomena hold significant promise for practical applications such as the dynamic control of resonant EM interactions using magnetic fields produced by the external currents, mitigation of co-site interference and improving isolation. Spectral positions, radiative lifetimes and quality factors of Fano resonances can be controlled by the magnitude of the external magnetic field. This class of effects may lead to a new generation of tunable and nonreciprocal Fano resonant systems for various applications where strong field enhancement, tunability and nonreciprocity are simultaneously required.

9546-51, Session 12

Using time-dependent effective gauge field for photons to achieve dynamic localization of light

Luqi Yuan, Shanhui Fan, Stanford Univ. (United States)

We study a problem of achieving three-dimensional dynamic localization of light in a dynamically-modulated resonator lattice. An effective gauge potential for photons has been previously shown to exhibit in such lattice. Dynamic localization of light can be achieved by varying the effective gauge potential sinusoidally in time. Furthermore, the rotating wave approximation was used in previous works on such effective gauge potential for photons. Here, we find that the effect of dynamic localization persists even in the regime where the counter-rotating term has to be taken into count.

9546-53, Session 12

Transport properties of pseudospin-1 photons *(Invited Paper)*

Che Ting Chan, Anan Fang, Zhao-Qing Zhang, Hong Kong Univ. of Science and Technology (Hong Kong, China); Steven G. Louie, Hong Kong Univ. of Science and Technology (Hong Kong, China) and Univ. of California, Berkeley (United States) and Lawrence Berkeley National Lab. (United States)

Pseudospin is of central importance in governing many unusual transport properties of graphene and other artificial systems which have pseudospins of ?. These unconventional transport properties are manifested in phenomena such as Klein tunneling, and collimation of electron beams in one-dimensional external potentials. Here we show that in certain photonic crystals (PCs) exhibiting conical dispersions at the center of Brillouin zone, the eigenstates near the "Dirac-like point" can be described by an effective spin-orbit Hamiltonian with a pseudospin of 1. This effective Hamiltonian describes within a unified framework the wave propagations in both positive and negative refractive index media which correspond to the upper and lower conical bands respectively. Different from a Berry phase of ϖ for the Dirac cone of pseudospin-? systems, the Berry phase for the Dirac-like cone turns out to be zero from this pseudospin-1 Hamiltonian. In addition, we found that a change of length scale of the PC can shift the Dirac-like cone rigidly up or down in frequency with its group velocity unchanged, hence mimicking a gate voltage in graphene and allowing for a simple mechanism to control the flow of pseudospin-1 photons. As a photonic analogue of electron potential, the length-scale induced Dirac-like point shift is effectively a photonic potential within the effective pseudospin-1 Hamiltonian description. At the interface of two different potentials, the 3-component spinor gives rise to distinct boundary conditions which do not require each component of the wave function to be continuous, leading to new wave transport behaviors as shown in Klein tunneling and supercollimation. For examples, the Klein tunneling of pseudospin-1 photons is much less anisotropic with reference to the incident angle than that of pseudospin-? electrons, and collimation can be more robust with pseudospin-1 than pseudospin-?. The special wave transport properties of pseudospin-1 photons, coupled with the discovery that the effective photonic "potential" can be varied by a simple length-scale change, may offer new ways to control photon transport. We will also explore the difference between pseudospin-1 photons and pseudospin-? particles when they encounter disorder.

Light scattering in pseudo-passive media with uniformly balanced gain and loss *(Invited Paper)*

Tsampikos Kottos, Ali Basiri, Wesleyan Univ. (United States); Ilya Vitebskiy, Air Force Research Lab. (United States)

We introduce a class of metamaterials with uniformly balanced gain and loss associated with complex permittivity and permeability constants. The refractive index of such a balanced pseudo-passive metamaterial is real. An unbounded uniform pseudo-passive medium has transport characteristics similar to those of its truly passive and lossless counterpart with the same real refractive index. However, bounded pseudo-passive samples show some unexpected scattering features which can be further emphasized by including such elements in a photonic structure.

9546-55, Session 13

Giant amplification of light in non-hermitian photonic materials *(Invited Paper)*

Hakan E. Tureci, Konstantinos G. Makris, Princeton Univ. (United States); Li Ge, College of Staten Island (United States)

In photonics and quantum optics, a key challenge facing any technological application has traditionally been the mitigation of optical losses. Recent work has shown that a new class of optical materials, called Parity-Time symmetric materials, that consist of a precisely balanced distribution of loss and gain can be exploited to engineer novel functionalities for propagating and filtering electromagnetic radiation. Here we show a generic property of optical systems that feature an arbitrary distribution of loss and gain, described by non-Hermitian operators, namely that overall lossy optical systems can transiently amplify certain input signals by several orders of magnitude. We present a mathematical framework to analyze the dynamics of wave propagation in media with an arbitrary distribution of loss and gain and construct the initial conditions to engineer such non-Hermitian power amplifiers.

9546-56, Session 13

Parity-time anti-symmetric parametric amplifier *(Invited Paper)*

Diana A. Antonosyan, Alexander S. Solntsev, Andrey A. Sukhorukov, The Australian National Univ. (Australia)

We consider a directional coupler composed of two waveguides in quadratically nonlinear medium, where one waveguide is lossy. The loss can be introduced, for example, by depositing a thin layer of metal. In the linear regime, at low light intensities, such coupler realizes PT-symmetric optical system. We analyze the process of optical parametric amplification based on nonlinear mixing between a strong pump, and signal and idler waves. We model the wave propagation in the undepleted pump regime using coupled-mode equations. We reveal that the Hamiltonian possesses an anti-PT symmetry (with a negative sign). We find that if the eigenmode profile is PT-symmetric, then generally the gain coefficients of modes are different. On the other hand, if the mode profile has a broken PT-symmetry, then there appear mode pairs with the same gain coefficients. We emphasize that the modal PT-symmetry has opposite relation to gain in contrast to the previously studied PT-symmetric systems.

We demonstrate that the modal PT-breaking can be controlled by the pump beam. Due to the electronic nature of quadratic nonlinearity, such tuning can be ultrafast, directly following the pump profile in real time. For a pump amplitude over the threshold, there appears one mode exhibiting strong gain, whereas at lower pump powers, signal periodically switches between the waveguides due to a beating between two modes exhibiting the same negative gain.

Intense terahertz-pulse generation by four-wave mixing process in induced gas plasma

Surawut Wicharn, Srinakharinwirot Univ. (Thailand); Prathan Buranasiri, King Mongkut's Institute of Technology Ladkrabang (Thailand)

In this article, we have numerically investigated an intense terahertz (THz) pulses generation in gaseous plasma based on the third-order nonlinear effect, four-wave mixing (FWM) process. We have proposed that the fundamental fields and second-harmonic field of ultra-short pulse lasers are combined and focused into a very small gas chamber to induce a gaseous plasma, which intense THz pulse is produced. To understand the THz generation process, the first-order multiple-scale perturbation method has been utilized to derive a set of nonlinear coupled-wave equations for interacting fields such as two fundamental fields, a second-harmonic field, and a THz field. Then, we have seek for the optimal conditions of intense THz-pulse generation, simulated output THz field using numerical method, and calculated output energy and conversion efficiency of this process.

Direct measure of the photo-induced nanoscale surface displacement in solids using atomic force microscopy

Samuel T. Souza, Eduardo J. Fonseca, Carlos Jacinto, Univ. Federal de Alagoas (Brazil); Nelson G. C. Astrath, Thiago P. Rodrigues, Luis C. Malacarne, Univ. Estadual de Maringá (Brazil)

The light-matter interaction induces a large number of effects that are of fundamental interest in the development and characterization of new materials. In this direction, phothothermal methods are largely employed in the determination of thermal, optical, and mechanical properties, in addition to the study of amplitude and dynamic of the material response. In this work, we investigate the photo-induced nano-expansion in solids by a direct measure using atomic force microscopy. The results were comparable with those ones obtained from the thermal mirror technique, presenting good agreement between the techniques. The results presented here open possibilities to optically induce nanoscale-controlled positioning in a bi-dimensional system

Using dilute-P GaNP alloy as improved visible active region

Chee-Keong Tan, Zhangji Zhao, Nelson Tansu, Lehigh Univ. (United States)

Group III-Nitride semiconductor alloy especially InGaN alloy has been extensively studied as the active region for the solid state lighting applications. Recent studies suggested dilute-As GaNAs alloy as an alternative candidate to improve the nitride-based active region due to the suppression of the interband Auger recombination. In conjunction with dilute-As GaNAs alloy, previous works indicated the potential of dilute-P GaNP alloy as a novel source for light emitters. Nonetheless the details of the electronic properties of dilute-P GaNP alloy are severely lacking, prohibiting further development of the alloys into effective photonic devices. Understanding the electronic properties of dilute-P GaNP alloy is thus a critical first step towards device implementation for realizing practical devices.

In this work we provide the analysis of the electronic properties of dilute-P GaNP alloys by utilizing First-Principle Density Functional Theory

(DFT) calculation. Our DFT analysis indicates significant band structure modifications of the GaN alloy when the N atoms are replaced with Phosphorus (P) atoms in the GaN alloy. The electronic properties of the dilute-P GaNP alloys are analyzed as follow: (a) band gap energy, (b) carrier effective masses and (c) split-off energy. Additionally, further analysis shows minimal interband Auger recombination in the dilute-P GaNP alloys as compared to InGaN alloy, implying the advantage of GaNP alloy as a visible light emitting material. The electronic properties of the dilute-P GaNP alloy will be discussed in details. The interband Auger recombination rates for the dilute-P GaNP alloy in comparison to InGaN alloy will also be provided.

Selectively reflective transparent sheets

Remi Wache, Steven K. Clowes, Marian Florescu, Stephen J. Sweeney, Univ. of Surrey (United Kingdom)

The aim of the present work is to investigate the possibility to selectively reflect certain wavelengths while maintaining the optical properties at other wavelengths. This is of particular interest for transparent materials which for specific applications may require reflection at a specific band gap. Although there exist currently techniques such as coatings to produce this selective reflection, this work focus on new approaches for a mass production of polyethylene sheet which incorporates either additives or surface patterning for selective reflection between 8 to 13 μm.

Typical additives used to produce a greenhouse effect in plastics include particles such as clays, silica or hydroxide materials. However, the absorption of thermal radiation is less efficient that the decrease of emissivity as it can be compared with the inclusion of lambertian materials.

Band gap engineering by the periodic structuring of metamaterials is known in nature for producing the vivid bright colours in certain insects via strong wavelength selective reflection. Research to artificially engineer such structures has mainly focused on wavelengths in the visible and near infrared. However few studies to date have been carried out to investigate the properties of metastructures in the mid infrared range even though the patterning of microstructure should be easier than the fabrication of nanostructures in photonic crystals. Preliminary results on the diffuse reflectivity given by simulation tools will be presented and the technical feasibility of these two approaches will be discussed.

9546-77, Session PWed

Omnidirectional mirror in two-dimensional photonic crystal with a periodic gain-loss modulation

Carlos Ivan Ham-Rodriguez, Jesus Manzanares-Martinez, Univ. de Sonora (Mexico); Paola Castro-Garay, Universidad de Sonora (Mexico); Betsabe Manzanares-Martinez, Yohan Jasdid Rodriguez-Viveros, Univ. de Sonora (Mexico); Damian Moctezuma-Enriquez, Ctr. de Investigación en Materiales Avanzados, S.C. (Mexico)

Recently has been demonstrated that the light propagation can be forbidden in gain-loss composite media as result of simultaneous absorption and enhancement of electromagnetic waves. The gain-loss media have a great potential in the design of electro-optical devices because the complex difractions of propagating and evanescent waves allow exotic possibilities for the modification of the spontaneous emission of atoms and molecules.

Gain-loss media has been for a long time an essential component in the design of Distributed Feedback Lasers. More recently gain-loss media has been intensively studied because in principle, it is possible to compensate the losses of evanescent fields such as the surface plasmons allowing new posibilities for the plasmonic-based technology.

In this work we study the Photonic Band Gaps (PBG) that are result of the destructive interference of electromagnetic waves interacting with a two-dimensional gain loss media. The composite system is made of cylinders with gain embedded in a lossy background. We have chose a combination of the constitutive parameters which give an zero average of gain or loss in the unit cell. We have found the parameters to obtain a robust band gap for the normal direction to the TX direction of a square lattice. We have also found the ambient conditions to design an Omnidirectional Mirror which have a stop band for all the imping propagating waves, irrespectively of their polarization or angle of incidence.

Moving femtosecond soliton in layered structure with cubic nonlinearity

Vyacheslav A. Trofimov, Tatyana M. Lysak, Lomonosov Moscow State Univ. (Russian Federation)

We discuss soliton mode of laser femtosecond pulse propagation in layered structure with cubic nonlinear response in certain layers. Soliton under consideration occupies a few layeres. It moves across the layers without its shape destroying. Using computer simulation we investigate the features of soliton reflection from ambient linear medium. Soliton reflection depens in strong way on optical properties for boundary layers. However, in any situation a part of soliton leaves the photonic crystal during some time interval.

9546-58, Session 14

Engineering light absorption in semiconductor metafilms *(Invited Paper)*

Mark L. Brongersma, Geballe Lab. for Advanced Materials (GLAM) (United States)

The optical properties of semiconductors are typically considered intrinsic and fixed. I will discuss how the rapid developments in the understanding of high-index semiconductor nano-antennas can be leveraged to create ultrathin semiconductor metafilms with designer absorption spectra. Such metafilms are constructed by placing one or more types of semiconductor antennas into a dense array with subwavelength spacings. As semiconductor antennas are only weakly-interacting and feature absorption cross sections that can exceed their geometrical cross section, very strongly absorbing metafilms can be created whose spectral absorption properties can directly be linked to the resonant properties of the constituent building blocks. The ability to create semiconductor metafilms with custom absorption spectra opens up new design strategies for planar optoelectronic devices and solar cells.

9546-59, Session 14

Exchanging Ohmic losses in metamaterial absorbers with useful optical absorption for photovoltaics *(Invited Paper)*

Durdu O. Guney, Michigan Technological Univ. (United States)

Using metamaterial absorbers, we have shown that metallic layers in the absorbers do not necessarily constitute undesired resistive heating problem for photovoltaics. Tailoring the geometric skin depth of metals and employing the natural bulk absorbance characteristics of the semiconductors in those absorbers can enable the exchange of undesired resistive losses with the useful optical absorbance in the active semiconductors. Thus, Ohmic loss dominated metamaterial absorbers can be converted into photovoltaic near-perfect absorbers with the advantage of harvesting the full potential of light management offered by the metamaterial absorbers. Based on experimental permittivity data for indium gallium nitride, we have shown that between 75%–95% absorbance can be achieved in the semiconductor layers of the converted metamaterial absorbers. Besides other metamaterial and plasmonic devices, our results

may also apply to photodectors and other metal or semiconductor based optical devices where resistive losses and power consumption are important pertaining to the device performance.

9546-60, Session 14

Optimized super-absorption in nano-structured thin films via a genetic algorithm *(Invited Paper)*

Alexandre Mayer, Jérôme Muller, Aline Herman, Olivier Deparis, Univ. of Namur (Belgium)

Genetic algorithms mimic natural selection in order to determine globally optimal solutions for complex problems in physics. The idea consists in working with a population of individuals, each of them representing a possible solution of the problem. The initial population consists of random individuals. We then select the best individuals. We breed them to determine new individuals for the next generation. We finally introduce random mutations in the coding of parameters. When repeated from generation to generation, this strategy leads to globally optimal solutions in a time that grows only linearly with the number of parameters to determine.

We used this approach to achieve super-absorption in nano-structured thin films (40 microns) of crystalline silicon. The device considered includes a periodic array of inverted pyramids on the front side with a conformal anti-reflection coating (SiNx and a-Si layers) and a reflector on the back side (a-Si and ITO layers). The geometrical parameters of these pyramids and the different layer thicknesses must be adjusted in order to maximize the absorption of solar radiation in the c-Si. The genetic algorithm provides solutions that lead to short-circuit currents of the order of 35-40 mA/cm?, which compare very well with the maximum of 43.5 mA/cm? one can achieve with c-Si.

A new avenue for high efficiency solar cells: interaction of hot electrons with plasmons *(Invited Paper)*

Krzysztof Kempa, Michael J. Naughton, Boston College (United States)

Hot electrons rapidly dissipate their extra free energy, typically into heat. This is the origin of the Shockley-Queisser efficiency limit of the single junction solar cells. An even faster mechanism of electron-plasmon scattering is available in metals. We demonstrate by detailed simulations, that an ultra-thin solar cell with a composite metamaterial/plasmonic collector could yield efficiency exceeding the Shockley-Quasar limit. The composite collector has a double function: firstly, it is designed to participate in efficiently trapping light, and secondly, it is a plasmonic resonator tuned to absorb the energy of hot electrons, thus protecting them from phonon losses.

Large-area, lithography-free perfect absorbers, color filters, and photodectors at visible frequencies using ultra-thin silver or amorphous silicon films

Zhongyang Li, Serkan Bütün, Koray Aydin, Northwestern Univ. (United States)

Plasmonic materials and metamaterials have been widely utilized to achieve spectral transmission, reflection and absorption filters based on localized or delocalized resonances arising from the interaction of photons with nanoscale patterns. However, the realization of visible-frequency, high-performance, large-area, optical filters based on nanoplasmonic materials is rather challenging due to nanofabrication related problems (cost, fabrication imperfection, surface roughness) and optical losses of metals. Here, we propose and demonstrate large-area perfect absorbers and transmission color filters and photodectors that could overcome the difficulties associated with nanofabrication using a lithography-free approach. Our resonant flat optical design is based on a modified, asymmetric metal-insulator/semiconductor-metal (MI/SM) based Fabry-Perot cavity incorporated with plasmonic, lossy ultra-thin (~ 30 nm) Ag or (~ 5-15 nm) amorphous Si films. We demonstrated a narrow bandwidth (~17 nm) super absorber with 97% maximum absorption with a performance comparable to nanostructure/nanoparticle-based super absorbers. We also investigated transmission filters in which different colors can be obtained by controlling the spacer thickness of silicon dioxide or amorphous silicon. With measured performance of transmission peak intensity reaching 60% and a narrow-band of ~ 40 nm, our color filters exceed the performance of widely studied plasmonic nanohole array based color filters and make a good candidate for large-area narrow-band photodetection devices. Such plasmonic loss incorporated Fabry-Perot cavities using ultra-thin metallic or semiconductor films could suggest active and practical applications in spectrally selective optical (color and absorber) filters, optoelectronic devices with controlled bandwidth such as narrow-band photodetectors, and light-emitting devices.

9546-63, Session 15

Transforming Cherenkov radiation in metamaterials *(Invited Paper)*

Vincent Ginis, Jan Danckaert, Irina Veretennicoff, Vrije Univ. Brussel (Belgium); Philippe Tassin, Chalmers Univ. of Technology (Sweden)

In this contribution, we explore the generation of light in transformation-optical media. When charged particles move through a transformation-optical material with a speed larger than the phase velocity of light in the medium, Cherenkov light is emitted. We show that the emitted Cherenkov cone can be modified with longitudinal and transverse stretching of the coordinates. Transverse coordinates stretching alters only the dimensions of the cone, whereas longitudinal stretching also changes the apparent velocity of the charged particle. These results demonstrate that the geometric formalism of transformation optics can be used not only for the manipulation of light beam trajectories, but also for controlling the emission of light, here for describing the Cherenkov cone in an arbitrary anisotropic medium. Subsequently, we illustrate this point by designing a radiator for a ring imaging Cherenkov radiator. Cherenkov radiators are used to identify unknown elementary particles by determining their mass from the Cherenkov radiation cone that is emitted as they pass through the detector apparatus. However, at higher particle momentum, the angle of the Cherenkov cone saturates to a value independent of the mass of the generating particle, making it difficult to effectively distinguish between different particles. Using our transformation optics description, we show how the Cherenkov cone and the cut-off can be controlled to yield a radiator medium with enhanced sensitivity for particle identification at higher momentum.

9546-64, Session 15

Guiding light by plasmonic resonant solitons in metallic nanosuspensions

Trevor S. Kelly, Akbar Samadi, Anna Bezryadina, San Francisco State Univ. (United States); Zhigang Chen, San Francisco State Univ. (United States) and Nankai Univ. (China)

In typical colloidal suspensions, the corresponding optical polarizability is positive, and thus enhanced scattering takes place as optical beams tend to catastrophically collapse during propagation. Recently, light penetration deep inside scattering suspensions has been realized by engineering dielectric or plasmonic nanoparticle polarizibilities. In particular, we have previously demonstrated two types of soft-matter systems with tunable optical nonlinearities - the dielectric and metallic colloidal suspensions, in which the effects of diffraction and scattering were overcome, hence achieving deep penetration of a light needle through the suspension.

In this work, we show that waveguides can be established in soft matter systems such as metallic nanosuspensions through the formation of plasmonic resonant solitons. First, we show that, due to plasmonic resonance, a 1064nm laser beam (probe) would not experience appreciable nonlinear self-action while propagating through 4cm cuvette containing the metallic nanosuspension of gold spheres (40nm), whereas a 532nm laser beam (pump) can readily form a spatial soliton due to nonlinear self-trapping. Second, we demonstrate effective guidance of the probe beam, which would otherwise diffract significantly through the nanosuspensions, due to the soliton-induced waveguide from the pump beam. Such guidance was observed when the power of the probe beam was varied from 20mW to 500mW at constant pump beam power, with more pronounced guidance realized from lower to higher probe beam power. Interestingly, due to the presence of the probe beam, the pump beam undergoes self-trapping at an even lower power. These results may bring about the possibility of engineering plasmonic soliton-based waveguides for many applications.

9546-65, Session 15

Magneto-optical switches in metal-dielectric-metal plasmonic waveguides

Ali Haddadpour, Vahid Foroughi Nezhad, Louisiana State Univ. (United States); Zongfu Yu, Univ. of Wisconsin-Madison (United States); Georgios Veronis, Louisiana State Univ. (United States)

The magneto-optical effect has been used to control the propagation of surface plasmon polaritons in plasmonic waveguides. Here we investigate single-interface metal-dielectric and metal-dielectric-metal plasmonic waveguides in which either the dielectric or the metal is a magneto-optical material. We derive the dispersion relation of these waveguides, and investigate the effect of an externally applied static magnetic field. We find that in metal-dielectric-metal waveguide structures in which the dielectric is a magneto-optical material, the symmetry of the structure prohibits any non-reciprocal propagation in the system. Moreover, the induced change in the propagation constant of the supported modes in the presence of an externally applied static magnetic field is relatively small. In addition, we find that using a magneto-optical metal in a single-interface metal-dielectric plasmonic waveguide results in non-reciprocal propagation of the plasmonic modes along the interface. We also find that in metal-dielectric-metal plasmonic waveguides in which the metal is a magneto-optical material, the propagation constant of the supported modes is dependent on the relative direction of the applied magnetic fields to the upper and lower metal regions. If the applied magnetic fields to the two metal regions are equal and in the same direction, the induced changes in the propagation constants of the modes propagating in the positive and negative directions are the same. On the other hand, if the directions of the applied external magnetic fields are opposite, the propagation constants of the modes propagating in the positive and negative directions are different. We finally investigate Fabry-Perot cavity magneto-optical switches.

9546-66, Session 15

Second order nonlinearity in Si by inhomogeneous strain and electric fields *(Invited Paper)*

Jörg Schilling, Clemens Schriever, Martin-Luther-Univ. Halle-Wittenberg (Germany); Federica Bianco, Scuola Normale Superiore (Italy); Massimo Cazzanelli, Lorenzo Pavesi, Univ. degli Studi di Trento (Italy)

Inhomogeneous strain was recently used to artificially generate a dipolar second order nonlinear susceptibility in silicon. However this is not the only way to break silicon's centrosymmetry. Second harmonic generation (SHG) was measured on several Si strip waveguides, which were strained by the deposition of stressed SiNx and SiO2 layers. A substantial offset of the SHG signal for all SiNx-covered waveguides was detected. This could be attributed to a local electric field near the Si/SiNx-interface generated by fixed charges in the cladding. This electric field induced SHG (EFISH) contributes constructively to the strain caused SHG and opens ways to electrically create and control a second order nonlinearity in Si waveguides.

In-the-cloud optimization tool for retrieving experimentally fitted conductivity of graphene

Ludmila J. Prokopeva, Purdue Univ. (United States) and Novosibirsk State Univ. (Russian Federation) and Institute of Computational Technologies (Russian Federation); You-Chia Chang, Univ. of Michigan (United States); Naresh K. Emani, Purdue Univ. (United States) and Data Storage Institute (Singapore); Ted Norris, Univ. of Michigan (United States); Alexander V. Kildishev, Purdue Univ. (United States)

Graphene is one of the emerging active nanophotonics materials with optical properties that can be controlled in real time by an applied bias voltage. Different applications from sensing to active nanophotonics have been discussed in the literature recently and the field is still developing especially with an eye on structured and multi-layer graphene. To design new devices there is a need for precise modeling of multivariate and dynamic optical responses of graphene elements in frequency and time domains. Taking into account the complexity that comes along with multiple unknown parameters, including edge effects in nanostructured graphene elements, graphene impurities, imperfections of characterization optics etc., it is hard to build an adequate multivariate model to reach good quantitative agreement with experiment.

Here, we present an approach that uses optimization methods to retrieve the optical properties of a given graphene sample from experiment. We show that with these techniques good quantitative agreement with experiments can be achieved; additionally we encapsulate our techniques in an online data-fitting tool. The tool includes several options to precisely fit the conductivity function to a given experiment - general spline approximations and physically meaningful random phase approximation models for frequency domain solvers, along with the relaxed Lorentz oscillator models for confident time domain simulations. A pilot version of

our free online tool entitled Photonics2D-Fit (to be staged at nanoHUB.org) is presented.

9546-69, Session 16

Enhanced infrared transmission from gold wire-grid arrays via surface plasmons in continuous graphene

Zizhuo Liu, Serkan Bütün, Edgar Palacios, Koray Aydin, Northwestern Univ. (United States)

Enhanced transmission of light through nanostructures has always been of great interest in the field of plasmonics and nanophotonics. With the aid of near-field effects, the transmission of the electromagnetic waves can be enhanced or suppressed. Much of the work on enhanced transmission has been shown to be frequency-selective. However it is possible to increase the transmission over a large frequency range by using graphene, which has shown broadband properties in many applications.

Here, we propose enhanced transmission in wire grid gold structure making use of continuous graphene sheets. We use finite-difference time-domain simulations to study the optical properties of this graphene-metal hybrid structure at mid infrared (mid-IR) wavelengths. The grating structure in wire grid gold provides an ideal platform to match the momentum and excite the surface plasmon polaritons (SPPs) in monolayer graphene. Our numerical calculations show that the local electromagnetic field around the graphene is largely enhanced due to surface plasmons. Moreover, with the highly confined SPPs coupling with the incident light, the transmission through the whole structure can be broadly enhanced in the mid infrared region. We also analyze the effect of the spectrum with different periods and gold nanowire widths to evaluate the size effects of the plasmons in graphene. In addition, by tuning the Fermi level, one can control the wavelength range at which the transmission is enhanced. The mechanism of the enhancement will be explained in the calculated electric field distribution. And we will also highlight the opportunities of graphene for applications such as tunable transmission and active photonic modulator.

9546-70, Session 17

Enhancing and inhibiting stimulated Brillouin scattering in photonic integrated circuits *(Invited Paper)*

Benjamin J. Eggleton, Moritz Merklein, Thomas F. S. Buettner, Irina V. Kabakova, The Univ. of Sydney (Australia)

On-chip nonlinear optics is a thriving research field, which creates transformative opportunities for manipulating classical or quantum signals in small-footprint integrated devices. Since the length scales are short, nonlinear interactions need to be enhanced by exploiting materials with large nonlinearity in combination with high-Q resonators or slowlight structures. This, however, often results in simultaneous enhancement of competing Q2 nonlinear processes, which limit the efficiency and can cause signal distortion. Here, we exploit the frequency dependence of the optical density-of-states near the edge of a photonic bandgap to selectively enhance or inhibit nonlinear interactions on a chip. We demonstrate this concept for one of the strongest nonlinear effects, stimulated Brillouin scattering using a narrow-band one-dimensional photonic bandgap structure: a Bragg grating. The stimluated Brillouin scattering enhancement enables the generation of a 15-line Brillouin frequency comb.

In the inhibition case, we achieve stimulated Brillouin scattering free operation at a power level twice the threshold

9546-71, Session 17

Optical pulse engineering and processing using nonlinearities of tapered and photonic crystal waveguides made of silicon *(Invited Paper)*

Nicolae-Coriolan Panoiu, Spyros Lavdas, Jie You, Univ. College London (United Kingdom); Richard M. Osgood Jr., Columbia Univ. (United States)

We present recent results pertaining to pulse reshaping and optical signal processing using optical nonlinearities of silicon-based tapered photonic wires and photonic crystal waveguides. In particular, we show how nonlinearity and dispersion engineering of tapered photonic wires can be employed to generate optical similaritons and achieve more than 10? pulse compression. We also discuss the properties of four-wave mixing pulse amplification and frequency conversion efficiency in long-period Bragg waveguides and photonic crystal waveguides. Finally, the influence of linear and nonlinear optical effects on the transmission bit-error rate in uniform photonic wires and photonic crystal waveguides made of silicon is discussed.

9546-72, Session 17

Nonlocal and quantum tunneling contributions to harmonic generation in nanostructures: electron cloud screening effects *(Invited Paper)*

Michael Scalora, U.S. Army Aviation and Missile Command (United States)

We investigate theoretically second and third harmonic generation from metal-based nanostructures and predict that nonlocal and quantum tunneling phenomena can significantly exceed expectations based solely on local, classical electromagnetism. Mindful that the diameter of typical transition metal atoms is approximately 3Å, we adopt a theoretical model that treats nanometer-size features and/or sub-nanometer size gaps or spacers by taking into account: (i) the limits imposed by atomic size to fulfill the requirements of continuum electrodynamics; (ii) spillage of the nearly-free electron cloud into the surrounding vacuum; and (iii) the increased probability of quantum tunneling as objects are placed in close proximity. Our treatment also includes the dynamics of bound charges in wavelength ranges where their contribution to the linear dielectric constant becomes pivotal. The model is an attempt to simplify a classical electrodynamic picture by incorporating a thin layer of free-electrons at the metal surface that screens an internal, polarizable medium.

9547-1, Session 1

Transverse spin of surface plasmon polaritons and spin-orbit coupling effects in light scattering by plasmonic nanostructures *(Invited Paper)*

Francisco J. Rodríguez-Fortuño, Daniel O'Connor, Pavel Ginzburg, Gregory A. Wurtz, Anatoly V. Zayats, King's College London (United Kingdom)

We will present the experimental and theoretical studies of the photonic spin-orbit coupling effects facilitated by a nanoparticle near a planar surface. Due to spin-orbit coupling, circularly polarized light of opposite handedness may take different trajectories when interacting with such a system, e.g. impinging on a polarizable particle placed above a metallic surface supporting surface plasmon polaritons or other guided modes. The transverse spin carried by surface plasmons is intimately linked to the polarisation of light after their scattering on nanostructures. Circular polarizations of opposite handedness are radiated into mirror-symmetric directions, dependent on the surface plasmon propagation direction. This spin-orbit coupling effect is an optical analogue of the inverse spin Hall effect and has important implications for optical forces, optical information processing, quantum optical technology and topological surface metrology.

9547-2, Session 1

Generation of quantum entangled states in nonlinear plasmonic structures and metamaterials

Alexander N. Poddubny, Ioffe Physical-Technical Institute (Russian Federation) and National Research Univ. of ITMO (Russian Federation); Andrey A. Sukhorukov, The Australian National Univ. (Australia)

The practical development of quantum plasmonic circuits incorporating non-classical interference [1] and sources of entangled states calls for a versatile quantum theoretical framework which can fully describe the generation and detection of entangled photons and plasmons. However, majority of the presently used theoretical approaches are typically limited to the toy models assuming loss-less and nondispersive elements or including just a few resonant modes. Here, we present a rigorous Green function approach describing entangled photon-plasmon state generation through spontaneous wave mixing in realistic metal-dielectric nanostructures.

Our approach is based on the local Huttner-Barnett quantization scheme [2], which enables problem formulation in terms of a Hermitian Hamiltonian where the losses and dispersion are fully encoded in the electromagnetic Green functions. Hence, the problem can be addressed by the standard quantum mechanical perturbation theory, overcoming mathematical difficulties associated with other quantization schemes. We derive explicit expressions with clear physical meaning for the spatially dependent two-photon detection probability, single-photon detection probability and single-photon density matrix. In the limiting case of low-loss nondispersive waveguides our approach reproduces the previous results [3,4]. Importantly, our technique is far more general and can quantitatively describe generation and detection of spatially-entangled photons in arbitrary metal-dielectric structures taking into account actual losses and dispersion. This is essential to perform the design and optimization of plasmonic structures for generation and control of quantum entangled states.

Efficient far field transmission of orbital angular momentum light states

Denis Garoli, Pierfrancesco Zilio, Istituto Italiano di Tecnologia (Italy); Giuseppe Parisi, twistoff s.r.l. (Italy); Francesco Tantussi, Istituto Italiano di Tecnologia (Italy); Felix Ritort, Univ. de Barcelona (Spain); Tommaso Ongarello, Institut d'Électronique Fondamentale (France); Francesco De Angelis, Istituto Italiano di Tecnologia (Italy); Yuri Gorodetski, Ariel Univ. (Israel)

Nowadays light carrying orbital angular momentum (OAM) constitutes the focus of multiple and variegate research interests, ranging from astronomy to microscopy and plasmonics. Surface plasmon polaritons carrying OAM, from now on called Plasmonic vortices (PVs), can be generated by exploiting particular chiral grating couplers, which have been called plasmonic vortex lenses (PVLs). Once generated, PVs can interact with nanostructures placed at the center of the PVL, creating a number of interesting optical effects. We introduce new simulative and experimental results on generation of OAM light states both in near and far-field optical regime. PVLs coupled with nanostructures placed at the center will be used in order to investigate interesting optical behaviors. We propose an innovative holey PVL architecture which is able to convert impinging light to an almost pure and well defined OAM state, both in its evanescent and propagating parts. We then extend the investigation by introducing a vertical nanotip at the center of our structure. Although this kind of structures has been investigated for its plasmonic nanofocusing effects, here we use it as a perfect plasmon-to-far-field OAM decoupler. Indeed, by increasing the curvature radius at the cone base, a perfect decoupling of plasmonic vortex into free space propagating structured light can be obtained, without any plasmonic back reflection at the tip base. This structure has interesting applications to nanoparticle trapping and manipulation. We show that the vertical nanotip can be actually used as "nano-launcher" of particles, inducing at the same time an non-zero angular momentum on their motion.

Magneto-optical response of a periodic metallic nano-structure *(Invited Paper)*

Yakov M. Strelniker, Bar-Ilan Univ. (Israel); David J. Bergman, Tel Aviv Univ. (Israel)

When an applied magnetic field has an arbitrary direction with respect to the lattice axes of a periodically nano-structured metal-dielectric metamaterial, the macroscopic or bulk effective permittivity tensor becomes anisotropic and all its components can be nonzero. This effect can be especially strong and significant in the vicinity of surface plasmon and cyclotron resonances (the frequencies of which are also sensitive to the value and direction of the applied external magnetic field). A similar effect for the case of dc effective conductivity is already verified experimentally (since magneto-conductivity tensor can be measured directly). However, this prediction for the permittivity has not yet been tested experimentally (since the permittivity tensor cannot be measured directly). What can be measured directly is the Voigt rotation, for which general exact analytical expressions were not published previously. In this work we have studied analytically and numerically the rotation and ellipticity of polarization of the light propagating through a metamaterial film with periodic nanostructure for arbitrary direction of the applied static magnetic field, including both Voigt and Faraday configurations. In the Voigt configuration we found a

strong dependence of the above mentioned effects on the direction of the applied magnetic field.

9547-5, Session 2

Perfect optical imaging of a Veselago Lens: Eigenstate based analysis *(Invited Paper)*

David J. Bergman, Asaf Farhi, Tel Aviv Univ. (Israel)

The Veselago Lens is analyzed by expanding the electric field of a time dependent point charge in a complete set of eigenstates of Maxwell's equations for a two-constituent composite medium with electric permittivities ?1, ?2 and a magnetic permeability equal to 1 everywhere which has the appropriate microstructure. An exact expression for the local electric field in the form of a one dimensional integral is obtained from which we are able to calculate that field numerically very rapidly and with great precision. In the quasistatic regime it was found earlier that this field diverges in some parts of the system when ?1/?2 = –1 and ?1, ?2 are both real. That is precisely where the Veselago Lens has been predicted to provide imaging the resolution of which is not limited by the wavelength. Moreover, the dissipation rate then also diverges sometimes. That analysis will now be extended to the non-quasistatic regime. Among the surprising results is the fact that the best sub-wavelength resolution is obtained not at the geometric optics foci of the Veselago Lens but at points on the ?1, ?2 interface.

Beam engineering for selective and enhanced coupling to multipolar resonances

Tanya Das, Jon A. Schuller, Univ. of California, Santa Barbara (United States)

Multipolar light-matter interactions in sub-wavelength nanostructures depend on both nanostructure properties and properties of the illuminating beam. Conventionally, researchers manipulate the former and engineer the resonant properties of nanostructures. Instead, we concentrate on the latter and demonstrate via electromagnetics calculations that unconventional light sources can be used to selectively excite and enhance coupling to specific multipolar resonances. Building on Mie theory, we describe an analytical method for determining the optical response of nanoparticles (NPs) illuminated by any focused beam of interest. The illuminating source is decomposed into an angular spectrum of plane waves, and the NP response is determined by superimposing the response of the plane waves. We show that the multipolar light-matter interaction can alternately be expressed as a product of illumination-independent multipole moments and particle-independent field quantities: a vastly simplified approach for calculating light scattering and absorption in complex illumination conditions. Using these methods, we study the scattering spectra of a spherical NP under several types of illumination. We show that the spectra vary significantly with different illumination conditions, and show how to achieve selective excitation of desired multipolar modes. Additionally, we demonstrate the existence of longitudinal quadrupole excitations that cannot be accessed with conventional linearly polarized illumination. This work enables a new understanding of light-matter interactions in metamaterials, and lays the foundation for researchers to identify, quantify, and manipulate multipolar light-matter interactions through optical beam engineering.

Ultrafast coherent dynamics of Rydberg electrons bound in the image potential near a single metallic nanoobject *(Invited Paper)*

Jörg Robin, Jan Vogelsang, Carl von Ossietzky Univ. Oldenburg (Germany); Benedek J. Nagy, Wigner Research Ctr. for Physics of the H.A.S. (Hungary); Petra Gross, Christoph Lienau, Carl von Ossietzky Univ. Oldenburg (Germany)

Image potential states are well established surface states of metallic films [1]. For a single metallic nanostructure these surface states can be localized in the near-field arising from illumination by a strong laser field. Thus single metallic nanostructures offer the unique possibility to study quantum systems with both high spatial and ultrafast temporal resolution. Here, we investigate the dynamics of Rydberg states localized to a sharp metallic nanotaper.

For this purpose we realized a laser system delivering few-cycle pulses tunable over a wide wavelength range [2]. Pulses from a regenerative titanium:sapphire amplifier generate a white light continuum, from which both a proportion in the visible and in the infrared are amplified in two non-collinear optical parametric amplification (NOPA) stages. Difference frequency generation (DFG) of both stages provides pulses in the near-infrared.

With a precisely delayed sequence of few-cycle pulses centered around 600 nm (NOPA#1 output) and 1600 nm (DFG output) we illuminate the apex of a sharply etched gold tip. Varying the delay we observe an exponential decay of photoemitted electrons with a distinctly asymmetric decay length on both sides, indicating the population of different states. Superimposed on the decay is a clearly discernible quantum beat pattern with a period of <50 fs, which arises from the motion of Rydberg photoelectrons bound within their own image potential. These results therefore constitute a step towards controlling single electron wavepackets released from a gold tip opening up fascinating perspectives for applications in ultrafast electron microscopy [3].

Heat generation, hot electrons, and transparency windows in plasmonic nanostructures *(Invited Paper)*

Alexander Govorov, Ohio Univ. (United States)

We investigate the effects of generation of heat and hot plasmonic carriers in metal nanostructures. The problem of heat release from optically-excited plasmonic nanocrystals is treated classically [1,2] whereas the hot electron problem is calculated using the quantum mechanical approach based on the equation of motion for the density matrix [3-5]. The energy distribution of optically-excited plasmonic carriers is very different in metal nanocrystals with large and small sizes. In large nanocrystals, most excited carriers have very small energies and the electron distribution resembles the case of a plasmon wave in bulk. For gold nanocrystal with smaller sizes (less than 20nm), the energy distribution of hot carriers becomes flat and has a large number of carriers with high energy [3-5]. Therefore, smaller nanocrystals are preferable for injection of plasmonic carriers into semiconductors or into molecules on the surface. The physical reason for the above behavior is non-conservation of momentum in a nanocrystal. The geometry, type of metal, and orientation of the external electric field are important to obtain high quantum efficiencies of generation and injection of plasmonic electrons [3-5]. Other important properties and limitations: (1) Intra-band transitions are preferable for generation of energetic electrons and dominate the absorption for relatively long wavelengths (approximately

>600 nm), (2) inter-band transitions efficiently generate energetic holes in the d-band of gold and (3) the carrier-generation and absorption spectra can be significantly different [3-5]. The d-band hole generation can be used for efficient plasmonic photochemistry [6]. Along with the optical-energy conversion processes, we are looking at plasmonic and hybrid metastructures with unusual properties such as strong chirality and transparency windows [7,8,9]. The results obtained in this study can be used to design a variety of plasmonic nanodevices based on hot electron injection for photo-catalysis, light-harvesting, and solar cells.

Thermal phenomena in quantum plasmonics *(Invited Paper)*

Andrey K. Sarychev, Institute for Theoretical and Applied Electrodynamics (Russian Federation); Gennady Tartakovsky, Advanced Systems and Technologies (United States); Sergey Vergeles, L.D. Landau Institute for Theoretical Physics (Russian Federation); Vladimir Parfenyev, Moscow Institute of Physics and Technology (Russian Federation)

Plasmon nanolasers, also known as SPASERs, were suggested by Bergman and Stockman in 2003. Quantum plasmonics attract much attention in recent years due to the numerous potential applications in the plasmonics. We consider thermal effects in the metal nanoresonator immersed in the active, laser medium. The size of the resonator is much less than the wavelength. The plasmon field inside the nanoresonator operates as a quantum object. Due to the nanosize of the resonator, the internal plasmon electric field is about the atomic field even for few plasmon quants. The coupling between the plasmon field and plasmon resonator is anomalous strong. We develop the quantum dynamics of the plasmon field and show that the SPASER may be the subject of thermal instability. The loss in SPASER increases with increasing the temperature when the average number of the plasmons is maintained at the stationary level. Therefore, the heat generation increases with increasing the temperature. This positive feedback results in the thermal instability. When the energy, accumulated in the plasmon nanoresonator, exceeds the instability threshold the temperature increases exponentially. We find the increment of the temperature growth and lifetime as function of the loss in metal and the structure of the plasmon resonator. We consider how the thermal instability influences the luminescence and find how the lasing threshold is changed. The coherence of the light emitted by the plasmon laser is also considered. The thermal stability of the nanolaser is crucial for any practical application.

9547-10, Session 3

Plasmonic laser sensors

Renmin Ma, Sadao Ota, Yimin Li, Sui Yang, Xiang Zhang, Univ. of California, Berkeley (United States)

Perhaps the most successful application of plasmonics to date has been in sensing, where the interaction of a nanoscale localized field with analytes leads to high-sensitivity detection in real time and in a label-free fashion. However, all previous designs have been based on passively excited surface plasmons, in which sensitivity is intrinsically limited by the low quality factors induced by metal losses. It has recently been proposed theoretically that surface plasmon sensors with active excitation (gain-enhanced) can achieve much higher sensitivities due to the amplification of the surface plasmons. Here, we experimentally demonstrate an active plasmon sensor that is free of metal losses and operating deep below the diffraction limit for visible light. Loss compensation leads to an intense and sharp lasing emission that is ultrasensitive to adsorbed molecules. We validated the efficacy of our sensor to detect explosives in air under normal conditions and have achieved a sub-part-per-billion detection limit, the lowest reported to date for plasmonic sensors with 2,4-dinitrotoluene and ammonium nitrate. The selectivity between 2,4-dinitrotoluene, ammoniumnitrate and nitrobenzene is on a par with other state-of-the-art explosives detectors. Our results show that monitoring the change of the lasing intensity is a superior method than monitoring the wavelength shift, as is widely used in passive surface plasmon sensors. We therefore envisage that nanoscopic sensors that make use of plasmonic lasing could become an important tool in security screening and biomolecular diagnostics.

9547-11, Session 3

Near-field imaging and spectroscopy of hybridized plasmons *(Invited Paper)*

Martin Aeschlimann, Technische Univ Kaiserslautern (Germany)

Understanding light-matter interactions such as the dynamic response of a metal to incident light is essential for advancing fundamental research and technological applications e.g. designing plasmonic devices such as nanoantenna directional emitters. The near-field response is determined on a length scale that is intrinsically smaller than the optical diffraction limit and so we use electrons to image the near-field distribution.

We combine photoemission electron microscopy (PEEM) with a variable wavelength laser light source, an optical parametric oscillator (OPO), to perform near-field imaging & spectroscopy of whispering gallery resonator (WGR)1 arrays. These ultrahigh spatially and spectrally resolved measurements show characteristic spectral peaks and near-field mode distributions due to the excitation of different plasmon resonances. Controlling the interference between dipole and quadrupole modes allows us to direct the emission from the nanoantenna.

Additionally we perform femtosecond 2-dimensional coherence spectroscopy2 on a microcavity system containing two well separated WGR nanoantennas. Hybridization of a propagating surface plasmon polariton and the localized surface plasmon in a cavity enables energy transfer between the two coupled nanoantennas.

9547-12, Session 4

Ultrafast nanoelectronics: steering electrons in infrared near-fields *(Invited Paper)*

Georg Herink, Claus Ropers, Georg-August-Univ. Göttingen (Germany)

Plasmonic nanostructures can break the diffraction limit and confine optical fields on the nanoscale. The coupling of intense femtosecond transients to the apex of metallic nanotips enables ultrafast electron point sources which find applications in ultrafast electron microscopy and time-resolved

diffraction instruments. In this contribution, we demonstrate the impact of near-field localization onto strong-field photoemission and present the control of electron trajectories via the momentary electric near-field. The photoemission dynamics at single gold and tungsten nanotips are experimentally studied over a broad range of excitation frequencies, spanning from 1 - 400 Terahertz (THz). The transition from oscillatory electron acceleration to a field-driven interaction is presented as a result of intense, long-wavelength and localized excitation.

The high field enhancement at lower frequencies is demonstrated to induce localized field emission from a nanotip with moderate incident fields as provided by table-top THz sources. Such THz-induced cold field emission can be used, e.g., for the temporal tracking of optically excited hot-electron dynamics in nanostructures. Moreover, the field-driven electron acceleration in the enhanced THz near-field is employed in a pump-probe scheme to temporally map the local THz-response of the nanostructure by projecting the momentary apex near-field onto the kinetic energy of femtosecond electron pulses. Besides the electrical characterization of nanostructures at THz-frequencies, the temporally and spatially confined interaction of free electrons with ultrashort near-fields is expected to enable a novel class of ultrafast vacuum micro- and nanoelectronic devices, and first applications are presented in this talk.

9547-13, Session 4

Mapping near-field plasmonic interactions of silver particles with scanning near-field optical microscopy measurements

Patrick Andrae, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany) and Freie Universtität Berlin (Germany); Min Song, Helmholtz Zentrum Berlin (Germany); Mohamed Haggui, Paul Fumagalli, Freie Univ. Berlin (Germany); Martina Schmid, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany) and Freie Univ. Berlin (Germany)

A scanning near-field optical microscope (SNOM) is a powerful tool to investigate optical effects that are smaller than Abbe's limit. Its greatest strength is the simultaneous measurement of high-resolution topography and optical near-field data that can be correlated to each other. However, the resolution of an aperture SNOM is always limited by the probe. It is a technical challenge to fabricate small illumination tips with a well-defined aperture and high transmission. The aperture size and the coating homogeneity will define the optical resolution and the optical image whereas the tip size and shape influence the topographic accuracy. Although the technique has been developing for many years, the correlation between simulated near-field data and measurement is still not convincing.

To overcome this challenge, the mapping of near-field plasmonic interactions of silver nanoparticles is investigated. Different nanocluster samples with diverse distributions of silver particles are characterized via SNOM in illumination and collection mode. This will lead to topographical and optical images that can be used as an input for SNOM simulations with the aim of estimating optical artifacts. Including tip, particles, and substrate, the COMSOL simulations are based on the real set-up and settings. Correlating the high-precision SNOM measurement and the detailed simulation of a full image scan will enable us to draw conclusions regarding near-field enhancements caused by interacting particles.

We will discuss how different tip shapes, particle distributions, and roughness can affect the optical image. Providing the influence of critical measurement parameters (tip-sample distance, step size, integration time), we will improve the SNOM set-up and the resolution of the resulting images.

9547-14, Session 4

Probing plasmonic hot spots on single gold nanowires using combined near field techniques

Patrick Hsia, Sylvie Marguet, CEA-Ctr. de SACLAY (France); Sergei Kostcheev, Renaud J. B. Bachelot, Institut Charles Delaunay (France) and Lab. de Nanotechnologie et Instrumentation Optique (France); Ludovic Douillard, Fabrice Charra, Céline Fiorini-Debuisschert, CEA-Ctr. de SACLAY (France)

Gold nanowires are known to sustain surface plasmons (SP) when they are excited by visible or near-infrared light. SPs correspond to the collective oscillation of conduction electrons which leads to high localized field enhancements called "hot spots". They find various applications such as the optimization of the efficiency of solar cells or the generation of nanosource of light. Comparative characterizations between wires made by colloidal chemistry and by e-beam lithography have been undertaken using complementary near field characterization techniques. Considering comparable excitation conditions, we show that wires made by colloidal synthesis exhibits rather stronger field enhancement effects, their two-photon luminescence (2PL) emission spectrum clearly revealing their crystalline properties.

Simultaneous characterization of the topography and the optical properties of single nanowires was performed both by correlated atomic force microscopy (AFM) coupled with 2PL and by combined low-energy and photoemission electron microscopy (LEEM/PEEM), respectively to get an insight in both the radiative and non-radiative channels of relaxation of the SP. Finally, we present a new near-field technique where the second harmonic signal generated by locally oriented molecules under a tip plays the role of an active probe, enabling to reveal the optical properties of nano-objects (hot spots). The optical resolution obtainable with this technique is directly linked to the tip apex while the resolution in 2PL depends on the size of the spot. This technique will be further compared to the ones mentioned above and its possibilities will be presented.

9547-15, Session 4

Ultrafast dynamics via coherent exciton-plasmon coupling in quantum dot-metallic nanoparticle systems

Seyed M. Sadeghi, The Univ. of Alabama in Huntsville (United States)

When a quantum dot is in the vicinity of a metallic nanoparticle and is driven by a laser field, quantum coherence can renormalize the plasmon field of the metallic nanoparticle, forming a coherent-plasmonic field (CP field). In this contribution we demonstrate that for a given form of variation of this laser field with time, the CP field around the metallic nanoparticle can have offer different forms of field ultrafast dynamics, depending on location. In other words, the coherent exciton-plasmon coupling in such a system can generate distinctive position-dependent coherent-plasmonic dynamics, designating each location around the metallic nanoparticle with a characteristic time-position coordinate. We discuss the way such a process depends on the applied laser field frequency and polarization, quantum dot transition energies, and spacing between the quantum dot and metallic nanoparticle. We also discuss how such a process allows quantum dot-metallic nanoparticle acts as coherent antenna, offering novel ways for adsorption-free detection of certain nanoscale materials. These investigations are carried out by demonstrating that the coherent dynamics responsible for these effects can persist even in the presence of the ultrafast polarization dephasing of the quantum dots. This part of our investigation highlights the prospect of generation and preservation of quantum coherence effects in hybrid quantum dot-metallic nanoparticle systems at elevated temperatures. Therefore, even when the decoherence times of the quantum dots are of the order of several hundreds of femtoseconds, as observed at room temperature, such coherent dynamics can remain quite distinct and observable.

9547-16, Session 4

Efficient coupling and transport of a surface plasmon at 780 nm in a gold nanostructure *(Invited Paper)*

Yu Gong, Alan G. Joly, Patrick El Khoury, Wayne P. Hess, Pacific Northwest National Lab. (United States)

Nonlinear photoemission electron microscopy (PEEM) is used to map propagating surface plasmons launched from lithographically patterned nanostructures, such as individual nanoholes nanohole arrays and trenches, in noble metal films. The propagation of a coherent surface plasmon is followed, in real time, using a pump-probe technique and locked femtosecond pulse pairs. In effect we produce a movie of plasmon propagation. The plasmon velocity is determined and dispersion properties characterized. Strong near field photoemission patterns are observed in the PEEM images. A damped elongated ring-like photoemission beat pattern is observed from individual nanoholes following low angle of incidence irradiation. In studies of plasmonic nanohole arrays, with sub-15 fs laser pulses centered at 780 nm, focusing of propagating plasmons is optimized as a function of the number of rows and columns constituting the array. The recorded photoemission patterns are attributed to constructive and destructive interference between propagating surface plasmons launched from the individual nanoholes which comprise the array. By exploiting the wave nature of propagating surface plasmons, we demonstrate how varying the array geometry (hole diameter, pitch, and number of rows/columns) ultimately yields intense localized photoemission patterns. Through a combination of PEEM experiments and finite-difference time-domain simulations, we identify the parameters for optimal array geometry for efficient light coupling and interferometric plasmonic lensing. We also describe an exemplary practical application of the nanohole array-based plasmonic lenses, namely, enhanced photoemission from a vertex of a strategically positioned gold triangle.

9547-18, Session 5

Multicolor fluorescence microscopic imaging of cancer cells on the plasmonic chip

Keiko Tawa, National Institute of Advanced Industrial Science and Technology (Japan) and Kwansei Gakuin Univ. (Japan); Chisato Sasakawa, Shohei Yamamura, Izumi Shibata, Masatoshi Kataoka, National Institute of Advanced Industrial Science and Technology (Japan)

A plasmonic chip which is a metal coated substrate with grating structure can provide the enhanced fluorescence by the grating-coupled surface plasmon field. In our previous studies, bright epi-fluorescence microscopic imaging of neuron cells and sensitive immunosesnsing have been reported. In this study, two kinds of breast cancer cells, MCF-7 and MDA-MB231, were observed with epi-fluorescence microscope on the plasmonic chip with 2D hole-arrays. They were multicolor stained with 4', 6-diamidino-2-phenylindole (DAPI) and allophycocyanin (APC)-labeled anti-epithelial cell adhesion molecule (EpCAM) antibody. Our plasmonic chip provided the brighter fluorescence images of these cells compared with the glass slide. Even in the cells including few EpCAM, the distribution of EpCAM was clearly observed in the cell membrane. It was found that the plasmonic chip can be one of the powerful tools to detect the marker protein existing around the chip surface even at low concentration.

9547-19, Session 5

NIR and MIR charge transfer plasmons in wire-bridged antennas

Yue Zhang, Fangfang Wen, Samuel Gottheim, Nicholas S. King, Yu Zhang, Peter Nordlander, Naomi J. Halas, Rice Univ. (United States)

We investigate optical properties of wire-bridged plasmonic nanoantennas. Here we found two spectral features: a dipolar plasmon in the visible and a Charge Transfer Plasmon (CTP) in the infrared. The CTP depends sensitively on the conductance of the junction wire, offering a controllable way for tuning the plasmon resonance to the desired wavelength regime via junction geometries. Here we use single-particle dark field spectroscopy from UV, visible to IR to identify plasmonic modes in different spectrum regimes. The simulations using Finite-difference time-domain (FDTD) method are in good agreement with experiment: Increasing the junction wire width and concurrently the junction conductance blue shifts resonance positions, and simultaneously modifies scattering strengths, the linewidth of CTP and dipolar plasmon. We notice that CTP in a much longer wavelength regime and preserving a narrow line width, an important implication for designing IR plasmons with a high quality factor for enhanced spectroscopy and sensing applications. We also extend the CTP to the IR regime by increasing the wire length to create IR plasmon while keeping the line width of the resonance. Our work offers a way for studying the charge transfer properties in plasmonic nanostructures. Not only it adds another degree in understanding the charge transfer properties in plasmonic nanostructures but also offers an optical platform for studying molecules transport at optical frequencies and related applications.

9547-20, Session 5

Nanoporous antennae for high quality factor infrared sensing

Denis Garoli, Eugenio Calandrini, Istituto Italiano di Tecnologia (Italy); Sandro Cattarin, CNR-IENI (Italy); Pierfrancesco Zilio, Alessandro Alabastri, Andrea Toma, Ermanno Miele, Francesco De Angelis, Istituto Italiano di Tecnologia (Italy)

In the last decade, the research efforts was focused on the quest of novel plasmonic materials. In particular, the mid-infrared and THz spectral ranges present the advantage of direct probing of the vibrational spectra of the sample but suffers the limit imposed by diffraction. The capability of plasmonics to squeeze and enhance the light in the so-called hot-spots offers a new path for the development of highly-selective optical sensors for biomedical applications.

We introduce a novel material platform for mid-infrared plasmonics and sensing based on nanoporous gold grown by means of Au and Ag co-sputtering. Nanoporous gold can be formed by dealloying Au–Ag alloys and its nanostructural features depends on the initial alloy composition. To this goal, co-sputtering technique offers the advantages of complete tuning of the growth parameters and high-scalability. The optical response is completely determined by the nanostructural film features.

Plasma frequency around 3000 cm-1 has been obtained and nanoantenna arrays have been fabricated by means of electron beam lithography and reactive ion etching. Antennas are engineered to support localized plasmon resonances in the 1500-1700 cm-1 range. This device is exploited for the detection of protein conformational states, in their native environment, at extremely low concentration, in the amide-I and –II band range. The employment of nanoporous gold offers the unique advantages of augmented analyte delivery by infiltration inside the sensor, high-effective surface area and versatile functionalization, without affecting the device fabrication by porousity.

9547-21, Session 5

Plasmonic holography: obtaining wide angle, broadband, and high efficiency *(Invited Paper)*

Jacob Scheuer, Yuval Yifat, Michal Eitan-Wiener, Zeev Iluz, Yael Hanein, Amir Boag, Tel Aviv Univ. (Israel)

We demonstrate wide-angle, broadband and efficient reflection holography by utilizing coupled dipole-patch nano-antenna cells to impose an arbitrary phase profile on of the reflected light. High fidelity images were projected at angles of up to 450 with respect to the impinging light with efficiencies exceeding 50% over an optical bandwidth of 200nm. The demonstration of such reflectarrays opens new avenues towards expanding the limits of large angle holography and rendering it a practical technology.

9547-87, Session 5

Tuning plasmonic cavity modes by the symmetry breaking of metasurface *(Invited Paper)*

Hui Liu, Nanjing Univ. (China)

A plasmonic cavity composed from metasurface is designed and experimentally demonstrated. Due to the symmetry breaking of the metasurface, the degeneracy of the different polarized cavity states is lifted. It shifts the resonating frequencies of two polarized cavity modes, in which one is blue-shifted and another is red-shifted. Combining with a photothermal effect, we demonstrate that the polarized cavity states can be experimentally tuned by varying the reflection phase of the metasurface through the incident laser intensity. This reported metacavity can be applied in cavity quantum optics, lasers and other light-matter interaction processes.

9547-22, Session 6

Strongly coupled plasmon-nanocavity modes for broadband, near-field induced absorption in ultrathin semiconductor coatings *(Invited Paper)*

Carl Hagglund, Uppsala Univ. (Sweden)

Ultrathin nanocomposite layers comprising noble metal nanoparticles and semiconductor coatings can support localized surface plasmon resonances (LSPRs) with very large cross sections for absorption and scattering of light. These plasmon resonances are highly sensitive to details of the geometry as well as to the permittivity of the metal and semiconductor components, allowing their effective optical properties to be adapted to a range of important applications including solar energy conversion.

By employing such a nanocomposite system as an essentially two dimensional absorber layer in an absorber/spacer/reflector stack, extreme levels of absorption per unit volume can be accomplished through optical impedance matching.1 This is of high interest for solar cells, where it may enable a two orders of magnitude reduction of the absorber layer thickness, implying potentially large gains in terms of cost reductions and conversion efficiency. However, in order to exploit such ultrathin nanocomposite layers for efficient solar energy conversion, the absorption must cover a broad spectral range and losses in the form of Joule heating of the metal components must be minimized.

These challenges may be approached by exploiting plasmon near-field induced absorption in heavily damping semiconductor coatings.2 The damping broadens the LSPR and channels a high fraction of the absorption into the semiconductor layer while it suppresses Joule heating. Additional benefits can be gained through strong coupling of the damped LSPR and a Fabry-Perot nanocavity mode supported by the absorber/spacer/reflector system. This results in additional peak width and even anticrossing behavior when the coupling is strong enough compared to the overall damping. Based on a 10 nm thick semiconductor coating grown on a gold nanoparticle array by atomic layer deposition, these effects are experimentally verified and used to demonstrate a very high average semiconductor absorption across the spectral range targeted for solar energy applications.

Cooperative energy transfer in plasmonic systems

Tigran V. Shahbazyan, Jackson State Univ. (United States); Vitaliy N. Pustovit, Augustine M. Urbas, Air Force Research Lab. (United States)

Forster's energy transfer between donor and acceptor fluorophores, e.g., dye molecules or semiconductor quantum dots, underpins diverse phenomena in biology, chemistry and physics. While Forster's transfer between isolated fluorophores is efficient only for relatively short donor-acceptor separations below 10 nm, plasmon-mediated transfer channels that arise when fluorophores are placed near metal nanostructures lead to significant increase of energy transfer rate for larger donor-acceptor distances. The fraction of the donor energy absorbed by the acceptor is determined by ta subtle interplay between transfer, radiation and dissipation channels. We describe a cooperative amplification mechanism for plasmon-mediated energy transfer from a large ensemble of donors to fewer acceptors. The plasmonic coupling between donors' gives rise to robust superradiant and subradiant states and the energy transfer takes place from these collective states rather than from many individual donors. We show that the transfer efficiency from superradiant states is significantly amplified relative to that from the same number of individual donors due to the large matrix element of superradiant states with acceptor's electric field. At the same time, energy transfer from subradiant states is amplified as well due to their reduced Ohmic and radiative losses.

Surface plasmon strengthened nonlinearity in indium-tin-oxide coated Cu-doped potassium sodium barium strontium niobate crystals

Hua Zhao, Liang Li, Jingwen Zhang, Harbin Institute of Technology (China)

Since the electromagnetic fields associated with the surface plasmon polaritons (SPPs) are localized at interfaces and often intensified greatly [1], the nonlinearity of optical materials were strengthened greatly [2]. In the past years, researchers tuned the plasma frequency of semiconductor indium tin oxide (ITO) thin films towards shorter wave by applying external electric field [3]. We used internal photovoltaic field to tune ITO plasma frequency from IR to visible band in lithium niobate [4]. In this work, we employed fast response, pyroelectric Cu-doped (K0.5Na0.5)0.2(Sr0.75 Ba0.25)0.9Nb2O6 (KNSBN) crystals in modifying ITO coating to support visible SPP to strengthen its nonlinearity in KNSBN. As the result, (1) a 2 dimensional diffraction pattern was observed with only two writing beams; (2) The reflectivity on the very first surface was changed 2.3%, equivalent to 0.023 refractive index change; (3) as high as 3.0% energy transferring to the reflection on the first surface was measured, resulting unambiguously from energy transferring in subwavelength scale. All these results, beyond reach of conventional photorefractive theory, consist with our theoretical consideration based on SPP excitation. The phase grating mediated SPP excitation is promising in designing photonic devices.

Enhancing second-order nonlinearity on Au-nanorods at localized surface plasmon resonance with nonlinear optical polymers

Atsushi Sugita, Takuma Hirabayashi, Shunsuke Nihashi, Atsushi Ono, Yoshimasa Kawata, Univ. of Shizuoka (Japan)

We will present second harmonic generations (SHG) from Au nanorods coated with nonlinear optical (NLO) polymers. Nonlinear Plasmonics, the technologies of mixing multiple Surface Plasmon (SP)-enhanced optical fields, have attracted great attentions as one of the most important basic technologies for next-generation high-speed, high-density and ultra-compact integrated photonic devices. Most of the previous studies have exploited the nonlinearities of metal surfaces, where the SP waves were generated. In the present study, we challenged enhancing the nonlinearities of the metal surfaces with the NLO polymers. The three kinds of the NLO polymers with different transition frequencies were prepared. The localized Surface Plasmon (LSP) waves were excited with Au-nanorods. The LSP resonant frequencies were tuned by changing the aspect ratio of the nanorods. The NLO polymer thin film with 50 nm-thickness was coated on the nanorods. When the excitation light wavelength agreed with the LSP resonant wavelength, the nanorods emitted the intense SHG waves, whether or not the NLO polymers were coated. However, the SHG conversion efficiency of the NLO polymer coated nanorods was higher than that of the pristine nanorods. Furthermore, the conversion efficiencies were higher, as the transition wavelengths of the NLO polymers were closer to the excitation light wavelength. The 3.5-fold enhancement in the conversion efficiency was recorded from the nanorods whose absorption peak was the closest to the LSP excitation wavelength, comparing with that from the pristine nanorods. The results proved that the enhancements of the nonlinearities due to the near-resonant excitations were available for the nonlinear plasmonics.

9547-26, Session 6

A comparative study of second-harmonic generation in plasmonic and dielectric gratings made of centrosymmetric materials

Martin Weismann, Univ. College London (United Kingdom) and Photon Design Ltd. (United Kingdom); Dominic F. G. Gallagher, Photon Design (United Kingdom); Nicolae-Coriolan Panoiu, Univ. College London (United Kingdom)

We present a new numerical method for the analysis of second-harmonic generation (SHG) in one- and two-dimensional (1D, 2D) diffraction gratings containing centrosymmetric quadratically nonlinear materials. Thus, the nonlinear optical properties of a material are determined by its symmetry properties: non-centrosymmetric materials lack inversion symmetry and therefore allow local even-order SHG in the bulk of the material, whereas this process is forbidden in centrosymmetric materials. The inversion symmetry of centrosymmetric materials is broken at their surface whence they allow local surface SHG. Additionally, centrosymmetric materials give rise to nonlocal (bulk) SHG.

Our numerical method extends the linear generalized source method (GSM), which is an efficient numerical method for solving the problem of linear diffraction in periodic structures of arbitrary geometry. The nonlinear GSM is a three-step algorithm: for a given excitation at the fundamental frequency the linear field is computed using the linear GSM. This field gives rise to a nonlinear source polarization at the second harmonic (SH) frequency. This nonlinear polarization comprises surface and bulk polarizations as additional source terms and is subsequently used to compute the nonlinear near- and far-field optical response at the SH.

We study the convergence characteristics of the nonlinear GSM for 1D and 2D periodic structures and emphasize the numerical intricacies caused by the surface SH polarization term specific to centrosymmetric materials. In order to illustrate the practical significance of our numerical method, we apply it to metallic gratings made of Au and Ag as well as dielectric grating structures made of silicon and investigate the relative contribution of the bulk and surface nonlinearity to the nonlinear optical response at the SH. Particular attention is paid to optical effects that have a competing influence to the nonlinear optical response of the grating structures, namely the resonant local field enhancement and optical losses.

9547-27, Session 7

Surface-enhanced Raman spectroscopy on engineered plasmonic metamaterials for “label free” biosensing *(Invited Paper)*

Massimo Rippa, Rossella Capasso, Marianna Pannico, Pietro La Manna, Pellegrino Musto, Consiglio Nazionale delle Ricerche (Italy); Jun Zhou, Ningbo Univ. (China); Lucia L. Petti, Consiglio Nazionale delle Ricerche (Italy)

The last decade has been characterized by artificial electromagnetic (EM) materials, including photonic crystals (PCs) and photonic quasi-crystals (PQCs), making these very attractive given that there are new possibilities to control the EM field in innovative way. Quasiperiodic crystals (QCs) are a new class of materials that have fascinating optical properties lying somewhere between those of disordered and period structures. With the use of PCs and PQCs, it is possible to synthesize novel artificial structures characterized by selective EM responses, which, in turn, undergo significant frequency shifts, in presence of biological material.

In the present work we studied artificial EM nanomaterials to develop innovative plasmonic nanobiosensors based on Surface Enhanced Raman Scattering (SERS) substrates and working in the visible and NIR frequency bands. Fabricated gold PQCs in a Thue Morse arrangement are proposed for the engineering of reproducible SERS substrates. Scanning electron microscopy, UV/Vis absorption spectroscopy, dark field microscopy and atomic force microscopy (AFM) are used to characterize the experimental structure. Using a molecular monolayer of pMA (p-mercaptoaniline) as a Raman reporter, we show that high values of SERS enhancement factors can be achieved in photonic structures.

9547-28, Session 7

Nonradiative Energy Transfer in Layered Metal-Dielectric Nanostructure Mediated by Surface Plasmon

Sepideh Golmakaniyoon, Nanyang Technological Univ. (Singapore) and LUMINOUS! Ctr. of Excellence for Semiconductor Lighting and Displays (Singapore); Xiaowei Sun, Hilmi V. Demir, Nanyang Technological Univ. (Singapore)

Plasmon resonance energy transfer has received great attention in semiconductor nanoparticles structures. The conventional sandwich configuration consists of donor-metal nanostructure-acceptor has been successfully applied to improve the nonradiative energy transfer efficiency from the excited donor dipole to the acceptor molecule via surface plasmon coupling at the interfaces. Here we demonstrate that the cascaded plasmon coupling gives rise to more efficient energy transfer mechanism compared to single plasmon coupling. The approach has been illustrated through the analytical simulation of an oscillating dipole near the stratified nanostructure of silver-dielectric-silver-acceptor. The overlaps of the surface plasmon modes at the silver-dielectric and dielectric-silver interfaces lead to the stronger cross coupling in comparison with the single silver layer configuration. Moreover, the experimental results are in good agreement with the analytical simulation. The consistency confirms more than 100% plasmon resonance energy transfer enhancement in the donor-silver-dielectric-silver-acceptor configuration compared to the donor-silver-acceptor structure. The current approach uniquely allows

designing the optoelectronic devices with less photoluminous quenching and more efficient energy transfer process due to the reduction in total metal thickness and stronger surface plasmon coupling at the boundaries, respectively.

9547-29, Session 7

Integrated ring grating-nanoantenna structure for plasmon/emitter coupling

Nancy Rahbany, Wei Geng, Rafael Salas-Montiel, Sylvain Blaize, Renaud J. B. Bachelot, Univ. de Technologie Troyes (France); Christophe Couteau, Univ. de Technologie Troyes (France) and Nanyang Technological Univ. (Singapore)

There is a growing interest nowadays in the study of strong light-matter interaction at the nanoscale [1], specifically between surface plasmon polaritons and emitters [2]. Researchers in the fields of plasmonics, nanooptics and nanophotonics are constantly exploring new ways to control and enhance surface plasmon launching, propagation, and localization [3]. Moreover, emitters placed in the vicinity of metallic nanoantennas exhibit fluorescence rate and quantum yield enhancement [4] due to the increase in the electromagnetic confinement in the region [5]. However, numerous applications such as optical electronics, nanofabrication and sensing devices require a very high optical resolution which is usually limited by the diffraction limit. Targeting this problem, we introduce a novel plasmonic structure consisting of metallic nanoantennas integrated in the center of ring diffraction gratings [6, 7]. Propagating surface plasmon polaritons (SPPs) are generated by the ring grating and couple with localized surface plasmons (LSPs) at the nanoantennas, which excites dye molecules placed in the gap. Numerical FDTD simulations as well as experimental optical characterization results are presented. Ring gratings containing nanoprisms, single bowtie nanoantennas and double bowtie nanoantennas were fabricated using Electron Beam Lithography (EBL). Plasmon-emitter coupling was studied upon measuring the photoluminescence spectrum of dye molecules placed in the nanoantenna gap, where a comparison between the different nanoantennas is provided. The combination of the sub-wavelength confinement of LSPs and the high energy of propagating SPPs in our structure leads to precise nanofocusing at the nanoscale, which can be implemented to reach the strong coupling regime between emitters and surface plasmons.

Fluorescence enhancement using Fano-resonant a plasmonic nanostructure with selective functionalization of molecules at the electromagnetic hot spot

Xiaolong Wang, Olivier J. F. Martin, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

In recent years, one has paid significant attention to plasmonic nanostructures due to their potential for practical applications. Especially, in most plasmonic nanostructures, the local density of optical states is strongly enhanced and confined in the nanogap region – like for example in plasmonic antennas – which results in the so-called electromagnetic hot spots. In this work, we use 4-nanorod structures made with silver to generate and tune Fano resonances exhibiting an asymmetric and narrow lineshape. In such a system, a strongly enhanced electromagnetic field is created in the nanogap when the two antenna modes undergo destructive interference, i.e. at the Fano resonance. The local near field is thus strongly enhanced since most of the energy is not radiated into the far field at that wavelength. We will show that using a 4-nanorod structure in silver, we can easily tune the Fano resonance through the fluorescence spectrum of the molecule under study, thus exploring the different resonance conditions between the molecule absorption/emission bands and the plasmonic nanostructure; both the excitation and emission rates of the molecule can be enhanced when it is placed within the hot spot. To this end, we have developed a double electron beam lithography process to fabricate the plasmonic nanostructures and then selectively immobilize the molecule in the hot spot, in order to investigate the fluorescence enhancement under well-controlled conditions. The fluorescence enhancement is demonstrated by measuring the fluorescence lifetime and the fluorescence count rate. The experimental results are supported by theoretical modelling and numerical calculations with the Green’s tensor method.

9547-31, Session 7

Plasmon enhanced linear and nonlinear photoluminescence in planar nanoparticle arrays

Gary F. Walsh, U.S. Army Natick Soldier Research, Development and Engineering Ctr. (United States) and Boston Univ. (United States); Luca Dal Negro, Boston Univ. (United States)

Light emission from metal nanoparticles has potential appications as a highly sensitive refractive index detector. In order for this protential to be realized the mechanics of plasmon enhanced photoluminescence (PL) in planar nanoparticle arrays must be understude. We present an experimental exploreation of emission spectra and realitive efficiency of gold PL in nanoplasmonic arrays. We demonstrate tunability of metal PL by nanoparticle size and discover the critical role of near-field interparticle coupling on emission efficiency. We show that direct excition of plasmon resonances by photoexcited electron-hole pairs is the primary contributer to the metalic nanoparticle emission spectrum. We additionally show that emission is quenched by near-field interactions between nanoparticles leading to spectral broading by increased non-radiative plasmon decay. Finally, we show a correlation between plasmon life-time and PL efficiency. We explore this phenominan for both linear and nonlinear PL. Experimental results are supported by numerical simulations of plasmon life-time.

9547-32, Session 7

Probing and controlling large Purcell enhancement in plasmonic nanoantennas

Maiken H. Mikkelsen, Duke Univ. (United States)

Plasmonic cavities and nanoantennas can strongly modify the excitation and decay rates of nearby emitters by altering the local density of states. Here, we demonstrate large enhancements of fluorescence and spontaneous emission rates of molecules embedded in plasmonic nanoantennas with sub-10-nm gap sizes. The nanoantennas consist of colloidally synthesized silver nanocubes coupled to a metallic film which is separated by a 5-15 nm self-assembled polyelectrolyte spacer layer with embedded molecules. Each nanocube resembles a nanoscale patch antenna whose plasmon resonance can be changed independent of its local field enhancement.

By varying the size of the nanopatch, we tune the plasmon resonance by ~200 nm throughout the excitation, absorption, and emission spectra of the embedded molecules demonstrating giant fluorescence enhancement for antennas resonant with the excitation wavelength [A. Rose, T.B. Hoang, F. McGuire, J.J. Mock, C. Ciraci, D.R. Smith & M.H. Mikkelsen, Nano Letters 14 , 4797 (2014)]. Next, we directly probe and control the nanoscale photonic environment of the embedded emitters including the local field enhancement, dipole orientation and spatial distribution of emitters. This enables the design and experimental demonstration of Purcell factors exceeding 1,000, while maintaining high quantum efficiency and directional emission [G.M. Akselrod, C. Argyropoulos, T.B. Hoang, C. Ciracì, C. Fang, J. Huang, D.R. Smith & M.H. Mikkelsen, Nature Photonics 8, 835 (2014)]. Full-wave simulations incorporating the nanoscale environment accurately predict the experimentally observed emission dynamics and reveal design rules for future devices. Finally, progress on coupling colloidal quantum dots to the plasmonic nanopatch antennas will be discussed.

9547-33, Session 8

Second harmonic excitation spectroscopy in studies of Fano-type coupling in plasmonic arrays

Gary F. Walsh, U.S. Army Natick Soldier Research, Development and Engineering Ctr. (United States) and Boston Univ. (United States); Jacob T. Trevino, The City Univ. of New York Advanced Science Research Ctr. (United States) and Boston Univ. (United States); Emanuele Francesco Pecora, Stanford Univ. (United States) and Boston Univ. (United States); Luca Dal Negro, Boston Univ. (United States)

Scattering by plasmon resonances of metallic nanoparticles can be tailored by particle material, size, shape, and local as well as long-range order. In this presentation we discuss a series of experiments in which long-range Fano-type coupling between grating resonances and localized surface palsmon (LSP) resonances were studied using second harmonic excitation (SH-E) spectroscopy. By tuning the excitation wavelength of a femtosecond laser and measuring the relative second harmonic (SH) signal we demonstrated that when long-range grating resonances spectrally overlap with those of the LSPs, electromagnetic field enhancement occurs on the surface of the nanoparticles leading to an increase in nonlinear scattering. This effect has been demonstrated for periodic arrays of monomers and dimers, bi-periodic antenna arrays for multi-spectral focusing to a single point, and chirped nanoparticle structures for broadband field enhancement. Results are supported by finite difference time domain simulations showing that electromagnetic fields are enhanced close on the surface of the nanoparticles when long-range structural resonances are excited. These studies have revealed design principles for engineering the interplay of photonic and plasmonic coupling for future linear and nonlinear plasmonic devices.

9547-34, Session 8

Predicting nonlinear properties of metamaterials from the linear response

Kevin O'Brien, Haim Suchowski, Junsuk Rho, Alessandro Salandrino, Boubacar Kante, Xiaobo Yin, Xiang Zhang, Univ. of California, Berkeley (United States)

Nanostructures and metamaterials have attracted interest in the nonlinear optics community due to the possibility of engineering their nonlinear responses. Much debate surrounds whether the nonlinear susceptibility can be represented by an anharmonic oscillator model (Miller's rule) which implies a direct relation between the nonlinearity and a product of its linear susceptibilities. In this work we show experimentally that Miller's rule does not apply in general and that nonlinear scattering theory accurately predicts the optimal geometry for nonlinear emission.

We study the geometry dependence of the second harmonic and third harmonic emission from gold nanostructures by designing arrays of nanostructures whose geometry varies from bars to split ring resonators. We change the length (and volume) of the nanostructure on one axis, and change the morphology on the other axis. We observed that the maximum second harmonic generation does not occur at the morphology indicated by a nonlinear oscillator model with parameters derived from the far field transmission; however, we find a near field overlap integral accurately predicts the optimal geometry. We show that the optimum geometry for nonlinear generation can be predicted from an overlap integral between the local nonlinear susceptibility and the mode of the nanostructure at the emission wavelength. This conclusion is independent of the specific structure studied and may be applied in order to predict the nonlinear generation from any plasmonic nanostructure or metamaterial.

9547-35, Session 8

Multi-coupled resonant splitting with a nano-slot metasurface and PMMA phonons

Michael F. Finch, Brian A. Lail, Florida Institute of Technology (United States)

Coupled-resonances can be used in applications that include, but are not limited to, surface-enhanced infrared spectroscopy (SEIRS), surface-enhanced Raman spectroscopy (SERS), biosensing, and index sensing. Fano resonance in analogue plasmonic systems has been described as the coupling of a bright (superradiant) mode and a dark (subradiant) mode via the near field. Dark and bright mode interactions are investigated with the use of a Fano resonant metamaterial (FRMM) where the metamaterial is a dual nano-slot metasurface on a silicon cavity. The FRMM is numerically simulated using Ansys high frequency structural simulator (HFSS). The FRMM is coupled to the carbon double bond in polymethyl methacrylate (PMMA) to demonstrate mode splitting and signal enhancement. Then the dual nano-slot is compared to the complementary dual nano-rod configuration.

9547-36, Session 8

Local field enhanced second-harmonic response of organic nanofibers

Oksana Kostiu?enko, Till Leißner, Jacek Fiutowski, Jonathan R. Brewer, Horst-Günter Rubahn, Univ. of Southern Denmark (Denmark)

Organic CNHP4 nanofibers showing a strong second-harmonic (SH) response have been successfully implemented as active components in a metal-organic hybrid system. Using nondestructive roll-on transfer technique nanofibers were transferred from the growing mica substrates onto electron-beam lithography-defined regular arrays of gold, titanium and silicon oxide. As shown in a femtosecond laser scanning microscopy study the fiber-substrate interplay leads (only) on gold to a significantly enhanced SH signal. We suggest that this effect is driven by the local field enhancement i.e. the excitation of surface plasmon polaritons (SPP) and lightning rod effects, since in case of Ti and SiO2 no SPPs are excited at a laser wavelength of 790 nm and the used array dimensions. Furthermore, we observe a considerably reduced fluorescence lifetime for the fibers deposited on gold arrays supporting the assumption of strong interaction between gold substrate and fibers. In summary we show that by adjusting substrate and fiber properties the SH response can be locally controlled.

9547-37, Session 8

Plasmonic coupling of gold curvilinear nanorods with nanogap

Yukie Yokota, Takuo Tanaka, RIKEN (Japan)

The local-mode surface plasmon resonances of a closely-spaced dimer of two identical metal nanostructures, such as straight nanorods, nanoparticles, strongly interact due to dipole-dipole coupling. These strong interactions have been exploited in various applications, such as surface-enhanced Raman scattering, biosensing, and near-field optical spectroscopy. Nevertheless, there are few reports about the spectral properties of LSP on a pair of two intricately-shaped nanostructures. We fabricated gold curvilinear nanorods dimers with various gap widths and structural configurations using electron beam lithography and lift-off technique. In this work we present detailed studies of plasmonic coupling of gold curvilinear nanorod dimer with controlling gap distance. When the linearly polarized light that oscillates parallel to the long axis of curvilinear nanorod is irradiated on the sample structures, transmission spectrum of gold curvilinear nanorod monomers has one resonant peak in near-infrared region and the peak position is the same as that of the structures of the arc length of curvilinear nanorod. Compared to transmission spectrum of curvilinear nanorod monomers, the plasmon resonance peak of curvilinear nanorod dimers that has 10nm nanogap with outside center of curved portion in the y-axis symmetry was blue shift.

9547-38, Session 9

Graphene plasmonics: multiple sharp Fano resonances in silver split concentric nanoring resonator dimers on a metasurface

Arash Ahmadivand, Nezih Pala, Florida International Univ. (United States)

Graphene plasmonics has been introduced as an alternative strategy in designing and fabricating plasmonic structures and devices in nanoscale regime. Tighter confinement and significant decay length are the major features which persuaded researchers to employ graphene plasmonics instead of regular noble metals in various applications. Herein, we propose to use graphene plasmons as a platform for inducing strong dark modes in silver split concentric nanoring resonator dimers on a multilayer metasurface composed of graphene sheet and silicon substrate. Using numerical methods, we examined the possibility of appearing pronounced double Fano resonant modes as strong hot spots and also, the influence of carbon atoms sheet in intensifying the intensity of Fano dips is reported. Employing the geometrical versatility of concentric rings in designing a colloidal dimer structure, we enhanced the tunability and performance of the appeared Fano resonant mode in the visible to the near infrared region. It is shown that a thin layer of graphene with a few nanometers thickness under the dimer structure helps to localized huge amount of optical energy to produce hot spots. Our theoretical results paves a method toward inducing pronounced Fano resonances via tremendous electromagnetic field confinement and ultrastrong near-field coupling. This understating opens new avenues to utilize simple dimers in designing metamaterial structures to use in fabricating biochemical and DNA sensors, and photodetectors.

9547-39, Session 9

Graphene spports the manipulating mode propagation in the hybird plasmonic nanowaveguides

Xiaosai Wang, Jiangnan Univ. (China); Jicheng Wang, Jiangnan Univ. (China) and Purdue Univ. (United States); Ci Song, Sinian Qu, Lin Sun, Jiangnan Univ. (China)

We propose a new type of plasmonic waveguide in a graphene-coated V-groove. A graphene layer treated as an ultra-thin “metal” layer could support transverse magnetic (TM) polarized surface plasmon polaritons (SPPs) when the imaginary of the graphene’s conductivity is larger than zero. The graphene permittivity can be controlled by varying the chemical potential in the terahertz frequencies. The subwavelength confinements and the propagation of the SPPs modes of the graphene waveguide structure are reached. The mode field energies can be well confined in the V-groove and be adjusted by changing the depth of the groove, the opening angle of the channel and the chemical potential of graphene. The mode confinements become weaker as increasing the depth of the groove, the angle of V-groove and the chemical potential of grapheme, respectively. The field energies of SPPs could be mainly focused at the bottom of graphene-coated V-groove if the groove is deep enough. In addition, the mode distributions of the graphene-coated nanowire are also discussed. By changing the nanowire radius and the chemical potential of graphene, we can reach different characteristic of SPP modes. And the m=5 mode can be achieved when the radius R=100nm at 30THz. The relationship between effective index and propagation length with the radius are discussed, respectively. Based on those two structures, we propose a hybrid plasmonic waveguide with a graphene-coated nanowire placing in a graphene-coated V-groove. The mode field energies are strongly confined between the graphene-coated nanowire and the V-groove.

9547-40, Session 9

Observation of Fano resonances in highly doped semiconductors plasmonic resonators

Thierry Taliercio, Vilianne Ntsame Guilengui, Univ. Montpellier 2 (France); Jean-Baptiste Rodriguez, Univ. of Montpellier (France); Laurent Cerutti, Eric Tournié, Univ. Montpellier 2 (France)

All-semiconductor plasmonics gives the opportunity to build new plasmonic structures with embedded resonators of highly doped semiconductor (HDSC) in a matrix of un-doped semiconductor for mid-IR applications. In this work, we report on the excitation of Fano resonances in the mid-infrared range using plasmonic resonators based on HDSC. Using adequate semiconductors, InAsSb and GaSb grown by molecular beam epitaxy (MBE), we have designed the right structure to obtain the expected optical properties. The samples are lattice matched to the GaSb substrate which offers the possibility to integrate the plasmonic resonators at the heart of photonic devices. The embedded nanostructures have been studied by high-resolution transmission electron-microscopy (HR-TEM) to accurately retrieve the geometrical parameters of the resonator. These actual geometrical parameters have then been used to model the optical properties of the HDSC resonators by the FDTD technique and a model based on Fano resonances. Excellent agreement has been achieved between simulation and experiments. We show that it is possible to control the optical properties of the plasmonic resonators by adjusting their geometrical parameters or the doping level of the HDSC. This work demonstrates the possibility to develop all-semiconductor plasmonics for photonic applications in the mid-IR range.

9547-41, Session 9

Alloyed thin-films and nanostructures with dielectric function on demand

Chen Gong, Allen Chang, Ellen Cesewski , Marina S. Leite, Univ. of Maryland, College Park (United States)

If one could arbitrarily modulate the dielectric function of metals, this would permit an exceptional control of the plasmon resonances in nanostructures and thin-films, leading to the development of a new class of materials with tunable optical responses for the fabrication of optoelectronic devices with unique characteristics. Here we present plasmonic thin-films and nanoparticles based on alloyed metals, formed by the combination of Ag, Al, Au and Cu. We modulate the dielectric function of the alloys by modifying its chemical composition. We measure the surface plasmon propagation for the different alloys, and control the angle of propagation as a function of the thin-film composition. Further, we fabricate nanoparticles also with tunable chemical composition and optical response. We spatially and spectrally resolve the scattering and transmission characteristics by NSOM measurements of the alloyed nanostrustures. Mie calculations are used to corroborate our results, showing that the scattering efficiency of the alloys

nanostructures strongly depend on its composition. These new materials can be used for the design of metamaterials with dielectric function on demand.

9547-42, Session 10

Plasmonics for the industry *(Invited Paper)*

Benjamin Gallinet, Ctr. Suisse d'Electronique et de Microtechnique SA (Switzerland)

Metallic nanostructures interact strongly with light through surface plasmon modes and many application fields have been proposed during the past decade, including light harvesting to sensing and structural colors. However, their implementation for the industry requires the development of up scalable and cost effective manufacturing processes. The fabrication at wafer scale of plasmonic nanostructures and metamaterials using nano imprint lithography is reported. After structuring, one or several evaporations of various plasmonic materials are performed with a tilt angle with respect to the substrate, which increases the light interactions with the different metallic layers as well as enlarges the design possibilities. A step and repeat process is used to increase further the area of nanostructured surface. The measured optical properties of the fabricated structures show a very good agreement compared to numerical calculations using the rigorous coupled wave analysis and the surface integral method. These numerical calculations together which structural characterization, increase the process control and enable the design of the nanostructures for specific applications. In particular, nanostructures with a shape similar to split ring resonators and which support high order plasmonic modes showing Fano resonances are shown to be promising for sensing applications. Another kind of plasmonic substrates is reported, which shows unique color effects with a large palette of colorations. With a specific design, the structural colors are associated with a strong interaction between the polarizations which increases the complexity of the color effect rendered to the user. Finally, the potential of plasmonic nanostructures for the management of solar light is discussed.

9547-43, Session 10

Optical dark field and electron energy loss imaging and spectroscopy of symmetry-forbidden modes in loaded nanogap antennas

Todd Brintlinger, U.S. Naval Research Lab. (United States); Andrew Herzing, National Institute of Standards and Technology (United States); James P. Long, Igor Vurgaftman, Rhonda Stroud, Blake S. Simpkins, U.S. Naval Research Lab. (United States)

Theoretical work has identified a new type of hybrid nanoresonator akin to a loaded-gap antenna, wherein the gap between two collinearly aligned metal nanorods is filled with active dielectric material. The gap optical load has a profound impact on resonances supported by such a "nanogap" antenna, and thus provides opportunity for (i) active modulation of the antenna resonance and (ii) delivery of substantial energy to the gap material. To this end, we have (i) used a bottom-up technique to fabricate nanogap antennas (Au/CdS/Au); (ii) characterized the optical modes of individual antennas with polarization- and wavevector-controlled dark-field microscopy; (iii) mapped the spatial profiles of the dominant modes with electron energy loss spectroscopy and imaging; and (iv) utilized full-wave finite-difference time-domain simulations to reveal the nanoscopic origin of the radiating modes supported on such nanogap antennas.

In addition to conventional transverse and longitudinal resonances, these loaded nanogap antennas support a unique symmetry-forbidden gap-localized transverse mode arising from the splitting of degenerate transverse modes located on the two gap faces. This previously unobserved mode is strong (E2 enhanced ~20), tightly localized in the nanoscopic (~30 nm separation) gap region, and is shown to red-shift with decreased gap size and increased gap dielectric constant. In fact, the mode is highly suppressed in air-gapped structures which may explain its absence from the literature to date. Understanding the complex modal structure supported on hybrid nanosystems is necessary to enable the multi-functional components many seek.

9547-44, Session 10

Epitaxial silver as a plsamonic materials platform: from plasmonic nanolasers to long range plasmonic wave propagations *(Invited Paper)*

Chih-Kang Shih, The Univ. of Texas at Austin (United States)

Plasmonics is an emerging field which harnesses surface plasmon polaritons (SPPs)—hybrid modes of photons and surface plasmons—to achieve confinement of electromagnetic fields at a deeply subwavelength scale. It has the potential of providing a true alternative to electronic circuits and operations, with orders of magnitude gains in terms of speed, frequency of operation and available bandwidths. Despite impressive conceptual demonstrations, the field of plasmonics faces a severe material limitation: SPPs are highly damped in current plasmonics materials and cannot travel beyond a few wavelengths if confined to sub-wavelength scales. Thus far, most plasmonics applications utilize thermally deposited noble metal (e.g. Ag and Au) films which are granular and are therefore subjected to high scattering loss. We show that this adverse effect can be eliminated by developing epitaxial silver films on semiconductor (EpSoS) a plasmonic platform. By using the EpSoS platform, we demonstrate two key applications: CW operation of plasmonic nanolaser with ultra-low thresholds and extra-ordinary long propagation length for SPP in the visible wavelength range. These demonstrations lay foundation for potential integration of nanophotonics.

*The research work on plasmonic nanolaser was carried out in collaboration with Professor S. Gwo of National Tsing-Hua University. The work on long range plasmonic wave propagations was carried in collaboration with Professor X.Q. Li of the University of Texas at Austin.

9547-45, Session 10

Femtosecond control of magneto-optical effects in magnetoplasmonic crystals *(Invited Paper)*

Andrey A Fedyanin, Maksim R Shcherbakov, Polina P Vabishchevich, Lomonosov Moscow State Univ (Russian Federation); Aleksandr Yu. Frolov, Lomonosov Moscow State Univ. (Russian Federation); Artem V Chetvertukhin, Tatiana V Dolgova, Lomonosov Moscow State Univ (Russian Federation)

In magnetoplasmonics, it is possible to tailor the magneto-optical properties of nanostructures by exciting surface plasmon-polaritons. Thus far, magnetoplasmonic effects have been considered to be static. Here, manifestations of a time-dependent transversal magneto-optical Kerr effect were experimentally demonstrated in femtosecond laser pulses reflected from a one-dimensional iron-based magnetoplasmonic crystal. The effect is attributed to exciting surface plasmons with magnetization-dependent dispersion. Measurements of temporal dependence of transversal magneto-optical Kerr effect were performed for a one-dimensional magnetoplasmonic crystal based on a commercially available digital versatile disk polycarbonate template that had periodic corrugations with a depth of approximately 50 nm and a period of 750 nm. The dielectric template was covered by a 100-nm layer of polycrystalline iron deposited by magnetron sputtering and protected by a 20-nm-thick silica layer from the top. The Kerr effect evolution was demonstrated to have either a positive or negative time derivative, depending on the position of the incident pulse's carrier wavelength with respect to the plasmonic resonance. Proper

justification was given for this effect using the Lorentzian spectral line shape approach. Iron-based plasmonic crystal studied is a promising tool for manipulating femtosecond laser pulses with an external magnetic field that may have applications in active, plasmon-based telecom devices.

9547-46, Session 10

A plasmonic walker *(Invited Paper)*

Na Liu, Max-Planck Institut für Intelligente Systeme (Germany)

Construction of 3D reconfigurable plasmonic nanostructures witnesses major technological limitations, arising from the required subwavelength dimensions and controlled 3D motion. There have been considerable efforts on integration of plasmonic nanostructures with active platforms using top-down techniques. Here we lay out and implement a multi-disciplinary strategy to create active 3D plasmonic nanostructures by merging plasmonics and DNA nanotechnology on the nanoscale.

We demonstrate the first plasmonic walker, which can carry out directional, progressive, and reverse nanoscale walking on a DNA origami track. The plasmonic walker comprises an anisotropic gold nanorod as its 'body' and discrete DNA strands as its 'feet'. Specifically, our plasmonic walker carries optical information and can in situ optically report its own walking directions and consecutive steps at nanometer accuracy, through dynamic coupling to a plasmonic stator immobilized along its walking track. The dynamic process can be read out using circular dichroism spectroscopy at visible frequencies in real time.

Our concept may enable a variety of smart nanophotonic platforms for studying dynamic light-matter interaction, which requires controlled motion at the nanoscale well below the optical diffraction limit.

9547-47, Session 10

From light modulation to far-field excitation of graphene plasmons: science and applications of graphene-integrated metasurfaces *(Invited Paper)*

Gennady B. Shvets, The Univ. of Texas at Austin (United States)

Graphene has emerged as a promising optoelectronic material because its optical properties can be rapidly and dramatically changed using electric gating. Graphene's weak optical response, especially in the infrared part of the spectrum, remains the key challenge to developing practical graphene-based optical devices such as modulators, infrared detectors, and tunable reflect-arrays. We demonstrate experimentally and theoretically demonstrated that a plasmonic metasurface with two Fano resonances can dramatically enhance the interaction of infrared light with single layer graphene.

An order of magnitude modulation of the reflected light was accomplished by designing a novel type of a metasurface supporting double Fano resonances and integrating it with an under-layer of graphene. The unique aspect of such modulator is its high baseline reflectivity and large reflectivity extinction coefficient (modulation depth). Using laser interferometry, we demonstrate that the phase of the reflected infrared light can also be modulated by back-gating graphene. This work paves the way to future development of ultrafast opto-electronic devices such as dynamically reconfigurable holograms, single-detector imagers, dynamical beam-steering devices, and reconfigurable biosensors. Moreover, we will show that strong non-local response of graphene can be induced by exciting graphene plasmons which are confined inside the narrow gaps in the plasmonic metasurface. Such graphene plasmons excitation dramatically boosts the intensity of the infrared light confined by the metasurface.

Surface plasmon resonance gas sensing by electrons injection

Enrico Gazzola, Michela Cittadini, Laura Brigo, Giovanna Brusatin, Massimo Guglielmi, Filippo Romanato, Alessandro Martucci, Univ. degli Studi di Padova (Italy)

Surface Plasmon Resonance (SPR) sensing is based on the principle that the conditions for the resonant excitation of a plasmonic mode by an incident light beam are highly sensitive to variations of the refractive index (RI) of the environment. We report a case in which this variation can be attributed to electrons injection by the analyte into the structure.

We fabricated two kinds of high-performance plasmonic structures for hydrogen sensing, based on nanoporous TiO2 anatase sensitive layers. In the first, a TiO2 film was deposited above a metallic plasmonic grating, which can support propagating surface plasmon polaritons. The second consisted of TiO2 film with embedded gold nanoparticles, supporting localized surface plasmon modes, deposited on a flat surface.

In both cases, reversible shifts of the resonance wavelength are observed when the sensors are exposed to 5% H2 in N2 carrier at 300°C, with respect to N2 alone at the same temperature. The shifts range from 2 to 7 nm and their direction is consistent with a decrease of the RI of the environment.

Since the presence of the analyte modifies in a negligible way the RI of the atmosphere, the observed shifts cannot be explained only by the RI change induced by the gas filling the pores in the sensitive layers.

For this reason we propose a different interaction mechanism. At 300°C, H2 can dissociate by reacting with oxygen into the TiO2 matrix and donate electrons; the high temperature also promotes the formation of intragap states in the TiO2 band structure that allows the injected electrons to reach the conduction band. According to the Drude-Lorentz model, the injection of electrons decreases the RI, causing the shift of the plasmonic resonance.

This interpretation is consistent with the observed effects in both kinds of structure.

9547-48, Session 11

Comparison between plasmonic and dielectric nanoantennas for surface-enhanced spectroscopies *(Invited Paper)*

Stefan A. Maier, Imperial College London (United Kingdom)

We evaluate the performance of dielectric nanoantennas composed out of silicon disks separated by a nanoscale gap for surface-enhanced spectroscopies. Contrary to plasmonic nanonantennas, the new system does not exhibit quenching of fluorescence, and can also sustain electromagnetic hot spots comparable in size to those of their plasmonic counterparts. Dielectric and metallic systems will be experimentally compared in terms of performance in surface-enhanced fluorescence and Raman, as well as in terms of local heat generation upon external illumination. Conclusions for applications in optical biosensing will be drawn.

9547-50, Session 11

Wafer-scale plasmonic and photonic crystal sensors

Matthew C. George, MOXTEK, Inc. (United States); Jui-Nung Liu, Univ. of Illinois at Urbana-Champaign (United States); Arash Farhang, Brent Williamson, Mike Black, Ted Wangensteen, James Fraser, Rumyana Petrova, MOXTEK, Inc. (United States); Brian T. Cunningham, Univ. of Illinois at Urbana-Champaign (United States)

200 mm diameter wafer-scale fabrication, metrology, and optical modeling results will be reviewed for surface plasmon resonance (SPR) sensors based on 2D metallic nano-dome and nano-hole arrays (NHA) as well as 1D photonic crystal sensors based on leaky-waveguide mode resonance, with potential applications in label free sensing, surface enhanced Raman spectroscopy (SERS), and surface-enhanced fluorescence spectroscopy (SEFS). Potential markets include micro-arrays for medical diagnostics, forensic testing, environmental monitoring, and food safety.

1-D and 2-D nanostructures were fabricated on glass, fused silica, and silicon wafers using optical lithography and semiconductor processing techniques. Wafer-scale optical metrology results are compared to FDTD modeling and presented along with application-based performance results, including label-free plasmonic and photonic crystal sensing of both surface binding kinetics and bulk refractive index changes. In addition, SERS and SEFS results from a line scan microscope will be presented for several 1D photonic crystal and 2D metallic array structures. Normal incidence extraordinary optical transmission (EOT) results for a 550 nm pitch NHA showed good bulk refractive index sensitivity, however an intensity-based design with 665 nm pitch was chosen for use as a compact, label-free sensor at both 650 and 632.8 nm wavelengths. The optimized NHA sensor gives an SPR shift of about 480 nm per refractive index unit when detecting a series of 0-40% glucose solutions, but shows about 10 times greater surface sensitivity when operating at 532 nm. Narrow-band photonic crystal resonance sensors showed quality factors over 200, with reasonable wafer-uniformity in terms of both resonance position and peak height.

9547-52, Session 11

Hot electron pump: a plasmonic rectifying antenna

Ahmet A. Yanik, Golam I. Hossain, Univ. of California, Santa Cruz (United States)

Plasmonic nanostructures have been widely explored to improve absorption efficiency of conventional solar cells, either by employing them as a light scatterer, or as a source of local field enhancement. Unavoidable ohmic loss associated with the plasmonic metal nanostructures in visible spectrum, limits the efficiency improvement of photovoltaic devices by employing this local photon density of states (LDOS) engineering approach. Instead of using plasmonic structures as efficiency improving layer, recently, there has been a growing interest in exploring plasmoinc nanoparticle as the active medium for photovoltaic device. By extracting hot electrons that are created in metallic nanoparticles in a non-radiative Landau decay of surface plasmons, many novel plasmonic photovoltaic devices have been proposed. Moreover, these hot electrons in metal nanoparticles promises high efficiency with a spectral response that is not limited by the band gap of the semiconductors (active material of conventional solar cell). In this work, we will show a novel photovoltaic configuration of plasmonic nanoparticle that acts as an antenna by capturing free space ultrahigh frequency electromagnetic wave and rectify them through an ultrafast hot electron pump and eventually inject DC current in the contact of the device. We will introduce a bottom-up quantum mechanical approach model to explain fundamental physical processes involved in this hot electron pump rectifying antenna and it's ultrafast dynamics. Our model is based on non-equilibrium Green's function formalism, a robust theoretical framework to investigate transport and design nanoscale electronic devices. We will demonstrate some fundamental limitations that go the very foundations of quantum mechanics.

9547-53, Session 11

Tunable optical extinction of nano-antennas for solar energy conversion from near-infrared to visible

Raymond A Wambold, The Pennsylvania State University (United States); James M Chen, Kansas State University (United States); Paul H Cutler, Nicholas M Miskovsky, Scitech Associates, LLC (United States); Jie Qi, The University of Connecticut (United States); Gary J Weisel, The Pennsylvania State University, Altoona (United States); Brian G Willis, The University of Connecticut (United States); Darin T. Zimmerman, Penn State Altoona (United States)

We demonstrate tunable optical extinction of nano-antennas, designed to collect and rectify solar radiation from near-infrared to visible. By employing a confocal, transmission arrangement with a broadband light source and detection from 400 - 1700 nm, we determine the spectrum of the (absorbed + scattered) light from a beam incident on thin-film metallic nano-antennas. The two-terminal rectifying antennas (rectennas) employ geometric asymmetry intended to produce a self-biased junction and a photo-assisted DC tunneling current. To fabricate the antenna arrays with junction gaps in the tunneling regime, we use standard electron-beam lithography of palladium, followed by selective atomic-layer deposition (ALD) of copper. We examine the variation in extinction spectra with device morphology and show that the resonance peak is progressively red-shifted with increasing cycles of ALD. Using actual device dimensions as determined from Scanning Electron Microscopy, we also demonstrate that our experimental results are in good agreement with three-dimensional Finite Difference-Time Domain simulation results.

9547-54, Session 12

3D chiral nanoplasmonics: fabrication, chiroptic engineering, mechanism, and application in enantioselection

Zhifeng Huang, Hong Kong Baptist Univ. (Hong Kong, China)

Chirality does naturally exist, and the building blocks of life (e.g. DNA, proteins, peptides and sugars) are usually chiral. Chirality inherently imposes chemical/biological selectivity on functional molecules; hence the discrimination in molecular chirality from an enantiomer to the other mirror image (i.e. enantioselection) has fundamental and application significance. Enantiomers interact with left and right handed circularly polarized light in a different manner with respect to optical extinction; hence, electronic circular dichroism (ECD) has been widely used for enantioselection. However, enantiomers usually have remarkably low ECD intensity, mainly owing to the small electric transition dipole moment induced by molecular sizes compared to the ECD-active wavelength in the UV-visible-near IR region. To enhance ECD magnitude, recently it has being developed 3D chiral nanoplasmonic structures having a helical path, and the dimensions are comparable to the ECD wavelength. However, it is still ambiguous the origin of 3D chiroplasmonics, and there is a lack of studying the interaction of 3D chiroplasmoncs with enantiomers for the application of enantioselection.

Herein, we will present a one-step fabrication of 3D silver nanospirals (AgNSs) via low-substrate-temperature glancing angle deposition. AgNSs can be deposited on a wide range of substrates (including transparent and flexible substrates), in an area on the order of cm2. A set of spiral dimensions (such as spiral pitches, number of turns and handedness) have been easily engineered to tune the chiroptic properties, leading to studying the chiroplasmonic principles together with finite element simulation and the LC model. At the end, it will be demonstrated that 3D chiroplasmonics can differentiate molecular chirality of enantiomers with dramatic enhancement in the anisotropy g factor. This study opens a door to sensitively discriminate enantiomer chirality.

9547-55, Session 12

Modeling and engineering of three-dimensional chiroplasmonic silver nano structures

Junhong Deng, Fan Bai, Jack Ng, Zhifeng Huang, Hong

Kong Baptist Univ. (Hong Kong, China)

Fabrication of 3D chiral nanoplasmonic structures is always challenging, while the principles for their chiroptical properties are still ambiguous.

We will present a combined experimental and theoretical study on 3D chiroplasmonic activity of silver nanospirals (AgNSs), fabricated on sapphire by low temperature glancing angle deposition. AgNSs exhibit bisignated CD spectra in the UV-visible range, in the form of not only individual AgNSs or an array. Compared to individual AgNSs, the array of AgNSs show CD with an intensity 3 order of magnitude higher. It is demonstrated the engineering of chiroplasmonic CD via adjusting spiral parameters, including spiral pitches, number of turns and handedness.

Finite element simulations were performed and are in good agreement with the experiments. A LC theory is also employed to explain the difference of chiroplasmonic CD in the UV and visible region.

9547-56, Session 12

Twisted nanosphere lithography: use colloidal Moiré patterns as masks

Kai Chen, National Institute for Materials Science (Japan); Bharath B. Rajeeva, Michael Rukavina, The Univ. of Texas at Austin (United States); Thang Duy Dao, Satoshi Ishii, Masakazu Aono, Tadaaki Nagao, National Institute for Materials Science (Japan); Yuebing Zheng, The Univ. of Texas at Austin (United States)

Nanosphere lithography (NSL) uses self-assembled layers of monodisperse micro-/nano-spheres as masks to fabricate plasmonic metal nanoparticles. Different variants of NSL have been proposed with the combination with dry etching and/or angled-deposition. These techniques have employed to fabricate a wide variety of plasmonic nanoparticles or nanostructures. Here we report another promising extension - twisted nanosphere lithography (T-NSL), which incorporates in-plane twisting between neighboring monolayers, to extend the patterning capability of conventional NSL. In conventional NSL, the masks, either a monolayer or bilayer, are formed by spontaneous self-assembly. Therefore, the resulted colloidal crystal configurations are limited. In this work we used sequential stacking of polystyrene nanosphere monolayers to form a bilayer crystal at the air/water interfaces. During this layer-by-layer stacking process, a crystal domain in the top layer gains the freedom to positon itself in a relative angle to that in the bottom layer allowing for the formation of Moiré patterns. Subsequent O2 plasma etching results in a variety of complex nanostructures that have not been reported before. Using etched Moiré patterns as masks, we further fabricated the corresponding gold nanostructures and characterized their scattering optical properties. We believe this facile technique provides a new strategy to fabricate novel and complex plasmonic nanostructures or metasurfaces.

9547-57, Session 12

Angled nanospherical-lens lithography as a high-throughput method to fabricate various nanodisk cluster arrays

Yi-Hsin Chien, Chang-Han Wang, Chi-Ching Liu, Yun-Chorng Chang, Academia Sinica (Taiwan)

Nanospherical-Lens Lithography (NLL) is a low-cost nano-fabrication technique that has the ability to fabricate nanodisk arrays that cover a very large area. Polystyrene nanospheres are functioning as nanoscale focusing lenses to focus the incoming ultraviolet light and exposure the underlying photoresist (PR) layer. PR hole arrays form after developing. Metal nanodisk arrays can be fabricated following metal evaporation and lifting-off processes. Nanodisk or nano-ellipse arrays with various sizes and aspect ratios are routinely fabricated in our research group.

In this study, we have expended the capabilities of NLL by performing the UV exposures with a designated tilted angle. The exposure will result in a PR hole at an off-center location. The distance between the PR hole and the center depends on the exposure angle. With this angled-exposure technique, we can successfully fabricate nanodisk oligomers by performing multiple angled-exposures. We can also control the size of each nanodisk by preciously controlling the exposure angle and duration. Array of self-similar nanodisk chain can also be obtained. Both nanodisk oligomers and self-similar chain have been demonstrated to exhibit huge field enhancement, which is especially important for sensitive Raman platforms. Technique proposed in this study will help to find suitable industrial applications since it is both high-throughput and low-cost. We also believe the proposed method is versatile enough to fabricate more complex nanodisk systems that will demonstrate novel function in the near future.

9547-58, Session 12

From nanoparticles to nanostructures for plasmonic-related applications *(Invited Paper)*

Bin Ren, Bowen Liu, Xu Yao, Shu Chen, Liang Zhang, Lei Wang, Zhilin Yang, Xiamen Univ. (China)

Compared with some precise nanofabrication methods, such as EBL and FIB, holographic lithography (HL) is a convenient way to fabricate periodic structures in a large area and with superb uniformity. In this work, we developed the deep UV HL with 266 nm laser to obtain structure with a periodicity between 100 nm to 1?m, which cannot be achieved by traditional photolithography. We further developed a strategy to fabricate hybrid periodical dimmer arrays by deep UV HL and lift-off process, followed by selectively surface functionalization. Thermal treatment was employed to as an effective approach to tune the gap size, which provides an additionally adjustable factor. By coating the substrate with gold and the obtained nanostructures with gold or silver, we have obtained periodic plasmonic structure with excellent figure of merit based on refractive index change and strong and uniform SER activity. Such a hybrid periodical dimmer arrays can be used as an effective plasmonics structure, and have potential application as a platform for high-efficiency surface- and bio- analysis.

9547-59, Session 13

Perfect light trapping in mid-IR using patterned ZnO structures *(Invited Paper)*

Shivashankar R. Vangala, Nima Nader, Justin W. Cleary, Air Force Research Lab. (United States); Junpeng Guo, The Univ. of Alabama in Huntsville (United States); Kevin D. Leedy, Joshua R. Hendrickson, Air Force Research Lab. (United States)

Plasmonic assisted mid-IR light trapping using 1D grating structures patterned in Ga-ZnO is demonstrated. FDTD simulations of these structures with proper grating period and depth show the light trapping into a resonant mode resulting in a close to 100% reflection dip in the 4-8 μm wavelength regime. The 1D grating structures of different periods are fabricated using standard photolithography followed by etching. The resonant reflection dips in the experimentally measured spectra well agree with the FDTD simulation, exhibiting light trapping in the mid-IR as predicted.

9547-60, Session 13

Terahertz metal grid polarizer with bridges on quartz substrate

John S. Cetnar, Air Force Research Lab. (United States); Junpeng Guo, The Univ. of Alabama in Huntsville (United States); Elliott R. Brown, Wright State Univ. (United States)

The metal wire-grid polarizer is a venerable device that is used on radiation throughout the electromagnetic spectrum. It usually consists of a 1D-periodic array of subwavelength metallic wires in free space or mounted on a low-loss dielectric substrate, the plane of the grid being oriented perpendicular to the propagation direction. Herein is presented a new structure, a subwavelength wire-grid polarizer for the terahertz region that acts not only as a wideband polarizer but also as a transparent electrode. This function is achieved by the addition of periodically placed metallic bridges that connect the parallel metal wires of the polarizer. The bridges allow for the uniform distribution of an electrostatic potential over all wires while maintaining the polarizing functionality of the metal wire grid polarizer.

Full-wave electromagnetic simulations were performed on the device. The transmittance was computed in both perpendicular polarization and parallel polarization from 100 to 4000 GHz, and the extinction ratio was calculated across the same range. Furthermore, fill-factor studies were performed to understand how device performance is affected by varying slot width and bridge length, as well as bridge offset. The simulation results showed extraordinary optical transmission through the device for perpendicular polarization, creating excellent transmittance and extinction ratios over the frequency range. The perpendicular polarization transmittance and extinction ratio at 1 THz was calculated to be -1 dB and -36 dB respectively. Meanwhile, the bridges allow the device to behave like a DC electrode.

9547-61, Session 13

Optical force acting on metallic nanostructure *(Invited Paper)*

Che Ting Chan, Shubo Wang, Kun Ding, Hong Kong Univ. of Science and Technology (Hong Kong, China); Xulin Zhang, Jilin Univ. (China)

Light can exert radiation pressure on any object it encounters and the resulting optical force can be used to manipulate particles. Conventional studies of optical force in typical systems are mainly concerned with the scattering force and gradient force. We show that rich physics can be explored when chiral nanostructures are considered. We present analytical formula and full-wave simulation results for optical forces acting on metallic helix nanostructures. We found that the structural chirality can be coupled with light's chirality (spin) and results in optical spin force terms which can be used to realize optical pulling force and sideway force acting on chiral particles. The sideway force can laterally push particles with opposite chirality to the different side of an interface and hence may serves as a possible approach to separate chiral particles or molecules. We also show that such chiral metallic nanostructures, when properly arranged, can induce scattering force through a dominating toroidal-moment mode which plays a clear and indispensable role in the view point of source (charge and current) distribution. We show that such a scattering force can also be explained by an electric dipole mode in the radiation far-field. Our results build the connection between the source picture and the field picture and help understanding the role played by complex electromagnetic multipoles in optical force system.

9547-62, Session 13

Electrothermoplasmonic flow for plasmon-assisted optical trapping *(Invited Paper)*

Justus Ndukaife, Alexander V. Kildishev, Agbai Agwu Nnanna, Steven T. Wereley, Vladimir M. Shalaev, Alexandra Boltasseva, Purdue Univ. (United States)

Plasmonic nanostructures, which support highly localized and enhanced electromagnetic field are now actively researched as a means for efficient trapping of nanoscale objects, not addressable by conventional diffraction-limited optical tweezers. An issue of critical concern is how to efficiently transport and deliver the suspended particles to the illuminated plasmonic nanostructure. There are primarily two main approaches that researchers employ for trapping of particles with plasmonic nanostructure(s) on a substrate. The first approach involves illuminating arrays of closely-spaced plasmonic nanostructures. However resonant illumination of the nanostructures results in collective heating and this produces strong fluid convection that exerts drag forces on the particles. Elucidating the roles of these heating-induced forces and optical gradient forces arising from plasmonic field enhancement have so far remained elusive. The other scheme involves illuminating a single plasmonic nanostructure. However, due to the absence of thermoplasmonic convection in this case, the dynamics of the suspended particle to be trapped becomes dictated by Brownian motion- an inherently slow process. We will discuss a new fluid flow mechanism, which we have termed electrothermoplasmonic (ETP) flow to resolve this dilemma. ETP flow harnesses intrinsic plasmonic heating combined with AC electric field to generate on-demand fluid and particle transport, which means that particles could be rapidly transported for trapping in sub-wavelength plasmonic hotspots only when desired, and without any competition between heating-induced forces and optical gradient forces. These new capabilities certainly provide new directions for research in the field of plasmon-assisted optical trapping, which will be discussed.

9547-63, Session 14

Non-quasi-static eigenstates of Maxwell's equations in a two-constituent composite medium and their application to a calculation of the local electric field of an oscillating electric dipole

Asaf Farhi, David J. Bergman, Tel Aviv Univ. (Israel)

In conventional optics the image is formed only by the propagating waves and the information encoded in the evanescent waves is lost. This limits the resolution which is inversely proportional to the wavelength of the light. A flat slab with a negative refractive index metamaterial can focus at a point the radiation from a point source. Such a slab can also amplify evanescent waves and thus enable the generation of an image by both propagating and non propagating waves, theoretically leading to unlimited resolution.

The imaging of an electric point charge in a composite structure composed of a $epsilon_1$ slab surrounded by a $epsilon_2$ medium, was recently analyzed by expanding the local electric potential in a series of the quasi-static eigenfunctions of the composite structure. Numerical evaluations of the electric potential, using realistic values for the electric permittivities and the slab thickness, revealed that the maximum concentration of the electric field occurs not at the geometric optics foci but at the interfaces between the negative permittivity slab and the surrounding medium.

Here we describe an exact calculation of the local electric field ${bf E}({bf r})$ for the full Maxwell's equations

where $mu=1$ everywhere in the system. For this purpose we first calculate all the eigenstates of Maxwell's equations for the composite structure. These eigenstates are then used to develop an exact expansion for the physical values of ${bf E}({bf r})$ in the system for the case of a time dependent point charge $q e^{-iomega t}$ in the $epsilon_2$ medium.

9547-64, Session 14

Retrieving the polarizability tensor of wire media

Jacob Ben-Yakar, Tel Aviv Univ. (Israel); Yonatan Sivan, Ben-Gurion Univ. of the Negev (Israel); David J. Bergman, Tel Aviv Univ. (Israel)

Metamaterials consisting of long, circular, cylinders are very popular. It is a fundamental challenge to characterize the effective electromagnetic response of such composites. In this framework, the radius of cylinder is assumed to be considerably smaller than the external wave length, thus the dominant scattered EM fields can be approximately replaced by dipole fields. Previous works dealt mainly with two dimensional (2D) scenarios, i.e.,

characterizing the effective electromagnetic response for light propagation perpendicular to the cylinder axis.

In this work, we generalize this treatment to three dimensions (3D), i.e., we characterize the effective electromagnetic response for light propagation at any angle, and find that the resulting electromagnetic response is non-local, i.e., it depends on the wavevector component parallel to the cylinder axis.

We retrieve analytically, the full polarizability tensor and show that it has different contributions for different polarized incoming EM waves (transverse electric and transverse magnetic with respect to the cylindrical axis).

It is also diagonal, i.e., it contains no magneto-electric coupling, showing that claims in previous studies were incorrect. Having closed form expressions for polarizability allows us to use effective medium approximation methods, and tailor the spectral response for both electric and magnetic dipolar contributions. It is important to emphasize that for the first time, this gives a fully systematic way to characterize the magnetism.

Our analysis holds for additional structures based on cylindrical geometry, such as hole arrays, all-dielectric metamaterials, and multi-layer cylinders. It can be used to explain the electromagnetic response of wire media attributed with a negative refractive index, effective magnetism and hyperbolic dispersion relations. In addition, this approach can be applied to more complex unit cells e.g., consisting of clusters of parallel cylinders.

9547-65, Session 14

Distinguishing between plasmon-induced and photoexcited carriers in a device geometry

Hangqi Zhao, Bob Y. Zheng, Alejandro Manjavacas, Michael J. McClain, Peter Nordlander, Naomi J. Halas, Rice Univ. (United States)

The use of surface plasmons, charge density oscillations of conduction electrons of metallic nanostructures, could drastically alter how sunlight is converted into electricity or fuels by increasing the efficiency of light-harvesting devices through enhanced light-matter interactions. Surface plasmons can decay directly into energetic electron-hole pairs, or “hot” carriers, which can be used for photocurrent generation or photocatalysis. However, little has been understood about the fundamental mechanisms behind plasmonic carrier generation. Here we use metallic nano-wire based hot carrier devices on a wide-bandgap semiconductor substrate to show that plasmonic hot carrier generation is proportional to field intensity enhancement instead of bulk material absorption. We also show that interband carrier generation results in less energetic carriers than plasmon-induced generation, and a plasmon is required to inject electrons over a large energy barrier. Finite Difference Time Domain (FDTD) method is used for theoretical calculations, which match well with experimental results. This work points to a clear route to increasing the efficiency of plasmonic hot carrier devices and drastically simplifies the theoretical framework for understanding the mechanisms of hot carrier generation.

9547-66, Session 14

Taming surface plasmons with adjacent molecules *(Invited Paper)*

Mikhail A. Noginov, Norfolk State Univ. (United States)

In this presentation, we will review the plethora of physical phenomena related to interaction of surface plasmons (and, more generally, metallic nanostructures and environments) with adjacent molecules. We will start the discussion with a more familiar subject of compensation of loss by gain and stimulated emission. After that we will review our recent experiments demonstrating strong coupling of surface plasmons and dye molecules as well as the effect of metallic surfaces on Förster energy transfer, van der Waals interactions, and chemical reactions.

Photoconductively excited plasmonic modulator-switch

John S. Cetnar, David E. Zelmon, David H. Tomich, Air Force Research Lab. (United States)

A novel plasmonic modulator-switch for the long-wave infrared (LWIR) region is presented. The device consists of a thin metal film, an underlying photoconductive substrate, input and output reflection gratings located on top of the film on opposite ends of the device, and a limited aperture detector located over the out-couple grating. LWIR incident at a given angle is in-coupled, generating surface plasmons (SPs). Since the underlying metal film is thinner than the SP penetration depth, the SPs are couple on both the top and the bottom of the thin film and propagate on both sides of the metal film toward the out-coupling grating. When free carriers in the photoconductive substrate are excited by laser illumination, the electrical properties of the substrate are changed. This change in substrate electrical properties is sensed by the propagating SPs and thus changes the wavevector of the SPs. The SP wavevector change will cause the out-coupled radiation magnitude and angle to change. Thus, the radiation incident on the detector is modulated implementing a plasmonic modulator-switch.

Full-wave electromagnetic simulations were performed on the device. The reflected power at various angles was calculated for a fixed incident angle at ? = 10 ?m using various geometries and substrate materials. The substrate materials modelled include III-V compound semiconductors and Si. The dielectric functions for these materials were computed as functions their free carrier concentration to simulate excited and unexcited states. This paper reports on how device performance was affected by variation of these geometric and material parameters.

Study of the plasmonic properties of ordered arrays of Ag and Au nanoparticles fabricated by a combination of nanosphere lithography with ion implantation

Octavio Graniel, Cecilia Salinas, Erick Flores-Romero, Univ. Nacional Autónoma de México (Mexico); Ulises Morales, Univ. de Guanajuato (Mexico); Juan-Carlos Cheang-Wong, Univ. Nacional Autónoma de México (Mexico)

Colloidal silica particles are being intensively studied due to their potential applications in catalysis, intelligent materials, optoelectronic devices, photonic bandgap crystals, masks for lithographic nanopatterning. In nanoscale electronic, photonic and plasmonic devices, feature dimensions shrink towards a critical limit, and new experimental approaches have to be explored in lithographic patterning to create ordered arrays of metallic nanostructures with useful optical properties. Nanosphere lithography uses self-assembled monolayers of spherical submicrometer-sized silica particles prepared by sol-gel and deposited onto silica glass plates. This silica monolayer is then used as a mask to create regular arrays of nanoscale features in the sample by 1-2 MeV Ag and Au ion implantation. By this way, after removal of the silica particles and an adequate thermal annealing of the as-implanted samples, the formation of Ag or Au nano-objects embedded in silica plates was confirmed by the presence of the surface plasmon resonance in the optical absorption spectra. The size and shape of the array of metallic nanostructures were studied by electron microscopy. The amount of implanted ions was measured by Rutherford Backscattering Spectrometry. The long range order of the metallic nanoparticle assembly and its plasmonic properties were characterized by a Fast Fourier Transform study and optical absorption measurements, respectively.

Plasmonic analog of electromagnetic-induced transparency of asymmetrical slots waveguide

Lin Sun, Jiangnan Univ. (China); Jicheng Wang, Jiangnan Univ. (China) and Purdue Univ. (United States); Baojie Tang, Xiaosai Wang, Jiangnan Univ. (China)

The optical phenomenon analogous to electromagnetically induced transparency (EIT) has been proposed numerically in the plasmonic system composed of unsymmetrical grooves shaped metal–insulator-metal (MIM) waveguide. Based on the coupled mode theory (CMT) and Fabry-Perot model, the formation and evolution mechanisms of plasmoninduced transparency by direct and indirect couplings are exactly analyzed. The analysis shows that the EIT-like spectral response and Fano resonances can be tuned easily by adjusting the geometrical parameters of the groove structures, including the coupling distances and groove lengths. We observe that both the wavelengths of resonance modes present red shift and the transparency window progressively widens with the increase of the difference of the two groove lengths. In addition, the plasmonic system with unsymmetrical third-groove structure is also proposed. The numerical results are simulated by finite element method (FEM) to validate the correctness of the uniform theoretical description. The results may open up avenues for designing nanoscale optical switch, ultrasensitive sensors, and slow light devices in highly integrated optical circuits.

Spectral magnetooptical tunability using Bragg plasmons

Emil Melander, Sebastian M. George, Uppsala Univ. (Sweden); Evangelos Th. Papaioannou, Technische Univ. Kaiserslautern (Germany); Marc A. Verschuuren, Philips Research (Netherlands); Björgvin Hjörvarsson, Vassilios Kapaklis, Uppsala Univ. (Sweden)

Magnetoplasmonics is a field where external magnetic fields are utilized to control the optical properties that come from plasmons. Active control of plasmonics has many applications in energy harvesting and nanosensing. [1]

We demonstrate experimentally the optical and magnetooptical response from Bragg plasmons [2] using diffraction from magnetoplasmonic nanodisks arranged in a periodic 2D square pattern from the coupled islands. The circular islands are 450 nm in diameter and have a lateral periodicity of 512 nm. This enables diffraction parallel to the surface which in turn yields Bragg plasmon excitation due to the electric field enhancement. The alloy is a combination of Fe and Pd, Fe20Pd80, in order to have a simple material that has both the magnetic functionality as well as the plasmonic.

Specular reflectivity and transverse magnetooptical Kerr effect (TMOKE) spectra [3] are compared to show how the optical measurements relate to the magnetooptical enhancement. The experimental data is compared to a simple diffraction model that accounts for the lateral dimensions of the nanostructure and the diffraction which gives the Bragg plasmon onset. In this way we show the link between the Bragg plasmon excitation and the changes in TMOKE asymmetry.

The effect of truncation in plasmon resonance of metal nanoprisms

Soad Alsheheri, Marjan Saboktakin, Mohammad Matin, Univ. of Denver (United States)

Plasmonic properties of gold and silver nanoparticles has several applications in the recent years. Of the several shapes of nanoparticles, triangular nanoprisms are of significant interest to us. The interest mostly arises from the multiple absorption bands in these particles associated with the multiple axes of their triangular shape as each of these axes can support propagating and localized surface plasmons. As a result, nanoprisms, are among the anisotropic plasmonic particles which exhibit LSPR in different orientations depending on the polarization of the incident light. Further, triangular nanoprisms provide us the opportunity of tuning their LSPR properties by suitably modifying their structural parameters such as particle thickness, particle edge length and height. Despite the several advantages of triangular nanoprisms, it has been a challenge to synthesize these nanomaterials with absolute precision in edge lengths. Often times, the triangular nanoprisms we synthesize through various methods will not have sharp edge lengths, instead they are seen as truncated. In this project, we have studied the effect of truncation in plasmon resonance. Truncation (TR = a/l). The TR values we studied are 0.006, 0.03, 0.06, 0.1, 0.13 and 0. The edge lengths we studied is 150 nm and thickness of prism is 15nm, 25nm, and 35 nm. Further, we measured the plasmon resonance for 1 snip, 2 snip and 3 snips. For 15 nm thickness of nanoprism, with edge length of 150 nm, with increase in TR value, plasmon resonance saw a blue shift for one snip. However, when the snips increased to 2 and 3 no shift in values of plasmon resonance were found. However, when the thickness of nanoprism changed from 15nm to 35 nm, plasmon resonance found a blue shift.

Plasmonic devices based on the dual coupled grapheme-integrated ring resonators

Jicheng Wang, Jiangnan Univ. (China) and Purdue Univ. (United States); Xiushan Xia, Jiangnan Univ. (China); Xiuye Liang, Jiangnan Univ (China); Jing Chen, Jiangnan Univ. (China); Dongdong Liu, Nanjing Univ. of Science & Technology (China)

We have proposed a couple of plasmonic devices based on graphene sheets and ring resonators. The highly frequency-tunable multi-mode plasmonically induced transparency (PIT) device based on monolayer graphene and rings for the mid-IR region is presented in theory firstly. The multi-mode transparency windows in the spectral responses and slow light effects can be achieved in plasmonic configuration composed of two graphene resonators coupled with single-layer graphene waveguide. By varying the Fermi energy of the graphene, the multi-mode PIT resonance can be dynamic controlled without reoptimizing the geometric parameters of the structures. Based on the coupled mode theory (CMT) and Fabry-Perot (FP), we numerically investigated direct coupling and indirect coupling in the graphene-integrated PIT systems. In addition, the theoretical plasmonic devices based on graphene sheets and ring resonators are also proposed to perform as 1?2 optical spatial switch or ultra -compact Mach-Zehnder interferometer. The finite element method (FEM) is carried on to verify our designs. Those designs may pave the ways for the further development of the compact high-performance plasmonic communication devices.

Fano resonances in nanoscale plasmonic structure

Yundong Zhang, Hui Li, Xuenan Zhang, Yongfeng Wu,

Harbin Institute of Technology (China)

We investigate a plasmonic waveguide system using the finite-difference time-domain method, which consists of a metal-insulator-metal waveguide coupled with a circle and a disk cavity. Numerical simulations results show that the sharp and asymmetric Fano-line shapes can be created in the waveguide. Fano resonance strongly depends on the structural parameters. This has important applications in highly sensitive and multiparameter sensing in the complicated environments.

Investigation of the reflection and transmission of nano-scale gold films

Haoliang Qian, Yuzhe Xiao, Dominic Lepage, Zhaowei Liu, Univ. of California, San Diego (United States)

With the shrunk of the plasmonic device dimensions into the nano region, the field of quantum plasmonics has emerged and drawn much attention recently. Ultra-thin metal film is an ideal platform to study the quantum behavior of electrons, and is the focus of this paper. This paper demonstrates a combined experimental and theoretical investigation of the optical properties of gold nano films with thickness varying from 30 nm to 2.5 nm. More specifically, accurate reflection and transmission measurements are performed for the gold films with thickness down to 2.5 nm. The optical constants (n and k) are extracted using Newton's method with a multilayer transmission code. A new theoretical model based on the self-consistent solution of the coupled Schrodinger and Poisson equations is applied to gold quantum wells for the first time and its predictions agree excellently experiment over a very broadband spectral range (1 to 2 um). This quantum model not only can explain the experimental results, it also predicts the values of the electron parameters in gold quantum well, such as the effective mass and relaxation time. Such a theory can be easily generalized to other quantum structures, such as quantum dots and quantum wires, and should be very useful in the field of quantum plasmonics.

9547-106, Session PWed

High order gap modes in film-coupled ?/10 nanoantennas

Chua-Zu Huang, Ming-Jing Wu, National Cheng Kung Univ. (Taiwan); Shiuan-Yeh Chen, National Cheng Kung Univ (Taiwan)

The high order gap modes in the film-coupled nanoantenna are identified experimentally and theoretically. Recently, several reports show that a particle-film structure with a gap on the few-nanometer scale provides a stable platform for investigating the induced enhanced field and its interaction with molecules nearby. The concentrated enhanced field within the gap is usually dominated by the well-known gap dipole mode. However, when the gap size decreases, the increasing high enhanced field is accompanied by the induced high order modes. These high order modes are usually thought to be "dark" (not radiate efficiently) and only affect the distribution of the near-field. However, in our far-field scattering measurements, it is found that these high order modes also have substantial influence on the far-field scattering profile. In addition, it is also shown that several high order modes could exist even in this small structure (~?/10) within the relatively narrow spectral range. Therefore, the evaluation of nanoantenna bandwidth needs to take this factor into account. The relation between far-field scattering profiles, spectra, and near-field distribution were elucidated through the optical measurements and simulations. Our findings provide a guideline for probing the interaction between the gap field and the molecules nearby and can be extended for designing extremely compact nanophotonic devices.

The influence of annealing on Au films deposited on Ge seed layers

Vesna Janicki, Jordi Sancho-Parramon, Boris Okorn, Institut Ruder Bo?kovic (Croatia); Eva Kova?evi?, CNRS/ Université d'Orléans (France); Hrvoje Zorc, Institut Ruder Bo?kovic (Croatia)

Ultrathin compact metal films are important for plasmonic and metamaterial devices. This kind of films can be obtained by electron beam evaporation technique on a pre-deposited Ge seed layer. The role of the seed layer is to reduce the percolation threshold of metal islands. In this way thinner compact metal layers having lower losses are formed. Similarly as the growth of metal island films is promoted if the substrate is heated, annealing of a compact metal film can result in breaking the surface continuity of the layer and formation of metal islands.

The influence of annealing on metal islands and compact Au films formed on the substrates with and without Ge seed layer is studied in this work. A serial of samples with different thicknesses of Au was annealed at different temperatures. Optical and structural measurements, ellipsometry and scanning electron microscopy at the first place, were performed and used for characterization of the samples. As expected, the obtained results present formation of discontinuous layers with the increase of the temperature. However, even in the conditions of elevated temperature, Ge seed layer is shown to promote percolation, postponing or even preventing the breakdown of the continuity of the film.

Influence of plasmonic nanoantennas on the optical properties of ultra-thin conjugated polymer films

Binxing Yu, Joseph Woo, Rutgers, The State Univ. of New Jersey (United States); Sarah Goodman, Massachusetts Institute of Technology (United States); Deirdre M. O'Carroll, Rutgers, The State Univ. of New Jersey (United States)

Conjugated polymers have been intensively studied in the recent years due to their remarkable electronic and optical properties which include high conductivities, excitonic absorption, photoluminescence and electroluminescence. However, their limited spectral absorption bandwidths have limited their applications in photodetection and photovoltaic devices, which makes improving light-harvesting in ultra-thin conjugated polymer active layers an ongoing topic of interest in the optoelectronic community.

Here, we present how a a metal nanoantenna/poly(3-hexylthiophene) (P3HT)/metal film system can be designed to affect the enhancement and localization of electric fields in polymer thin films. We theoretically and experimentally investigate the tunability of the subwavelength resonant modes supported by the system and their impact on the spectral response of sub-50 nm thick conjugated polymer layers. Significant absorption enhancement up to 6 times in polythiophene is obtained using this system which is also validated by agreement with full-field electromagnetic simulation data.Single nanoparticle dark-field scattered-light spectroscopy and simulations also revealed evidence for the excitation of both localized surface plasmons (LSPs) of the nanoparticle and propagating surface plasmon polaritons (SPPs) of the metallic film. Distinct resonance features observed in the scattering spectra were assigned to specific modes based on an image-dipole interaction model as well as the coupling and interplay between LSPs and SPPs.Upon modifying factors such as: polymer spacer thickness, nanoparticle height and material type, we could alter bandwidth, intensity of the individual modes and optimize degree of electromagnetic field localization in the polymer. The analysis in this study would be useful for proposing new concepts for manipulation and control of light-matter interactions in nanoscale material volumes, which is of utmost importance for the optimization of ultra-thin film devices exploiting near-field

phenomena, such as surface plasmon-enhanced thin-film solar cells and light-emitting devices.

Surface plasmon resonance in diabolo metal bar optical antenna arrays

Junpeng Guo, Hong Guo, The Univ. of Alabama in Huntsville (United States)

Surface Plasmon Resonance in Diabolo Metal Bar Optical Antenna Arrays

Hong Guo, Blake Simpkins, Joshua Caldwell, Junpeng Guo

Abstract: We investigated a new configuration of optical antennas: metal bar antennas with reduced waist width with respect to rectangular bars. Previously investigated bowtie optical antennas consist of two triangle shape metal patches with a small gap between the two metal patches. The excitation polarization is along the small gap of the triangle metal patches and the electromagnetic field enhancement occurs inside the gap between the two metal patches. For the narrow waist metal bar antennas investigated here, there are no gaps in the structure. The excitation polarization is along the longitudinal dimension of the metal antennas. It was found that the resonance wavelength and near field enhancement of diabolo metal bar antennas can be tuned by varying the waist width of the Diabolo Metal Bar Optical Antennas.

A two-electrode electrochemical surface plasmon resonance sensor for investigating the electropolymerization of polyaniline

Bing Zhang, Zhejiang Univ. (China); Yazhuo Li, Jianghan Univ. (China); Yizhang Wen, Peijun Cai, Xiaoping Wang, Zhejiang Univ. (China)

A novel electrochemical surface plasmon resonance (EC-SPR) sensor has been developed based on the surface plasmon resonance (SPR) combined with a two-electrode electrochemical configuration. The theory of potential-modulated for EC-SPR was described, and several factors which can induce the change of the SPR resonance angle were revealed. Comparing with the conventional three-electrode electrochemical system, the reference electrode has been eliminated in this design, and the active carbon (AC) electrode employed as the counter electrode. Due to the large specific surface area, AC presents considerable double layer capacitance at the interface of electrode and electrolyte, which can provide a constant potential during the electrochemical reactions. Using an angle modulation SPR sensor and the resolution of that is 5?10-6 RIU (refractive index units), a real-time data-smoothing algorithm is adopted to reduce the noise of the data, which can guarantee an accurate result of the resonance angle of SPR. The EC-SPR setup was used for investigating the electropolymerization of polyaniline by applying a potential of cyclic voltammetry, both of the electrochemical current and the resonance angle shift of SPR are recorded to monitor the growth process of the polymer. Comparing with the three-electrode configuration, the novel AC two-electrode system can also obtain detailed information about the polymerization process from the resonance angle shift curves, including the change of thickness and dielectric constant, deposition and transitions between different redox states of the polymer film. Experimental results demonstrated that this two-electrode EC-SPR configuration is suitable for analyzing the electropolymerization process of a conducting polymer.

Surface plasmons leaky radiation of the flat metal

Ping Wang, Sichuan University (China)

We derive the Fano equation to present the reflection spectrum derived from the three-layer Fresnel reflection equation, which are asymmetric curves resulted from interference between direct reflectance and surface plasmons leaky radiation. When surface plasmons propagate on the metal surface, part of the excited surface plasmons leaks out as a radiation wave into prism. Therefore the reflection consists of two parts: direct reflectance and the leaky radiation. The whole incident light energy can be divided into three parts: direct reflectance, the surface plasmons leaky radiation and propagating surface plasmons which is confined in metal and ultimately converts into heat because of the metal absorption. By fitting the rigorous electromagnetic calculation with the Fano equation, we obtain each contribution to reflection of the three parts. The surface plasmons leaky radiation decreases with the increase of metal thickness. It approximates to zero with metal thickness thicker than 35nm and the leaky radiation is quite strong at ultra-thin metal film due to the optical tunneling effect. When the sum of direct reflectance and leaky radiation reach the value close to zero the propagating surface plasmons reach the value close to unity at about 45nm metal thickness.Compares to our investigation of grating coupler, we learn the surface plasmons leaky radiation of flat metal is quite weak than resonance radiation coupled out by grating, especially at thick metal, because they are in different radiation mechanism.

Polarization conversion with crossed plasmonic polarizers

Xiaobin Cui, Chengping Huang, Nanjing Tech Univ. (China)

Conventionally, a pair of linear polarizers can be used to generate and rotate the linear polarization. However, according to the Malus law, the transmission or conversion efficiency decreases with the rotating angle. It is well known that, when the two linear polarizers are orthogonal to each other, the transmission of light will be blocked. This effect also prohibits the 90-degree polarization conversion with two crossed polarizers. We propose that a pair of specially-designed orthogonal plasmonic polarizers may break through the above limitation to induce both high transmission and 90-degree polarization conversion. We present the experimental demonstration of such effect in both optical frequency and microwave regime. Moreover, based on this effect, a super polarization converter that switches the incident polarization to arbitrary direction has also been designed and realized in the microwave band. The results may be used to construct new types of plasmonic devices, e.g., the polarization converters, one-way transmitters, subwavelength switches and modulators, etc.

9547-113, Session PWed

Hybrid spherical cap plasmonic waveguide for tight mode confinement and long propagation length

Kai Li, Maojin Yun, Xiaohui Ge, Weijin Kong, Qingdao Univ. (China)

The special abilities of plasmonic waveguide including tight field confinement and beyond diffraction limit within nano-scale structure have been exploited in many different fields. In order to overcome the trade-off between tight mode confinement and long propagation length, many kinds of nano-scale structures have been proposed in recent years. In this paper, a novel hybrid plasmonic waveguide consisting of the layer of metal Ag, a spherical cap with low-index dielectric layer placed above the metal Ag and a high-index dielectric layer placed above the spherical cap is proposed and analyzed theoretically. The relations between the characteristics of

the bound modes, such as mode confinement, propagation lengths, and parameters of the spherical cap, the curvature and width, are numerically investigated in detail. The simulation results show that the nano-scale confinement can be realized. The simulation results show that the performance of the proposed spherical cap hybrid plasmonic waveguide is better than the rectangle or cylindrical hybrid plasmonic waveguide. Such hybrid plasmonic waveguide has a tight mode confiment and long propagation length. This novel stucture provides promising applications for high-integration density photonic components.

9547-114, Session PWed

Cylindrical hybrid plasmonic waveguide for a nano-scale light confinement

Chao Liu, Mei Wang, Maojin Yun, Weijin Kong, Qingdao Univ. (China)

In order to improve integration density, it is essential to develop a nano-scale optical waveguide which is the key element to build varies of optical components. In this paper, a novel cylindrical hybrid plasmonic waveguide, which has a air core surrounded by a metal-layer and a silicon layer, is proposed to achieve nano-scale confinement of light at the operating wavelength of 1550nm. And there is a low-index material nano-layer between the metal layer and the silicon layer, in which the field enhancement provides a nano-scale confinement of the optical field. The relations between the characteristics of the bound modes, including the effective mode indices, propagation lengths, mode sizes, mode shapes and parameters of the plasmonic waveguide are numerically investigated in detail. The simulation results show that the nano-scale confinement can be realized and the proposed hybrid plasmonic waveguide has a potential application in high density photonic integration.

Plasmon enhanced luminescence upconversion in Au and NaYF4:Yb3+,Er3+ nanoparticle clusters

Chenchen Mao, Univ. of Colorado at Boulder (United States); Liangcan He, Jennifer N. Cha, Univ. of Colorado Boulder (United States); Wounjhang Park, Univ. of Colorado at Boulder (United States)

Rare-earth activated upconversion materials present exciting new possibilities in solar energy conversion, bioimaging and medicine. For viable applications, however, the efficiency must be enhanced which may be accomplished by surface plasmon. Also, solution-processed nanocomposites are desired for most bio-applications and organic devices.

In this study, SiO2 coated NaYF4: Yb3+, Er3+ upconversion nanoparticles (UCNPs) by the co-precipitation method. Then, Au nanostars or nanospheres were synthesized, thiol-streptavidin stabilized, and attached to the biotinylated UCNPs through the strong interaction between biotin and streptavidin. The Au-UCNP clusters showed various extinction spectra depending on the shape of the Au nanomaterial. Au nanospheres presented resonance at 520 nm while two types of Au nanostars exhibited resonances at 700 nm and 980 nm, respectively. The plasmon resonance can lead to enhanced upconversion through a complex mechanism involving absorption, emission and energy transfer. Also, metal surface introduces quenching which has to be minimized mainly by adjusting the SiO2 coating thickness.

Due to the interplay of many different processes, the upconversion luminescence was highly sensitive to the exact geometry of the nanocluster. Among the set of Au-UCNP clusters we studied, the highest enhancement was observed from the UCNP coupled to Au nanostar with 700 nm resonance. Enhancement factors for green and red emission were 3.4 and 2.7, respectively. The SiO2 coating thickness was 10 nm. A complete analysis of the experimental data together with quantum electrodynamics based theoretical models will be presented at the conference.

9547-117, Session PWed

Plasmonic local heating beyond diffraction limit by the excitation of magnetic polariton

Liping Wang, Hassan Alshehri, Arizona State Univ. (United States)

In recent years, optical local heating in the nanoscale has attracted great attention due to its unique features of small hot spot size and high energy density. Plasmonic local heating can provide solutions to several issues such as data storage and cancer treatment. Research conducted in this field to achieve plasmonic local heating has mainly utilized the excitation of localized surface plasmon (LSP) or surface plasmon resonance (SPR). However, achieving plasmonic local heating by the excitation of magnetic polariton (MP) has not been researched extensively yet.

In this work, we numerically investigate the radiative properties of a metamaterial nanostructure composed of a gold nanowire suspended on a gold thin film. HFSS (High Frequency Structural Simulator) simulation shows that the proposed structure exhibits a selective absorption peak at 655 nm due to the excitation of MP at the resonance wavelength. The electromagnetic field of the structure at resonance is plotted to explain the mechanism of MP. Geometric and incidence angle effects on the resonance wavelength and the absorptance spectra are also studied, and the physical mechanisms are elucidated. Furthermore, an inductor-capacitor circuit model is employed to predict the resonance wavelength for MP and compare with the HFSS results. Temperature distributions of the respective simulations are then obtained employing ANSYS steady state thermal software. Temperature distributions show relatively high temperature where electromagnetic energy is confined; hence localized heating is achieved. The findings of this work may facilitate applications in the fields of data storage, optical local heating, and optical sensing.

Enhancing resonance dynamics in plasmonics

Ashok Kodigala, University of California, San Diego (United States); Thomas Lepetit, Boubacar Kante, Univ. of California, San Diego (United States)

A budding topic of interest is that of applications in the field of plasmonics which currently range from chemical and biological sensing to enhanced photovoltaics. At the core of these plasmonic devices are resonances that govern their unique function and the ability to manipulate said resonances is crucial to their design. In order to manipulate resonances, we must be able to observe them quantitatively. Conventionally, the approach to examining plasmonic resonances is to identify the peaks and troughs of reflection and transmission spectra. This methodology is qualitative in nature and is

insufficient for non-symmetric or Fano resonances. This approach is even worse for cases with multiple overlapping resonances. Here, we describe an effective Hamiltonian formalism to study and tailor plasmonic resonances at optical frequencies. Using this approach, we compute the complex poles of the scattering matrix which quantitatively relate to both the resonance frequencies and linewidths. As such, we are able to track the dynamics of resonances and study in detail the coupling behavior between multiple plasmonic particles. As a further consequence, we can design novel plasmonic systems that offer a very large degree of resonance tunability.

9547-119, Session PWed

Optica fiber tip with point light source of SPPs driven by three-dimensional nanostructured asymmetric metal-insulator-metal layer cap

Yasushi Oshikane, Motohiro Nakano, Osaka Univ. (Japan); Kensuke Murai, National Institute of Advanced Industrial Science and Technology (Japan)

Numerical analysis of three dimensional optical electro-magnetic field in a circular-truncated conical optical fiber covered by asymmetric MIM structure has been performed by a commercial finite element method package, COMSOL Multiphysics coupled with Wave Optics Module. The outermost thick metallic layer has twin nano-hole, and the waveguiding twin-hole could draw surface plasmon polaritions (SPPs) excited in the MIM structure to the surface. Finally the guided two SPPs could unite each other and may create a single bright spot. The systematic simulation is continuing, and the results will give us valuable counsel for control of surface plasmon polaritons (SPPs) appearing around the MIM structure and twin nano-hole. (1) Optimal design of the 3D FEM model for 8-core Xeon server and rational approach for the FEM analysis, (2) behavior of SPPs affected by wavelength and polarization of light travel through fiber, (3) change in excitation condition of SPPs caused by shape of the MIM structure and twin-hole, (4) effectiveness of additional nanostructures that are aimed at focusing control of two SPPs come out from the corners of twin-hole, (5) scanning ability of the MIM/twin-hole probe at nanostructured sample saurface (i.e. amount of forward and backward scattering of SPPs) will be presented and discussed. Several FIBed prototypes and their characteristic of light emission will also reported.

Revealing the dispersive phase change in a slit-groove plasmonic interferometer structure

Xie Zeng, Univ. at Buffalo (United States); Haifeng Hu, Northeastern Univ. (China); Yongkang Gao, Alcatel-Lucent Bell Labs. (United States); Dengxin Ji, Nan Zhang, Haomin Song, Kai Liu, Qiaoqiang Gan, Univ. at Buffalo (United States)

The investigation on light interaction with individual slits has a long history in physical optics, resulting in many fundamental progresses. In recent years, there has been considerable growth in plasmonics research due to their subwavelength confinement of electromagnetic (EM) waves. To better understand surface plasmon polariton (SPP) mediated interactions between optical nano-objects at metallodielectric interfaces, researchers have performed numerous theoretical and experimental studies of the physics of nanostructures. However, there are still many open questions regarding fundamental understanding on surface plasmon waves. For instance, phase is an inherent and important feature for coherent processes, particularly for EM waves. In previously reported literature, the phase change during the SPP coupling was considered as a constant for different wavelengths, resulting in a mismatch between experiment and theoretical modeling. In this work, we propose an approach to extract the phase change dispersion during the interaction between free-space light, SPPs and nanogrooves. Using the far-field transmission and scattering image from a tilted slit-groove plasmonic interferometer structure, the intrinsic phase dispersion ?0(?) as the function of wavelength was successfully extracted, revealing more fundamental physics of SPP-nano-object interactions. This approach can also be applied to extract intrinsic phase dispersion of other plasmonic nano-objects with different shapes, which is essential for plasmonic subwavelength optics on a chip.

Enhanced light emission and absorption from monolayer MoS2 using single plasmonic optical antenna

Edgar Palacios, Serkan Bütün, Spencer Park, Lincoln J. Lauhon, Koray Aydin, Northwestern Univ. (United States)

In the last few years 2D transition metal dichalcogenides exhibiting direct bandgap behavior have received much attention because of their performance advantages in field-effect transistors, detector applications and flexible electronic devices operating in the visible spectrum. Among these materials, MoS2 has shown impressive results but the advantages stemming from its monolayer thickness also present a disadvantage- reduced light-matter interaction. By utilizing the light confining effects of plasmonic nano-structures it is possible to strongly couple plasmonic resonances with single layer MoS2 and increase light matter interactions. Recently, we have modeled and experimentally verified the strong optical interactions of localized surface plasmons from Ag nanodiscs with monolayer MoS2 resulting in a twelve-fold photoluminescence enhancement. Herein, we will present our latest results on the detection of single Au nanoantennas through enhanced photoemission from monolayer MoS2. By engineering the length of Au dipole and bowtie nanoantennas we tune the resonant frequency to support the excitation or emission fields resulting in improved light emission and absorption for the next generation of 2D based photonics, detectors and solid state lighting.

Plasmonic dark modes excited by strongly focused illumination

Jordi Sancho-Parramon, Institut Ruder Bo?kovic (Croatia) and Univ. of Barcelona (Spain); Salvador Bosch Puig, David Maluenda, Univ. de Barcelona (Spain); Hrvoje Zorc, Institut Ruder Bo?kovic (Croatia)

Surface plasmons with a charge distribution having a net dipole moment are known as bright modes, as they can easily couple to light. On the other hand, resonances with a zero dipole moment are termed dark as they cannot be excited by homogeneous illumination. Over the last years, dark modes have attracted significant interest due to their potential for sensing applications. Compared to bright modes, they show strong electromagnetic near-field enhancement and high quality factors. In addition, the interference of dark and bright modes can lead to Fano-like resonances.

In symmetric structures, dark plasmon modes can be excited by non-optical means such as an electron beam. Generation of dark modes by light requires breaking the excitation symmetry that can be achieved using inhomogeneous illumination, evanescent waves, retardation effects, localized emitters or spatial phase shaping. In the present work, we show that strongly focused illumination can lead to excitation of dark modes. We first use rigorous vectorial diffraction theory to compute the distribution of light at the focus and then numerically calculate the response of particle clusters and core-shell particles. Controlling the distribution of light arriving at the focusing lens by, for instance, pupil filters enables enhancing the excitation of dark modes. Overall, these results present guidelines for the excitation of dark plasmon modes using standard optical instrumentation.

Fabrication of alternative plasmonic materials with room temperature high-power impulse magnetron sputtering

Zih-Ying Yang, Yi-Hsun Chen, National Chiao Tung Univ. (Taiwan); Bo-Huei Liao, Instrument Technology Research Ctr. (Taiwan); Kuo-Ping Chen, National Chiao Tung Univ. (Taiwan)

Low loss alternatives plasmonic materials like titanium nitride (TiN), have received significant interests in recent years. TiN has low loss in the visible and NIR wavelengths and the optical properties can be adjusted. In addition, the high melting temperature and bio-compactable properties make TiN with strong potentials in many applications. However, there is less discussion on the relevance of electrical and optical characteristics of TiN thin films. In this work, the room temperature fabrication process of TiN thin film is proposed, which is suitable for flexible substrate. Compared to the conventional magnetron sputtering, reactive high power impulse magnetron sputtering (HiPIMS) could provide higher degree of ionization of the sputtered metal and higher rate of molecular gas dissociation. Thus, the improvement in density, roughness, and electrical conductivity at lower temperature process could be achieved. Since TiN are non-stoichiometric materials, their composition could be changed by preparation method. In this study, 40 nm TiN thin films were deposited on B270 glass by HiPIMS at room temperature. First, the effects of DC power parameter on the conductivity, crystallinity, optical resonant properties of the TiN thin film will be investigated. Then, the relationship between electrical and optical properties will be shown. When the DC power is increasing, the ellipsometry results show that the dielectric function will change from dielectric to conductor. From four-point probe measurements, the resistivity decreases to 1/16 times as the power increases. In addition, increasing power would result in plasmon resonance blue-shifted from 515 nm to 460 nm.

Plasmonic hydrogels for ultrasensitive and in situ detection of a quorum-sensing signaling molecule by surface-enhanced Raman scattering spectroscopy

Verónica Montes García, Gustavo Bodelon-Gonzalez, Sergio Rodal-Cedeira, Vanesa López Puente, Celina Costas, Univ. de Vigo (Spain); Luis M. Liz-Marzán, CIC BiomaGUNE (Spain); Isabel Pastoriza-Santos, Jorge Perez-Juste, Univ. de Vigo (Spain)

In nature most bacteria exist in biofilms regulated by a cell-to-cell communication process termed quorum sensing (QS). The understanding of how microbial populations communicate and behave is important for developing new therapeutic compounds. Herein we report the use of Surface-enhanced Raman scattering (SERS) spectroscopy as an ultrasensitive tool for direct, in vivo plasmonic detection of a Pseudomonas aeruginosa QS-regulated molecule termed pyocyanin. With this aim, we report the design and characterization of a novel nanostructured plasmonic substrate to be used as SERS active sensing platform.

The nanostructure is based on poly(N-isopropylacrylamide) (pNIPAM) hydrogels doped with gold nanorods with high scattering contribution. The plasmonic substrates allowed simple, fast and ultrasensitive detection (up to 10-10 M) and quantification of pyocyanin produced from bacteria grown in liquid culture. Importantly, the inherent properties of the plasmonic hydrogels enabled bacterial growth as biofilm and simultaneous SERS detection of pyocyanin. This study shows for the first time in situ plasmonic imaging and monitoring of QS, demonstrating the suitability of this plasmonic platform for spectroscopic analysis of microbial communication and behavior.

9547-125, Session PWed

Mapping of transmission spectrum between plasmonic and nonplasmonic single slits

Shih-Hui Chang, Yulun Su, National Cheng Kung Univ. (Taiwan)

In contrast to conventional emphases on plasmonic effects, mapping of the transmission spectrum between a plasmonic and non-plasmonic 2D single slit are demonstrated. At resonant transmission, plasmonic and non-plasmonic single slits exhibit similar near-field mode at their corresponding resonant wavelengths. Their resonant transmission wavelengths can be transformed via a simple mapping with surface plasmon dispersion relation. To further extend the mapping for non-resonant condition, complex reflection and transmission coefficients at the end faces of a semi-infinite slit are analyzed to reconstruct the whole transmission spectra. The complex reflection coefficients are found similar at the same effective wavelength for both plasmonic and non-plasmonic cases. The reconstructed spectrum by a Fabry-Perot model matches the transmission spectrum of a non-plasmonic slit and can be transformed into that of a plasmonic case by wavelength stretching with plasmonic waveguide dispersion. The transmission cross section is bounded by ?/(ϖd). Width-dependent red shifts of the transmission spectrum are associated with effective capacitances at the slit end faces. Same mapping method applies for a single slit with substrate or periodic structure. Furthermore, the optical property of a plasmonic slit can be achieved by a non-plasmonic slit via dimension scaling. The focusing lens effect of a plasmonic slit array can be mimicked by a non-plasmonic slit array with dimension scaling. The unified transmission properties of plasmonic and non-plasmonic 2D single slits can simplify the design of slit structures for plasmonic applications.

Detectivity comparison of bolometric optical antennas

Alexander Cuadrado, José Manuel López-Alonso, Juan Carlos Martínez-Antón, Jose-Miguel Ezquerro, Univ. Complutense de Madrid (Spain); Francisco Javier González, Univ. Autónoma de San Luis Potosí (Mexico); Javier Alda, Univ. Complutense de Madrid (Spain)

The actual application of optical antennas in detection devices strongly depends on its ability to produce an acceptable signal-to-noise ratio for the given task. It is known that, due to the intrinsic problems arising from its sub-wavelength dimensions, optical antennas produce very small signals. The quality of these signals depends on the involved transduction mechanism. The contribution of different types of noise should be adapted to the transducer and to the signal extraction regime. Once noise is evaluated and measured, the specific detectivity, D*, becomes the parameter of interest when comparing the performance of antenna coupled devices with other detectors. In this contribution we are interested in the evaluation and comparison of D* values for several arrangements of bolometric optical antennas working in the infrared. The values obtained for D* will be related with those characterizing conventional optical detectors. At the same time, some strategies, related with the adequate choice of materials and geometries will be discussed in order to improve this parameter.

Analysis of the spectral response of fractal antennas related with its geometry and current paths

Alexander Cuadrado, José Manuel López-Alonso, Juan

Carlos Martínez-Antón, Jose-Miguel Ezquerro, Univ. Complutense de Madrid (Spain); Francisco J. Gonzalez, Univ. Autónoma de San Luis Potosí (Mexico); Javier Alda, Univ. Complutense de Madrid (Spain)

Fractal antennas have been proposed to improve the bandwidth of resonant structures and optical antennas. Their multiband characteristics are of interest in radiofrequency and microwave technologies. In this contribution we link the geometry of the current paths built-in the fractal antenna with the spectral response. We have seen that the actual currents flowing through the structure are not limited to the portion of the fractal that should be geometrically linked with the signal. This fact strongly depends on the design of the fractal and how the different scales are arranged within the antenna. Some ideas involving materials that could actively respond to the incoming radiation could be of help to spectrally select the response of the multiband design.

Nanoporous gold leaves: preparation, optical characterization, and biosensing capabilities

Gianluca Ruffato, Univ. degli Studi di Padova (Italy); Denis Garoli, Eugenio Calandrini, Pierfrancesco Zilio, Francesco De Angelis, Istituto Italiano di Tecnologia (Italy); Filippo Romanato, Univ. degli Studi di Padova (Italy); Sandro Cattarin, CNR-IENI (Italy)

Porous gold films have recently attracted increasing interest due to the unique properties related to their very high specific surface area. This particular material finds applications in many fields from electrochemistry to nanofluidic, solar cell and enhanced spectroscopy. Among the different fields of application, nanoporous gold (NPG) demonstrates also intriguing properties as plasmonic material. There is still a great desire to develop materials with optimized photonic properties taking advantage of electromagnetic resonances and concomitant enhancement of the electromagnetic near-field owing to surface plasmons. NPG has been extensively studied also as plasmonic platform for biosensing applications. In almost the cases it was prepared as thin film on a bulk substrate. A possible alternative approach is to prepare the NPG as self-standing film. This leads to a perfect symmetric configuration where the metal is immersed in an homogeneous medium. In order to exploit symmetric plasmonic modes this configuration can be extremely interesting. Here we present a reproducible NPG self-standing leaves preparation. We then investigate the material's optical response from the visible up to the medium infrared (MID-IR). The material has been nanostructured in order to support propagating symmetric plasmonics modes. Biosensing performances have been tested both in the optical and in the MID-IR spectral range. This platform was exploited for the detection of both self-assembly monolayer of very small molecules (alcane-thiol) and of protein conformational states. The employment of nanoporous gold offers the unique advantages of augmented analyte delivery by infiltration inside the sensor and versatile functionalization.

9547-129, Session PWed

Optical monitoring of the doping level of semiconductor by Brewster "mode"

Thierry Taliercio, Eric Tournié, Laurent Cerutti, Univ. Montpellier 2 (France); Jean-Jacques Greffet, Lab. Charles Fabry (France)

Develop plasmonic materials compatible with complementary metal oxide semiconductor (CMOS) technology is one of the fundamental challenges for plasmonics to imagine a possible industrialization of plasmonic applications other than bio-detection. Several approaches have been proposed to reach this goal notably using highly doped semiconductor (HDSC). However, it is indispensable to control accurately the plasma frequency, wp, of the HDSC to adjust the plasmonic resonances of the metallic nanostructures. We have developed a new non-destructive optical technique to measure wp by the intermediate of the Brewster "mode". When we investigate highly-doped InAsSb layers lattice matched onto GaSb substrates by angular-dependent reflectance, we evidenced a resonant dip near the plasma frequency of thin layers. Based on Fresnel coefficient in the case of transverse electromagnetic wave, we propose that this resonance is due to the excitation of a leaky electromagnetic mode, the Brewster "mode", propagating in the metallic layer deposited on a dielectric material. Investigating series of samples allowed us to realize abacus linking plasma frequency to carrier density. Potential interest of this mode for in-situ monitoring during device fabrication is also discussed.

9547-130, Session PWed

Fabrication of plasmonic thin films and its characterization by optical method and FDTD simulation technique

Anton Kuzma, Frantisek Uherek, Slovenska Technicka Univ. (Slovakia) and International Laser Ctr. (Slovakia); Jaroslava ?kriniarová, Slovenska Technicka Univ. (Slovakia); Du?an Pudi?, Univ. of ?ilina (Slovakia); Martin Weis, Martin Donoval, Slovenska Technicka Univ. (Slovakia)

In this paper we present optical properties of thin metal films deposited on the glass substrate by the physical vapor deposition system. Localized surface plasmon polaritons of different film thicknesses have been spectrally characterized by optical methods. Evidence of the Au and Ag nanoparticles in deposited thin films have been demonstrated by Scanning Electron Microscope (SEM) and Atomic Force Microscope (AFM) and their dimensions as well as separations have been evaluated. As a first approximation, the simulation model of deposited nanoparticles without assuming their dimension and separation distributions has been created. Simulation model defines relation between the nanoparticle dimensions and their separations. Model of deposited nanoparticles has been simulated by the Finite-Difference Time-Domain (FDTD) simulation method. The pulsed excitation has been used and transmission of optical radiation has been calculated from the spectral response by Fast Fourier Transform (FFT) analyses. Plasmonic extinctions have been calculated from measured spectral characteristics as well as simulated characteristics and compared with each other. The nanoparticle dimensions and separations have been evaluated from the agreement between the simulation and experimental spectral characteristics. Surface morphology of thin metal film has been used as an input for the detail simulation study based on the experimental observation of metal nanoparticle distribution. Hence, this simulation method includes appropriate coupling effects between nanoparticles and provides more reliable results. Obtained results are helpful for further deep understanding of thin metal films plasmonic properties and simulation method is demonstrated as a powerful tool for the deposition technology optimizations.

Bianisotropic metamaterials for enhanced chiral fields and forces

Hossein Alizadeh, Björn M. Reinhard, Boston Univ. (United States)

The two enantiomers (mirror-images) of a biomolecule can show drastically different behaviors, requiring the development of sensitive approaches for their identification and separation. Plasmonic nanostructures have shown promise for enhancing the sensitivities of chiral spectroscopies, but the generation of chiral near fields with a specific handedness in the spatial domain surrounding the plasmonic structures remains a challenge. Here we demonstrate that achiral bianisotropic structures, which couple the electric and magnetic fields, can achieve high enhancements of optical chirality in an extended spatial region. Magneto-electric coupling in such structures

facilitates electrically excited magnetic resonances in the near IR and optical regimes, which in turn can result in highly enhanced optical chirality in an extended region of space. We apply this concept to achiral double split ring resonators (DSRRs) and demonstrate their potential in generating enhanced chiral fields and forces. Also, the behavior of optical chirality density gradient and chirality flux in such structures is examined, and it is shown that plasmonically generated chiral forces may pave the way to a new class of chiral biosensors.

Engineering metal-nanoantennae/dye complexes for maximum fluorescence enhancement

Xiang Meng, Richard R. Grote, Jerry I. Dadap Jr., Columbia Univ. (United States); Nicolae-Coriolan Panoiu, Univ. College London (United Kingdom); Richard M. Osgood Jr., Columbia Univ. (United States)

We theoretically investigate the fluorescence enhancement of a molecule placed in a variable (4 - 20 nm) gap of a plasmonic dimer, with different dye molecules as well as different nanoparticle geometries, using a fully vectorial three-dimensional finite-difference time-domain (3D FDTD) method. This work extends previous studies on molecular fluorescence in the vicinity of metal interfaces and single nanoparticles and shows how the radiative emission of a molecule can be further enhanced by engineering the geometry of a plasmonic structure. Through the use of rigorous 3D FDTD calculations, in conjunction with analytic guidance based on temporal coupled-mode (TCM) theory, we achieve accurate fluorescence enhancement calculations for arbitrary-shaped metal nanoparticle antennae. We have obtained the antennae configurations for the optimimized fluorescence enhancement of each of a selected set of dye molecules, which are matched to three different antennae geometries. Our results provide guidance for the rational design of optimized metallic nanoparticle complexes for maximum fluorescence enhancement. Finally, we note that this approach provides a design procedure for antennae assemblies that is useful both for general understanding of molecule-metal structure interaction and experimental efforts in plasmon-enhanced molecular spectroscopy.

Plasmon resonance in ellipsoids and ellipsoidal dimers

Catalina B. Lopez-Bastidas, Univ. Nacional Autónoma de México (Mexico); Leonardo Baez, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico); Jesus Manzanares-Martinez, Univ. de Sonora (Mexico)

Ellipsoidal nanoparticles represent an interesting system to study beyond spherical nanoparticles since the loss of symmetry is easily controled by a single parameter.

The resulting split in plasmon resonance frequency can be tuned modifying the same parameter. Furthermore the presence of more than one mode can be controled by the polarization of the exciting field. When two or more such structures are present the enhancement of the local fields can have strong effects on the optical spectra of system.

We calculate the optical properties of ellipsoidal nanoparticles and ellipsoidal dimers and compare quasi-static approximations with numerical solution of electrodynamic equations.

Prospect of detection and recognition of single biological molecules using ultrafast coherent dynamics in quantum dot-metallic nanoparticle systems

Seyed M. Sadeghi, The Univ. of Alabama in Huntsville (United States)

Conventional plasmonic sensors are based on intrinsic resonances of metallic nanoparticles (localized surface plasmons). In such sensors detection is done by investigating wavelength shifts of such resonances. In this contribution we propose ultra-sensitive time-domain nanosensors based on the impact of ultra-small changes in environmental conditions on the coherent dynamics of hybrid systems consisting of one metallic nanoparticle and one quantum dot. Interaction of these systems with a laser field generates quantum coherence, allowing us to convert minuscule changes in the environment into dramatic optical events detectable by conventional and simple electronic and optical means. These sensors are not based on excitons or plasmons as in conventional sensors, but rather they utilize the way ultra-small changes in the refractive index of environment modify dynamics of coherent exciton-plasmon coupling and the collective molecular resonances (plasmonic meta-resonances) of the hybrid quantum dot-metallic nanoparticle systems. We show when the laser field and the structural conditions of these systems are properly adjusted such that these systems are close to their collective resonances, adsorption of a single molecule to can make the dark (non-emissive), offering large extinction ratio of detection. We show one can adjust the laser field, in terms of its temporal width and intensity, such that these processes can be sensitive for a certain size of molecule, suggesting the possibility of recognition of molecules. A prime feature of our investigation is that it includes the ultrafast quantum dephasing of quantum dots which can happen at elevated temperatures.

Field enhancement with plasmonic nano antennas on silicon-based waveguides

Mahsa Darvishzadeh Varcheie, Caner Guclu, Regina Ragan, Ozdal Boyraz, Filippo Capolino, Univ. of California, Irvine (United States)

Plasmonic nanoantennas have been investigated due to the capability to provide strong near-field enhancements when illuminated by an external electromagnetic field. Surfaces made of plasmonic nanoantennas have been demonstrated to increase signal intensity in surface enhanced Raman scattering by several orders of magnitude. Measurement techniques, however, are expensive and bulky using standard methods for illumination and detection of Raman scattering signals. Our goal is to investigate novel optical structures to develop spectroscopy systems that are inexpensive and mobile by utilizing nanoantennas that are integrated with dielectric waveguides. Particularly, dimers made of gold nanospheres assembled from colloidal solution on top of silicon nitride waveguide are used in this work. This optical structure eliminates the complexity of illumination and detection in traditional schemes, reducing both cost and volume. Resonant dimer nanoantennas are excited by the guided field that exhibits evanescent decay outside of the waveguide. Simulations show that a very strong electric field builds up in the dimer gap with a 25-100 fold field enhancement as compared to the waveguide's modal field at the same location. We further investigate how the field enhancement varies with the dimer location and orientation and how it depends on the waveguide geometry and modes. This is important information to guide level of control of placement on waveguide surfaces using colloidal assembly. Full-wave simulations demonstrate the effectiveness of the investigated optical structures to achieve similar signal enhancement obtained with standard instrumentation measuring signals from dimers scattered light on a planar substrate illuminated by a plane wave.

Angle-resolved far-field scattering spectra of single Ag nanowire over the entire semi-meridian

Jinhyung Kim, Ho-Seck Ee, KAIST (Korea, Republic of); Min-Soo Hwang, Kwang-Yong Jeong, Korea Univ. (Korea, Republic of); Ju-Hyung Kang, Korea Univ. (Korea, Republic of) and KAIST (Korea, Republic of); Hong-Gyu Park, Korea Univ. (Korea, Republic of); Min-Kyo Seo, KAIST (Korea, Republic of)

Scattering properties of a plasmonic nanowire have been investigated through dark-field microscopy, back-focal plane imaging and so on. Surface plasmon polaritons (SPPs) supported by the metallic nanowire have a large wavevector and cause strong scattering radiations to the direction of a large angle even beyond the numerical aperture (N.A.) of the microscope objective employed in the conventional methods. To overcome this limitation and obtain the full information of scattering characteristics, we directly measured far-field scattering spectra of a single Ag nanowire over the entire semi-meridian with varying detection angle. SPPs of the nanowire on a coverslip are excited by white-light illumination focused on one end of the nanowire by an objective. The detection part, 0.23 m distant from the nanowire, scans the entire northern semi-meridian with an angular resolution of 2 degrees and collects scattering radiations into an optical fiber attached to a spectrometer. Beyond the N.A. of the focusing objective, purely scattered signal is detected, while, within the N.A., the extinction by the nanowire is observed. The angle-resolved scattering spectra reveal that the far-field scattering pattern of the nanowire carries two features of the near-field: Fabry-Perot resonances of SPPs propagating along the nanowire and phase-matching conditions between SPPs and free-propagating radiation depending on the emission angle and wavelength. The dispersion relation of SPPs can also be precisely retrieved, since the resolved angle corresponds to the wavevector. We believe that the study on the angle-resolved far-field scattering spectra will be useful to understand scattering characteristics of a desired optical nanostructure.

A low-cost, high-sensitivity surface enhanced raman scattering substrate by Si nanowire arrays decorated with Au nanoparticles and backplane

Bi-Shen Lee, National Tsing Hua Univ. (Taiwan); Ding-Zheng Lin, Industrial Technology Research Institute (Taiwan); Ta-Jen Yen, National Tsing Hua Univ. (Taiwan)

Raman spectra provide rich vibrational signals that represent the fingerprint of molecules, and more importantly, such signals are insensitive to water so that recently the technique of Raman scattering emerges a promising method for environmental and biological trace analysis. Nevertheless, the scattering cross section of Raman signals is usually small, and therefore it is crucial to further enhance the signals of Raman scattering. In this work, we demonstrate a low-cost and highly sensitive surface enhanced Raman scattering (SERS) substrate, which is comprised of the silicon nanowire (SiNW) array decorated with Au nanoparticles (AuNPs) on the surface and incorporated with a layer of Au backplane at the bottom. Firstly, the SiNW array was prepared by a metal-assisted chemical etching (MaCE) method as a template of the SERS substrate. Then, the gold nanoparticles (AuNPs), which were decorated on the surface of SiNWs array by an electron-beam evaporator under oblique angle deposition (OAD), enable localized surface plasmon resonance (LSPR) to substantially intensify the signal of Raman scattering from the analyte. Besides, we deposited an additional Au layer at the bottom of the SiNW array by electron-beam deposition under normal incidence. This additional Au layer, termed as a metal backplane (MBP), facilitates to reflect the back-scattered field rather than being absorbed by the silicon substrate, leading to the further enhancement of the SERS signals. Finally, the performance of this SERS substrate was optimized by a statistical Taguchi method. Our experimental verification indicates that for the analyte of 10-2 M self-assembled monolayer (S.A.M.) of thiophenol molecules, our tailored SERS substrate presents the average Raman signal up to1740 counts per second under a near infrared laser excitation (785 nm), which is 1.78 times stronger than a commercialized SERS substrate (Klarite®). Furthermore, our low-cost and high-sensitivity SERS substrate preforms reliably, showing a small coefficient of variation (C.V.) about 4.2%

Nanoscale dimples for field enhancement of organic thin films

Arkardiusz J. Goszczak, Jost Adam, Pawel P. Cielecki, Jacek Fiutowski, Horst-Günter Rubahn, Univ. of Southern Denmark (Denmark)

A promising method for improving the power conversion efficiencies of organic solar cells (OSCs) is by incorporating structured electrodes in their thin film architecture, improving the light absorption in the device's active layers. A cheap and large-scale production compatible method for structuring the electrodes in OSCs is by the use of Anodic Alumina Oxide (AAO) membranes. Here, nano-scale pores of controlled dimensions are formed through anodic oxidation of sputter deposited high purity aluminum (Al) films. The Al deposition conditions are controlled in order to modify the roughness and the grain size of the Al layers, as those parameters critically affect the subsequent pore formation during the anodization process. The anodization of the Al layers occurs in an electrochemical cell in H2SO4, H2C2O4 and H3PO4 solutions, in order to tune the AAO pore diameter and interpore distance. Following anodization, the fabricated AAO is selectively etched away in H2CrO4/H3PO4 mixtures, in order to reveal the underlying Al nanoscale dimples, which are present at the bottom of the pores. We investigate the light-trapping properties of these dimples as a function of their dimensions and ordering. The dimples' optical properties are characterized via reflection measurements, supported by non-destructive laser ablation of polymer coatings. The resulting polarization-dependent field enhancement measurements are compared to FDTD calculations to further explain the mechanisms of light-trapping in dimple-structured organic thin film devices.

9547-140, Session PWed

Structure, configuration, and sizing of Ni nanoparticles generated by ultrafast laser ablation in different media

David Muñetón Arboleda, Ctr. de Investigaciones Ópticas (Argentina); Jesica M. Santillán, Ctr. de Investigaciones Ópticas (Argentina) and Univ. Nacional de Catamarca (Argentina); Luis J. Mendoza Herrera, Ctr. de Investigaciones Ópticas (Argentina); Marcela B. Fernández

van Raap, Univ. Nacional de la Plata (Argentina) and Facultad de Ciencias Exactas (Argentina); Diego Muraca, Univ. Estadual de Campinas (Brazil); Daniel C. Schinca, Lucia B. Scaffardi, Ctr. de Investigaciones Ópticas (Argentina) and Univ. Nacional de la Plata (Argentina)

In recent years, nickel nanoparticles (Nps) have increased scientific interest because of their extensive prospects in catalysts, conducting pastes, information storage, large-scale batteries and biomedicine.

Several works on Ni Nps generation by laser ablation have appeared in the literature in the last years, using different pulsed laser regimes and different media have been published recently.

However, there are no works reporting on the use of fs-regime laser ablation of Ni in liquids and the corresponding characterization of the obtained colloids. In this work we analyze the characteristics of species, structure (bare core or core-shell), configuration and size distribution of Nps generated by fs pulse laser ablation over a Ni solid target in n-heptane and water. We report the presence of NiO-Ni core-shell and hollow Ni Nps in these colloids obtained, discussing a mechanism for the formation of different species present in the colloidal suspensions. These were experimentally characterized using AFM and TEM microscopy, as well as Optical Extinction Spectroscopy (OES). Extinction spectra were modeled using Mie theory through an appropriate modification of the complex experimental dielectric function, taking into account a size-dependent corrective term for each free and bound electron contribution. Experimental UV-visible-NIR spectra were reproduced considering a size distribution of bare core, hollow and core-shell structures Nps.

In both media, Ni Nps shape and size distribution agrees with that derived from TEM and AFM analysis.

9547-141, Session PWed

Surface plasmon polariton interface of left-handed metamaterial with cylindrical anisotropy and dielectric medium

Semen Andronaki, Egor Gurvitz, Mikhail Khodzitsky, Anna Vozianova, ITMO Univ (Russian Federation)

In recent years the role of surface plasmons polaritons (SPP) in nano-optics [1] gaining popularity because of the wide applications in areas such as the development of waveguides, biosensors, near-field microscopy and cloaking devices [2]. Therefore it needs to search new ways to generate the SPP due to high actuality of plasmonic applications in terahertz frequency range. In this paper the mechanism of excitation of SPP at the interface of left-handed metamaterial with cylindrical anisotropy and dielectric medium at THz frequency range [3]. Numerical simulation of this structure was performed using COMSOL Multiphysics, Frequency Domain solver.

Fabrication and optical properties of gold nano aperture array using plating technique for plasmonic infrared filter

Hong-Kun Lyu, Hui-Sup Cho, Young-Jin Park, DGIST (Korea, Republic of); Sung-Hyun Jo, Jang-Kyoo Shin, Kyungpook National University (Korea, Republic of)

We report on plating technique to fabricate the gold nano aperture array and the optical properties. Firstly, we designed a structural model of the gold nano aperture array and simulated the spectral variation in the wavelength transmission. For the simulation, we used a commercial computer simulation tool utilizing the FDTD method. SiO2 was used as the substrate insulator, top-side insulator, and the fill material in the cylindrical aperture. We applied gold as the metal layer; dispersion information for gold was derived from the Lorentz–Drude model. Next, we fabricated the nano aperture array on the glass substrate. To apply a plating technique, the seed layer was formed on the substrate, and the PR pattern of the nono aperture array was built up using electron-beam lithograph machine. And then, we formed the gold plating layer in an optimized bath. Finally, the PR pattern was removed in the PR stripper. Furthermore, we measured the optical characteristics of gold nono aperture array using UV-VIS-IR spectrophotometer.

Separation of surface plasmon polariton modes generated in a multilayer structure

Boram Kim, Hong-Gyu Ahn, Kyongseok Kim, Sung-Ho Lee, Daeyeon Kim, Yu-mee Jeoug, Seung-Han Park, Yonsei Univ. (Korea, Republic of)

In a thin metallic film surrounded by the dielectric media with different refractive indices, two different modes of surface plasmon polariton (SPP) are generated. These two modes are called long-range SPP and short-range SPP, respectively. By varying the thickness of the metallic film, amplitude ratio of the two modes can be controlled. In addition, these modes can be mixed as long as the film thickness is thin enough (closed to the skin depth). In this talk, the field distributions generated by the SPPs are presented.

9547-77, Session 15

Imaging metallic nanostructures with second and third order nonlinear optical response *(Invited Paper)*

Emeric Bergmann, Christian Jonin, Emmanuel Benichou, Pierre-François Brevet, Institut Lumière Matière (France)

Imaging metallic structures to determine their nanoscale optical properties is of utmost importance not only to reveal their morphology but also their ability to be incorporated into devices. Combining linear and nonlinear optical imaging may then turn to be highly fruitful because the corresponding optical responses stem from different origins. For instance, odd order responses like the first linear and the third order responses essentially probe volume effects whereas even orders like the second order response probe surface effects in centrosymmetric media, like gold and silver. These effects may arise from the fabrication methods employed to produce the structures like manufacturing defects appearing as shape distortions. This striking difference between the different contributions to the nonlinear optical response of these metallic structures can therefore be used to reveal a highly refined picture of the nanostructures.

We report in this study the combined first, second and third order responses from single gold metallic nanoparticles as well as their assemblies. The different features observed will be discussed in light of the origin of the different orders observed.

Interfacing ion-exchanged waveguide for the efficient excitation of surface plasmons

Josslyn Beltran Madrigal, Univ. de Technologie Troyes (France); Martin Berthel, Institut NÉEL (France); Florent Gardillou, Teem Photonics S.A. (France); Ricardo Tellez Limon, Christophe Couteau, Univ. de Technologie Troyes (France); Denis Barbier, Teem Photonics S.A. (France); Aurelien Drezet, Institut NÉEL (France); Rafael Salas-Montiel, Univ. de Technologie Troyes (France); Serge Huant, Institut NÉEL (France); Sylvain Blaize, Univ. de Technologie Troyes (France)

Several works have already shown that the excitation of plasmonic structures through waveguides enables a strong light confinement and low propagation losses [1]. This kind of excitation is currently exploited in areas such as biosensing [2], nanocircuits[3] and spectroscopy[4].

Efficient excitation of surface plasmon modes (SPP) with guided modes supported by high-index-contrast waveguides, such as silicon-on-insulator waveguides, had already been shown [1,5], however, the use of weak-confined guided modes of an ion exchanged waveguide on glass as a source of excitation of SPP represents a scientific and technological breakthrough. This is because the integration of plasmonic structures into low-index-contrast waveguide increases the bandwidth of operation and compatibility with conventional optical fibers.

In this work, we describe how an adiabatic tapered coupler formed by an intermediate high-index-contrast layer placed between a plasmonic structure and an ion-exchanged waveguide decreases the mismatch between effective indices, size, and shape of the guided modes. This hybrid structure concentrates the electromagnetic energy from the micrometer to the nanometer scale with low coupling losses to radiative modes. The electromagnetic mode confined to the high-index-contrast waveguide then works as an efficient source of SPP supported by metallic nanostructures placed on its surface.

We theoretically studied the modal properties and field distribution along the adiabatic coupler structure. In addition, we fabricated a high-index-contrast waveguide by electron beam lithography and thermal evaporation on top of an ion-exchanged waveguide on glass. This structure was characterized with the use of near field scanning optical microscopy (NSOM). Numerical simulations were compared with the experimental results.

Controlling light scattering and emission at subwavelength scale with plasmonic nanopatch antennas

Zilong Wu, Yuebing Zheng, The Univ. of Texas at Austin (United States)

Controlling light scattering and emission at subwavelength scale has significant implications for solar energy conversion, sensing, and nanophotonic devices. Plasmonic nanopatch antennas (PNAs), which consist of plasmonic nanoparticle coupled with metallic films, have shown directionality of radiation and large emission rate enhancement due to the strong plasmonic waveguide modes within the spacer layer. Herein, we comparatively study the light scattering and emission behaviors of a series of plasmonic nanopatch antennas (PNAs) with different plasmonic nanoparticles (i.e., nanosquare, nanotriangle, nanorod, and nanodisk) to develop the design rules of the PNAs. Using finite-difference time-domain (FDTD) simulations, we show that the shape and size of plasmonic nanoparticles can be tuned to control the resonance peak, intensity, directionality, and spatial distribution of the scattering light as well as the directionality, spatial distribution, spontaneous emission rate, quantum efficiency, and radiation enhancement factor of light emission. For example, high radiative quantum efficiency (0.74) and radiation enhancement factor (>20) can be achieved by disk PNA, while triangle PNA shows remarkable spontaneous emission rate enhancement of over 2,500. The effects of locations of emitters relative to the PNAs on the emission properties are also examined. Our results pave the way towards the rational design of PNAs for the optimal light scattering and emission as required by targeted applications.

Controlling the ultrafast hot electron dynamics in hybrid plasmonic nanostructures

Hayk Harutyunyan, Emory Univ. (United States)

Plasmons hold promise for applications in photonic circuitry because of their ability to squeeze light into sub-wavelength dimensions and also for their ultrafast response times. To this end, it is important to fabricate plasmonic systems that can generate large optical signals at ultrafast timescales. Plasmonic devices based on Kerr-type nonlinear optical effects, typically demonstrate picosecond timescales attributed to electron -- phonon scattering. By designing and fabricating metal-oxide hybrid nanosystems with ultra-high field enhancements we were able to demonstrate much faster, femtosecond dynamics of the optical response based on hot electron generation. Moreover, our experiments show that the nonlinear optical response can be further tuned in both time and spectral domains by tuning the material composition of our hybrid nanomaterials.

9547-81, Session 15

Resonant elements contactless coupled to bolometric micro-stripes

Alexander Cuadrado, José Manuel López-Alonso, Juan Carlos Martínez-Antón, Jose-Miguel Ezquerro, Univ. Complutense de Madrid (Spain); Francisco J. Gonzalez, Univ. Autónoma de San Luis Potosí (Mexico); Javier Alda, Univ. Complutense de Madrid (Spain)

One of the main technical difficulties in the fabrication of optical antennas working as light detectors is the proper design and manufacture of auxiliary elements as lead lines and signal extraction structures. These elements need to be quite small to reach the location of the antennas and should have a minimal effect on the response of the device. Unfortunately this is not an easy task and signal extraction lines resonate along with the antenna producing a complex signal that usually masks the one given by the antenna. In order to decouple the resonance from the transduction we present in this contribution a parametric analysis of the response of a bolometric stripe that is surrounded by resonant dipoles with different geometries and orientations. We have checked that these elements should provide a signal proportional to the polarization state of the incoming light.

9547-82, Session 15

Hybridization models of gold nanoantennas arrays in polarization dependent evanescent waves

Kuo-Ping Chen, Yi-Hsun Chen, Che-Yuan Chang, Yu-Lun Kuo, Zhen-hong Yang, National Chiao Tung Univ. (Taiwan)

The plasmonic coupling of nanoantennas could be explained by the plasmon hybridization model introduced. For symmetric nanoparticles pairs, the coupled mode can be shifted to higher or lower frequencies, depending on the phase of the fields from each nanoparticle. In p-polarization, the in-phase response is called bonding mode and out of phase response is called antibonding mode, which are analogous to the molecular orbital theory. The bonding mode, located at a lower energy level, could be strongly excited by normal incidence, but antibonding mode, located at a higher energy level, could hardly excited by normal incident plane wave and which is not easy to be observed. In literatures, the antibonding mode could only be excited by highly focused laser beams, the radiation from a local emitter, and the evanescent field produced by total internal reflection9. Although the observation is not easy, the antibonding mode has brought a lot of attention because of the slower radiative decay and narrower linewidths. However, there are not many researches discussing the sensor application of the plasmonic antibonding mode of nanoantenans arrays.

In this work, gold nanoantennas antibonding mode in TM and TE polarized evanescent field is investigated and the sensitivity to the refractive index change of surrounding medium is compared to bonding mode in normal incidence. Furthermore, in normal incidence, due to the impedance mismatch between the dielectric and substrate, strong reflectance happens at the resonance in bonding mode which could reduce the coupling efficiency. In order to achieve higher energy coupling efficiency, total internal reflection could be used to minimize the impedance mismatch and transfer the input energy into antibonding mode plasmonic resonance.

Detecting single DNA molecule interactions with optical microcavities *(Invited Paper)*

Frank Vollmer, Max-Planck-Institut für die Physik des Lichts (Germany)

Detecting molecules and their interactions lies at the heart of all biosensor devices, which have important applications in health, environmental monitoring and biomedicine. Achieving biosensing capability at the single molecule level is, moreover, a particularly important goal since single molecule biosensors would not only operate at the ultimate detection limit by resolving individual molecular interactions, but they could also monitor biomolecular properties which are otherwise obscured in ensemble measurements. For example, a single molecule biosensor could resolve the fleeting interaction kinetics between a molecule and its receptor, with immediate applications in clinical diagnostics.

We have now developed a label-free biosensing platform that is capable of monitoring single DNA molecules and their interaction kinetics[1], hence achieving an unprecedented sensitivity in the optical domain, Figure 1. We resolve the specific contacts between complementary oligonucleotides, thereby detecting DNA strands with less than 2.4 kDa molecular weight. Furthermore we can discern strands with single nucleotide mismatches by monitoring their interaction kinetics.

Our device utilizes small glass microspheres as optical transducers[1,2, 3], which are capable of increasing the number of interactions between a light beam and analyte molecules. A prism is used to couple the light beam into the microsphere.

Ourr biosensing approach resolves the specific interaction kinetics between single DNA fragments. The optical transducer is assembled in a simple three-step protocol, and consists of a gold nanorod attached to a glass microsphere, where the surface of the nanorod is further modified with oligonucleotide receptors. The interaction kinetics of an oligonucleotide receptor with DNA fragments in the surrounding aqueous solution is monitored at the single molecule level[1].

The light remains confined inside the sphere where it is guided by total internal reflections along a circular optical path, similar to an acoustic wave guided along the wall of St. Paul's Cathedral. These so called whispering gallery modes (WGM) propagate with little loss, so that even a whisper can be heard on the other side of the gallery. In the optical case, the light beam can travel many thousand times around the inside of the microsphere before being scattered or absorbed, thereby making numerous interactions with an analyte molecule, bound to microsphere from surrounding sample solution. The most part of the light intensity, however, remains inside the microsphere, just below the reflecting glass surface, resulting in a relatively weak interaction between the light and the bound molecule.

To enhance this interaction further, we attach tiny 42 nm x 12 nm gold nanorods to the glass surface. When passing a nanorod, the lightwave induces oscillations of conduction electrons, resulting in so called plasmon resonance. These nanorod plasmons greatly enhance the light intensity on the nanorod, so that the interaction of the light with a molecule attached to the nanorod is also enhanced[4-6]. This enhanced interaction results in an increase in sensitivity by more than a factor of one thousand, putting our experiments of single DNA molecule detection within reach.

For the specific detection of nucleic acids, we attach single-stranded DNA to the nanorod and immerse our device in a liquid solution. When a matching, i.e. complementary DNA fragment binds from solution to the "bait" on the nanorod, the enhanced interaction with the light results in an observable shift of the WGM wavelength. Since light propagates in a WGM only for a very precise resonance wavelength or frequency, this shift can be detected with great accuracy[3]. On our current biosensor platform, we detect wavelength shifts with an accuracy of less than one femtometer, resulting in an extremely high sensitivity for biosensing, which we leverage for the specific detection of single 8 mer oligonucleotides as well as the detection of less than 1 kDa intercalating small molecules[1].

Impedance-matching analysis in IR leaky-wave antennas

Navaneeth Premkumar, Yuancheng Xu, Brian A. Lail, Florida Institute of Technology (United States)

Planar leaky-wave antennas (LWA) that are capable of full-space scanning have long since been the pursuit for applications including integration onto vehicles and into cameras for wide-angle of view beam-steering scenarios. Recently such a leaky-wave surface (LWS) was designed for long-wave infrared frequencies with frequency scanning capability. The LWS is based on a microstrip patch array design of a leaky-wave impedance surface and is made up of gold microstrip patches on a grounded zinc sulphide substrate. A 1D composite right/left-handed (CRLH) metasurface made by periodically stacking a unit cell of the LWS in the longitudinal direction to

form a LWA was designed. This paper deals with loading the LWA with a nickel bolometer to collect leaky-wave signals. The LWA radiates a backward leaking wave at 30 degrees at 28.2THz and scans through broadside for frequencies 20THz through 40THz. The paper deals with effectively placing the bolometer in order for the collected signal to exhibit the designed frequency regime. An effective way to impedance match the load to the antenna is also explored. The benefit of such a metasurface/holographic antenna-coupled detector is its ability to provide appreciable capture cross-sections while delivering smart signals to sub-wavelength sized detectors. Due to their high-gain, low-profile, and ease of fabrication, this IR LWA harbors great potential in the areas of high resolution infrared imaging and uncooled multiband focal plane arrays.

9547-85, Session 16

Infrared surface phonon polariton waveguides on SiC substrate

Yuchen Yang, Franklin Manene, Brian A. Lail, Florida Institute of Technology (United States)

Surface plasmon polariton (SPP) waveguides harbor many potential applications at visible and near-infrared (NIR) wavelengths. However, the highly lossy metal in the waveguide yields very weak or nonexistent response in the mid and long wave infrared range. This is one of the major reasons for the rise in popularity of surface phonon polariton (SPhP) waveguides in recent research and micro-fabrication pursuit. Silicon carbide (SiC) is a good candidate in SPhP waveguides since it has negative dielectric permittivity in the LWIR spectral region, indicative that coupling to surface phonon polaritons is realizable. Introducing surface phonon polaritons for waveguiding provides good modal confinement and enhanced propagation length. A hybrid waveguide structure at long-wave infrared (LWIR) is demonstrated in which an eigenmode solver approach in Ansys HFSS was applied. The effect of a three layer configuration i.e., silicon wire on a benzocyclobutene (BCB) dielectric slab on SiC, and the effects of varying their dimensions on the modal field distribution and on the propagation length, is studied.

9547-86, Session 17

Broadband toroidal response in three-dimensional plasmonic metamaterial *(Invited Paper)*

Din Ping Tsai, Academia Sinica (Taiwan) and National Taiwan Univ. (Taiwan); Chun Yen Liao, Wei Ting Chen, Pin Chieh Wu, Yao-Wei Huang, Wei-Yi Tsai, Mu Ku Chen, Hao Tsun Lin, Yi-Teng Huang, Ting-Yu Chen, Jia Wern Chen, National Taiwan Univ. (Taiwan); Vassili Savinov, Nikolay I. Zheludev, Univ. of Southampton (United Kingdom)

The unusual property of toroidal dipole response [1] is a non-radiating configuration which results from destructive interference between electromagnetic fields [2]. The toroidal dipole moment is usually neglected because of the intensity is much weaker than electric or magnetic dipole moment. Recently, the toroidal moments signal has been amplified significantly by using metamaterials [3, 4].

In this paper, we design a new toroidal metamaterials by using mutual coupling between a dumbbell-shaped gold plate and a vertical split-ring resonator (VSRR). Using double alignment e-beam lithography technology, we fabricate sample that shows the resonant toroidal responses at optical region. The numerical calculation of radiated power for various multipole moments is also performed for the verification of toroidal response.

Low-cost and high-throughput realization of metasurface-based absorber/emitter for thermal-photovoltaic cells

Alireza Bonakdar, Sung Jun Jang, Hooman Mohseni, Northwestern Univ. (United States)

A thermal photovoltaic cell (TPV) is an optical heat engine that can extract energy from an emitter with elevated temperature. In theory, the efficiency of a TPV can reach to 80% by wavelength conversion, yet in practice, only 3.2% efficiency has been achieved. The main physical drawback is to maintain the device operation at very high temperature while managing total solar spectrum absorption and efficient coupling of the narrow-band thermal radiation into the photovoltaic cell. In this vein, utilizing of a nanophotonic structure to undergo the wavelength conversion of solar energy is inevitable. Furthermore, low cost, large area and high throughput realization of such a structure brings TPV beyond the research lab.

Simultaneous tailoring of UV/visible and mid-infrared spectrums requires sub-100-nm feature size, which is challenging with conventional photolithography if it is not impossible. We have developed a microsphere deep-UV lithography that can produce minimum feature size of ~ 50 nm at extremely low cost and high throughput. In this work, we demonstrate a metasurface platform fabricated with this lithography technique which has omni-polarization and -angle absorption in visible spectrum and efficient emission at mid-infrared as confirmed both by FDTD simulation and Fourier transform infrared spectroscopy (FTIR) measurement. The developed technique is promising technology to expedite TPV in real-life energy harvesting applications.

9547-89, Session 17

Determination of effective permittivity and permeability for plasmonic absorber metamaterials in infrared

Yongqian Li, Xiaoying Li, Northwestern Polytechnical Univ. (China)

The estimation of effective optical properties of the nanostructures absorber materials will help to understand its absorption, reflection and radiation characteristics. The effective optical parameters of the metamaterials are estimated by the S-parameters proposed by Smith D.R in 2002, which assumes the inhomogeneous metamaterials to be homogeneous bulk material. Here we present an analytical theory in which the Drude-Lorentz model is adopted to describe the dispersion relations of plasmonic absorber metamaterials in infrared. Based on the effective electron density and the equivalent circuit analysis, a functional description between the geometrical parameters and its optical parameters has been built. The model establishes the quantitative relationship between structure parameters, material parameters and its optical constants. The present simulations and experiments result illustrated the proposed algorithm and the impact on

the retrieved optical parameters of the perfect absorption metamaterials. An accurate prediction for their dispersive behavior can be obtained at IR wavelengths.

9547-90, Session 17

Structured light-matter interactions in optical nanostructures *(Invited Paper)*

Natalia M. Litchinitser, Jingbo Sun, Mikhail I. Shalaev, Tianboyu Xu, Yun Xu, Univ. at Buffalo (United States); Apra Pandey, CST of America, Inc. (United States)

We show that unique optical properties of metamaterials open unlimited prospects to "engineer" light itself. For example, we demonstrate a novel way of complex light manipulation in few-mode optical fibers using metamaterials highlighting how unique properties of metamaterials, namely the ability to manipulate both electric and magnetic field components, open new degrees of freedom in engineering complex polarization states of light. We discuss several approaches to ultra-compact structured light generation, including a nanoscale beam converter based on an ultra-compact array of nano-waveguides with a circular graded distribution of channel diameters that coverts a conventional laser beam into a vortex with configurable orbital angular momentum and a novel, miniaturized astigmatic optical element based on a single biaxial hyperbolic metamaterial that enables the conversion of Hermite-Gaussian beams into vortex beams carrying an orbital angular momentum and vice versa. Such beam converters is likely to enable a new generation of on-chip or all-fiber structured light applications. We also present our initial theoretical studies predicting that vortex-based nonlinear optical processes, such as second harmonic generation or parametric amplification that rely on phase matching, will also be strongly modified in negative index materials. These studies may find applications for multidimensional information encoding, secure communications, and quantum cryptography as both spin and orbital angular momentum could be used to encode information; dispersion engineering for spontaneous parametric down-conversion; and on-chip optoelectronic signal processing.

9547-91, Session 18

On chip integration and light-matter interactions in active plasmonic devices *(Invited Paper)*

Uriel Levy, Liron Stern, Boris Desiatov, Meir Grajower, The Hebrew Univ. of Jerusalem (Israel)

In this talk we demonstrate light matter interactions in active plasmonic devices. We begin by describing our recent results on plasmonic enhanced silicon Schottky detectors for the near IR and the role of structural optimization in enhancing the functionality of these detectors. Next, we deal with the important task of measuring the temperature of plasmonic devices at the nanoscale. Finally, we describe our recent results related to a coupled plasmonic-atomic system which provides the capability of controlling the resonant lineshape at will.

9547-92, Session 18

Optical switching of nematic liquid crystal film arising from induced electric field of localized surface plasmon resonance

Makiko T. Quint, Silverio Delgado, Zachary S. Nuno, Linda S. Hirst, Sayantani Ghosh, Univ. of California, Merced (United States)

We demonstrate a method to control nematic liquid crystal (LC) molecular orientation in a few micron thick films by utilizing the localized surface plasmon (LSP) effect of gold nano-particles (AuNPs). This re-orientation is reversible and repeatable, and does not require any specific alignment coatings and additional applied electric field, instead responding to excitation resonant with the LSP absorption band. Our samples have AuNPs with peak absorption in the spectral range of 500 – 550 nm and these AuNPs are deposited on a glass slide with a coating of LC molecules on top. We use optical techniques for quantitative analysis, such as measuring the LC switching time-scales and threshold power requirements in our samples, and we analyze these characteristics by plotting the optical transmission through the samples as a function of time to extract the time-scale over which the LC re-orientation takes place. Our results show that while the total transmission intensity increases strongly with incident power, it shows weak dependence on temperature. Further, we are able to control and vary the in-plane directionality of the LC molecules by altering the linear polarization of the incident excitation. Based on our results, these devices have the potential to act as optically activated LC switches and enhance the performance of current LC devices. It may lead to the design of completely new devices such as electronic skins, ultra-thin low power displays, and autonomous filters.

9547-93, Session 18

TCO/metal hybrid structures for surface plasmon enhanced light emitting in the near infrared range

Xu Fang, Shiyu Zhang, Liang Xia, Hui Ye, Zhejiang Univ. (China)

Transparent conductive oxides (TCOs, such as Sn:In2O3, Al:ZnO, Ga: ZnO et al) have re-drawn people's attention as alternative candidates of noble metals (particularly Ag or Au) in the field of plasmonic for the reasons of property tunable and low losses et al. However even for Sn:In2O3 (ITO, reported highest conductivity), the metallic property lies in the near infrared (NIR) range exhibiting the real part permittivity ?' was around -3 at communication wavelength of 1.55?m. Under this circumstance, surface plasma polaritons (SPPs) was hard to be exited on the interface between ITO and surrounded dielectric materials with large permittivity. Hence, in order to explore the potential use of TCOs in the applications of silicon photonics (for permittivity of silicon and germanium are 11.6 and 16 at 300K, respectively), we design a hybrid structure of ITO/metal or ITO/metal/ITO as surface plasmonic materials in NIR. The electrical and optical property of hybrid structure was manipulated accordingly by changing the portion of the introduced metal while maintaining a lower loss than bare metals. The highest carrier concentration of the hybrid structure reached 3?10^22cm^-3, definitely the same magnitude of noble metals. Magnetron sputtering and atomic layer deposition (ALD) can be used to deposit the hybrid ITO/metal structure, in which metal represents gold (Au), and iridium (Ir). The normalized radiative decay rate of light emitted by germanium quantum dots reaches a maximum enhancement of ~8-fold with the assistance of ITO/metal hybrid structure according to the finite difference time domain (FDTD) simulation.

9547-94, Session 18

Optics and nonlinear buckling mechanics in large-area, highly stretchable arrays of plasmonic nanostructures

Hui Zhang, Rice Univ. (United States); Li Gao, Univ. of Illinois at Urbana-Champaign (United States); Yihui Zhang, Northwestern Univ. (United States); Xu Xie, Univ. of Illinois at Urbana-Champaign (United States); Sage Doshay, Stanford Univ. (United States); Hui Fang, Univ. of Illinois at Urbana-Champaign (United States); Jonathan A. Fan, Stanford Univ. (United States); Peter Nordlander, Rice Univ. (United States); Yonggang Huang, Northwestern Univ. (United States); John A. Rogers, Shad Deesha, Siyi Xu, Univ. of Illinois at Urbana-Champaign (United States)

Large scale, dense arrays of plasmonic nanodisks (Au) on low modulus, high elongation elastomeric substrates (PDMS) represent a class of tunable optical system, with reversible ability to shift plasmon resonances, originating from array deformation, over a range of nearly 600nm in the visible region. At the most extreme levels of mechanical deformation (strains >100%), non-linear buckling processes transform initially planar arrays into three dimensional configurations, in which the nanodisks rotate out of the plane, giving rise to an increase of transition rate, to form linear arrays with 'wavy' geometries. Analytical and finite element models capture not only the physics of these buckling processes, including all of distinct modes that occur, but also the quantitative effects of these deformations on the plasmonic responses. The results have relevance to mechanically tunable optical systems, with potential relevance to soft optical sensors that integrate on or in the human body.

9547-95, Session 18

Exploiting local light helicity to direct emission *(Invited Paper)*

Laurens K. Kuipers, FOM Institute for Atomic and Molecular Physics (Netherlands)

Beams propagating in free space can carry angular orbital momentum [1]. The heart of such a beam is typically formed by a vortex or optical singularity. Optical singularities occur in many far-field optical phenomena, e.g., diffraction patterns or caustics [2]. It turns out that such singularities also readily occur in light fields surrounding photonic nanostructures. This is of particular interest as those near fields often contain all 6 vector components of the electro-magnetic field, i.e., the waves cannot be considered as purely transverse.

Here, we will show how ubiquitous optical singularities at the nanoscale seem to be. We illustrate this by visualizing the fields around two prototypical photonic nanostructures: a subwavelength hole in a metal film and a photonic crystal waveguide. Vector-field-selective near-field microscopy is used to locate the singularities and investigate their topology. We show that by controlling the incident beam, in the case of the hole, we can control the spatial positions of the singularities [3]. For the photonic crystal waveguide we identify both phase- and polarization singularities. By separating the contributions for the electric and magnetic field [4,5] we show that singularities indeed occur in both fields. We trace the positions of the singularities at different heights, i.e., orthogonal to the propagation direction of the light. The lateral positions are not fixed with respect to the geometry and, perhaps more interestingly, that the trajectory of the electric fields singularities are different from their magnetic cousins [6].

The existence of the singularities at the nanoscale results in a local helicity in the field. We show that this helicity can be used to control the emission of circular dipoles, i.e., dipoles that are associated with orbital angular momentum-changing transitions which are prevalent in solid-state qubits. We experimentally map the coupling of classical, circular dipoles to photonic modes in a photonic crystal waveguide. We show that, depending on the combination of the local helicity of the mode and the dipole helicity, circular dipoles can couple to left- or rightwards propagating modes with a near-unity directionality. The maps are in excellent agreement with calculations [7]. Our measurements, therefore, demonstrate the possibility of coupling spin to photonic pathway opening avenues for new ways to process quantum information.

Interaction between spin and orbital angular momentum of light in optical tweezers *(Invited Paper)*

Halina Rubinsztein-Dunlop, David Carberry, Timo A. Nieminen, The Univ. of Queensland (Australia); Daryl C. Preece, Univ. of California, San Diego (United States); Alexander B. Stilgoe, The Univ. of Queensland (Australia)

Since 1995 the transport of optical angular momentum by optical vortex beams or/and Gaussian beams carrying spin angular momentum has been applied to the rotation and twisting of microscopic objects in optical traps. Even earlier, optical vortex traps had been proposed as a method to reduce the scattering forces that oppose optical trapping; in the ray optics picture, only high-angle rays contribute to the gradient force, and the use of a hollow beam eliminates the low-angle rays that would still contribute to the scattering force.

A large variety of methods have been used to sculpt beams carrying orbital angular momentum and spin angular momentum and to determine the optimum geometries that yield maximum efficiency of transfer of these light momenta to microscopic objects. The transfer of spin can be quantitatively measured by simply analysing the state of polarisation of the light transmitted through a spinning object if only all of the transmitted light can be collected for analysis. However a direct measurement of orbital angular momentum for highly focused beams is more difficult. We present overview of these methods and describe a direct quantitative measurement of the orbital angular momentum, in non-paraxial geometry. We study the coupling between the spin and orbital angular momentum. We also investigate, both theoretically and experimentally optimal geometries of these beams to couple to optimally designed microstructures and their applications in studies of biological and bioanalog systems.

Angular momentum transfer to trapped particles in vacuum

Kishan Dholakia, Yoshihiko Arita, Tom Vettenburg, Juan Aunon, Univ. of St. Andrews (United Kingdom); Ewan Wright, College of Optical Sciences, The Univ. of Arizona (United States); Susan E. Skelton, Michael Mazilu, Univ. of St. Andrews (United Kingdom)

Optical manipulation of mesoscopic particles remains a very powerful method for both fundamental and applied science. The field has seen great advances for the biosciences including new studies of single molecules and force studies on cells. In the physical sciences, studies have also seen groundbreaking work in many areas. In this paper we describe some of the recent work at St Andrews looking particularly at the trapping of particles in liquid, air and vacuum with an emphasis on optical angular momentum transfer.

An optically trapped nano- or micro- particle in vacuum is an ideal system for investigating quantum effects as the particle is well isolated from the thermal environment. Recently, we have worked on the rotation of birefringent particles (vaterite) in vacuum and also studied these particles and silica particles in beams with orbital angular momentum.

Optical trapping using focused optical vortices with broadband flat spiral zone plates

Mark Jayson M. Villangca, DTU Fotonik (Denmark); Shengtao Mei, Muhammad Qasim Mehmood, Cheng-Wei Qui, National Univ. of Singapore (Singapore); Jesper Glückstad, DTU Fotonik (Denmark)

Light has been used to exert microscopic force on dielectric particle through conservation of linear momentum as light refracts through the particle. In the past years, it has been realized that light can also impart orbital angular momentum (OAM) by incorporating a helical phase profile. This is normally done using a spatial light modulator (SLM) and the generated beam is commonly called as optical vortex or Laguerre-Gaussian (LG) beam. It has been used in trapping of low-index particles [1] and has been extended to optical communications [2]. However, increasing the topological charge of LG beam results in large dark spot in the center due to phase singularity and thus not suitable for applications requiring high photon density. One approach is to use helico-conical beam or optical twister where the phase profile is dependent on the radial and angular coordinates [3]. Experimental results show that optical twister is capable of trapping particle and imparting OAM [4]. In this work, we demonstrate nanostructured logarithmic-spiral flat spiral zone plates (LSZP); etched through 100 nm chromium film followed by the electron beam lithography (EBL). Numerical calculations and optical characterizations of the LSZP, on the transmission side, reveal the phenomenon of spatial focusing of optical vortex. Further investigations unveil that our device maintains its intriguing ability of OAM focusing under entire visible spectrum and different polarization states [5]. Owing to compactness of the LSZP, it may be integrated in microfluidics systems to perform localized trapping and stirring, while putting an array of LSZPs may be useful for applications such as particle sorting.

Resonance near field coupling induced optical counter torque for plasmonic particle cluster

Jun Chen, Shanxi Univ. (China) and Hong Kong Baptist Univ. (Hong Kong, China); Neng Wang, Fudan Univ. (China) and Hong Kong Baptist Univ. (Hong Kong, China);

Liyong Cui, Xiao Li, Hong Kong Baptist Univ. (Hong Kong, China); Zhifang Lin, Fudan Univ. (China); Jack Ng, Hong Kong Baptist Univ. (Hong Kong, China)

Light induced torques are common tools for micro-particle manipulation. While novel and interesting ways were invented, applying strong optical torque over a large area is still a challenging task. One major reason is that angular momentum conservation must be fully fulfilled.

A simple argument shows the tendency for two strongly scattering objects to develop counter torques that are much stronger than the total torque. The effect is quite significant for metal particle cluster at resonance, but can also be observed in other structures. Advantages include, but not limited to, strong torque that is significantly stronger than that of a single isolated object, and large torque to extinction cross section ratio allowing multiple rotors to work in tandem. Our work contributes to the understanding of optical rotation and introducing novel ways to manipulate the internal degree of freedom of a structured particle.

Trapping of highly birefringent rutile nanocylinders in the optical torque wrench

Yera Y. Ussembayev, Seungkyu Ha, Richard Janissen, Maarten M. van Oene, Nynke H. Dekker, Technische Univ. Delft (Netherlands)

The optical torque wrench (OTW) is a powerful technique to measure the torsional properties of different biomolecules, including DNA, DNA-processing protein complexes and rotary motors, such as the bacterial flagellar motor. To date, quartz (SiO2) has proven to be a convenient birefringent material out of which to synthesize the micron-sized particles essential for this technique. However, the relatively low birefringence of quartz, which limits the maximal torque that can be applied in OTW, hampers the study of certain biological systems. A more attractive material is rutile (TiO2), which has a thirty-fold higher birefringence. To date, however, the application of rutile in the trapping has been restricted due to its high refractive index, which results in low trapping efficiency. Here, we have employed finite element method calculations to determine the optimal dimensions of submicron-sized rutile cylinders for tight stable optical trapping. Using these calculations as a guideline, we have designed and developed a nanofabrication protocol that allows us to produce rutile cylinders with the desired sizes at high yield. We have characterized the fabricated cylinders in the OTW setup and quantified both their linear and angular trapping properties. In addition, we demonstrate full translational and rotational control of these functionalized cylinders tethered to individual DNA molecules for use in single-molecule applications.

9548-7, Session 2

Initiating optics immersions

Gabriel C. Spalding, Illinois Wesleyan Univ. (United States)

To ensure an increased supply of well-prepared graduate students, and to spread awareness of the research opportunities we offer, it is proposed that your institution serve as a site for a 2.5-day training workshop for those advanced lab instructors who mentor undergraduates at the stage when they are considering their graduate school options. Data clearly suggests that enormous impact can be achieved by reaching out to an identifiable and relatively small cohort of individuals who collectively play a crucial role in the experimental instruction of nearly all students with a major or minor in physics at US institutions. Mentor stipends are available, and logistics, advertising, registration, and follow-up for these Optics Immersions will be coordinated by ALPhA, the “Advanced Laboratory Physics Association.”

9548-8, Session 2

A simple explanation of opto-mechanical cooling by the back action of cavity photons

Masud Mansuripur, College of Optical Sciences, The Univ. of Arizona (United States)

We present a simple classical analysis of the light reflected from a Fabry-Perot cavity consisting of a fixed (dielectric) front mirror and a vibrating rear mirror. In the adiabatic approximation, the returning light exhibits sideband symmetry, which will go away as the photon lifetime becomes comparable to or longer than the oscillation period of the rear mirror. When the oscillation period is short compared to the cavity photon lifetime, one must approach the problem differently, treating the vibrating mirror as a scatterer which sends a fraction of the incident light into the sideband frequencies. With proper detuning, the internal radiation pressure can be shown to slow down the oscillating mirror. This is the principle of cooling a vibrating mirror by the back action of the cavity photons.

9548-9, Session 3

Nano-optomechanics with optically levitated dielectric nanoparticles *(Invited Paper)*

Levi Neukirch, Brandon Rodenburg, Mishkatul Bhattacharya, Nick Vamivakas, Univ. of Rochester (United States)

The inability to leverage resonant scattering processes involving internal degrees of freedom differentiates optical cooling experiments performed with levitated dielectric nanoparticles, from similar atomic and molecular traps. Trapping in optical cavities or the application of active feedback techniques has proven to be effective ways to circumvent this limitation. We present our nanoparticle optical cooling apparatus, which is based on parametric feedback modulation of a single-beam gradient force optical trap. This scheme allows us to achieve effective center-of-mass temperatures well below 1 kelvin for our ? 1 ? 10?18 kg particles, at modest vacuum pressures. We will also discuss experiments in which the levitated nanoparticle contains a single optically active quantum emitter. The method provides a versatile platform, with parameter tunability not found in conventional tethered nanomechanical systems. Potential applications include investigations of nonequilibrium nanoscale thermodynamics, ultra-sensitive force metrology, and mesoscale quantum mechanics and hybrid systems.

9548-10, Session 3

Experimental opto-mechanics with levitated nanoparticles: towards quantum control and thermodynamic cycles *(Invited Paper)*

Nikolai Kiesel, Florian Blaser, Uros Delic, David Grass, Univ. Wien (Austria); Andreas Dechant, Eric Lutz, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); Marzieh Bathaee, Sharif Univ. of Technology (Iran, Islamic Republic of); Markus Aspelmeyer, Univ. Wien (Austria)

Combining optical levitation and cavity optomechanics constitutes a promising approach to prepare and control the motional quantum state of massive objects (>10^9 amu). This, in turn, would represent a completely new type of light-matter interface and has, for example, been predicted to enable experimental tests of macrorealistic models or of non-Newtonian gravity at small length scales. Such ideas have triggered significant

experimental efforts to realizing such novel systems.

To this end, we have recently successfully demonstrated cavity-cooling of a levitated sub-micron silica particle in a classical regime at a pressure of approximately 1mbar. Access to higher vacuum of approx. 10^-6 mbar has been demonstrated using 3D-feedback cooling in optical tweezers without cavity-coupling.

Here we will illustrate our strategy towards trapping, 3D-cooling and quantum control of nanoparticles in ultra-high vacuum using cavity-based feedback cooling methods and clean particle loading with hollow-core photonic crystal fibers. We will also discuss the current experimental progress both in 3D-cavity cooling and HCPCF-based transport of nanoparticles.

As yet another application of cavity-controlled levitated nanoparticles we will show how to implement a thermodynamic Sterling cycle operating in the underdamped regime. We present optimized protocols with respect to efficiency at maximum power in this little explored regime. We also show that the excellent level of control in our system will allow reproducing all relevant features of such optimized protocols. In a next step, this will enable studies of thermodynamics cycles in a regime where the quantization of the mechanical motion becomes relevant.

9548-11, Session 3

Dispersive light-matter interaction in programmable optical tweezers

Bianca J. Sawyer, Milena S. J. Horvath, Amita B. Deb, Niels Kj?rgaard, Univ. of Otago (New Zealand)

Off-resonant probing via the dispersive light-matter interaction is a powerful metrological tool in the manipulation and control of trapped ultracold gases. We have developed a robust interrogation system that uses frequency modulation spectroscopy to measure the quantum state-dependent phase shift incurred on an off-resonant optical probe when transmitted by an atomic medium. This is routinely used to track a number of dynamic atomic processes in real time. An important design consideration for such a scheme is the three-dimensional mode-matching at the interface between light and matter when coupled by this dispersive interaction. The geometry of the ellipsoidal ensemble of trapped atoms should be adjusted such that scattering of the axially propagating probe field is optimized in the forward direction. This allows the maximum signal to be collected by the photo-detection optics.

The trapping potential for our ultracold gas is generated by programmable optical tweezers, which preform precise spatial micro-manipulation of the ensemble. The unit consists of a versatile vertical tweezer beam and intersecting static horizontal waveguide. The vertical beam can be split into multiple time-averaged potentials, producing a one-dimensional array of cold clouds.

As an application, we use the tweezers as a pair of laser “test tubes” to independently prepare two clouds of ultracold 87Rb in different internal quantum states. The samples are then brought together and an external magnetic field is swept across a Feshbach resonance. Dispersive probing is used to track the resulting dynamics and identify the resonant magnetic field value.

9548-13, Session 4

Extinction cross section measurements for a single optically trapped particle *(Invited Paper)*

Michael I. Cotterell, Univ. of Bristol (United Kingdom); Thomas C. Preston, McGill Univ. (Canada); Bernard J. Mason, Univ. of Bristol (United Kingdom); Andrew J Orr-Ewing, Jonathan P Reid, University of Bristol (United Kingdom)

Bessel beam (BB) optical traps have become widely used to confine single and multiple aerosol particles across a broad range of sizes, from a few microns to < 200 nm in radius. The radiation pressure force exerted by the core of a single, zeroth-order BB incident on a particle can be balanced by a counter-propagating gas flow, allowing a single particle to be trapped over many hours. The pseudo non-diffracting nature of BBs enables particles to be confined over macroscopic distances along the BB core propagation length; the particle’s position along this length can be finely controlled by modulating the BB laser power. We exploit this property to optimise the particle’s position at the centre of the TEM00 mode of a high finesse optical cavity, allowing cavity ring-down spectroscopy (CRDS) to be performed on single aerosol particles and their optical cross section, ?ext, measured. Further, the variation in the light from the illuminating BB elastically scattered by the particle is recorded as a function of scattering angle. Such intensity distributions are fitted to Mie theory to determine the particle’s radius. The trends in ?ext with particle radius are modelled using cavity standing wave Mie simulations and a particle’s varying refractive index with changing relative humidity is determined. We demonstrate ?ext measurements on sub-micrometre aerosol and determine the lowest limit in particle size that can be probed by this technique. The BB-CRDS method will play a key role in reducing the uncertainties associated with atmospheric aerosol radiative forcing, among the largest uncertainties in climate modelling.

9548-14, Session 4

Quadruple Bessel beam trap for single droplet studies

Grégory David, Ruth Signorell, ETH Zürich (Switzerland)

Metastable submicron droplets play an important role in atmospheric processes. In this context, we use Bessel beam optical traps, which enable us to isolate a single submicron droplet for a long time (several hours or days) in air. However, the stability of a single counter-propagating Bessel beam (CPBB) trap is very sensitive to the alignment [1]. Its trapping position may change with the particle size and the particle may wobble by several tens of micrometers. This can be a major problem for single droplet studies, such as broadband light scattering and photo-acoustic measurements. We suggest a new type of trap, which is much less sensitive to small optical misalignment [1]: the quadruple Bessel beam trap (QBB) consisting of two sets of CPBBs perpendicularly arranged. This presentation shows the first experimental realization and characterization of the stability and confinement of single droplets in a QBB trap and compares it with numerical simulations of the three-dimensional droplet dynamics [2].

The QBB trap is shown to be more predictable and several times more stable than the CPBB trap, while it confines the particle much more tightly by several orders of magnitude. QBB traps are thus better suited for single droplet studies. In addition we will present results for the water uptake/release and for the aging of metastable submicron droplets.

Measuring forces and dynamics for optically levitated 20um PS particles in air using electrostatic modulation

Haesung Park, Thomas W LeBrun, National Institute of Standards and Technology (United States)

Optical trapping in air and vacuum has become the subject of increased attention due its applications to precision measurement and fundamental physics. Unlike traditional studies of trapping in fluids (in support of biological measurement, colloid science, cell sorting, and nanotechnology), trapping in air or vacuum can present an underdamped system where inertia rather than damping dominates dynamics. Under these conditions, the full

nonlinear, three-dimensional nature of the trapping force can give rise to much more complex behavior. We use electrostatic modulation to study the forces on a 20μm polystyrene bead trapped in air, and measure the dynamics of the particle's motion under impulse excitation.

A ring-type piezoelectric launcher allows us to introduce a selected target particle into the optical trap, where it remains stably trapped indefinitely (> 6 hrs). We combine quadrant photodiode measurement with video microscopy to measure the particle motion after electrostatic impulse both accurately and at high speed. An advantage of electrostatic modulation is the ability to excite particle motion rapidly and without changing the trapping beam or surrounding medium. We use this to determine the stiffness and damping directly and independently of each other without assumptions about temperature. In addition, we show that the full force curve can be measured with no assumptions beyond Newton's equations.

9548-16, Session 4

Optical trapping of individual gold nanoparticles in air

Liselotte Jauffred, Lund Univ. (Sweden); Seyed Mohammad-Reza Taheri, Univ. of Zanjan (Iran, Islamic Republic of); Regina K. Schmitt, Heiner Linke, Lund Univ. (Sweden); Lene B. Oddershede, Niels Bohr Institute (Denmark)

Since the ground breaking particle levitation experiments by Ashkin in 1975, huge efforts have been put into controlling micro- and nanometer sized particles in both air and liquids. Till date, most progress has been done in liquids with aerosol trapping proving more challenging. By utilizing an air chamber designed to have a minimum of turbulence [1] and a laser beam with a minimum of aberration, we succeeded to trap individual gold nanoparticles with diameters between 80 nm and 200 nm in air using a 1064 nm laser. The positions visited by the trapped gold nanoparticle were quantified using a quadrant photodiode placed in the back focal plane. The time traces were analyzed and the trapping stiffness characterizing gold aerosol trapping determined and compared to aerosol trapping of nanometer sized silica and polystyrene particles. Calibration, however, is not trivial as the 'normal' assumption of an underdamped system, underlying the Langevin approach, is not a priori valid in the case of trapping metallic nanoparticles in air. Based on our analysis, we conclude that gold nanoparticles trap more strongly in air than similarly sized polystyrene and silica particles, and that the spring constants characterizing aerosol trapping of gold nanoparticles are approximately half of those characterizing trapping of gold nanoparticles in water [2]. The gold nanoparticles absorb part of the irradiating laser light and we also discuss the associated nanoparticle heating, which is even more pronounced in air than in water [3] due to a lower thermal conductance.

Optical trapping of microdroplet containing a single nanomaterial in helium gas *(Invited Paper)*

Yosuke Minowa, Masaaki Ashida, Ryoichi Kawai, Osaka Univ. (Japan)

Quantum dots or nanometer-sized semiconductor nanocrystals are fascinating quantum emitters having a discrete energy level structure which is tunable through the quantum confinement effect. In particular, chemically synthesized colloidal quantum dots are promising as they can be mass produced and their size can be precisely controlled. Colloidal quantum dots can be treated as an isolated single particle. Therefore, manipulation and alignment of colloidal quantum dots would enable the realization of the ideal platform to investigate the mutual interaction among quantum emitters and the ultra strong coupling between light and matter. Optical manipulation is one of the universal techniques to control the motion/position of microparticles and atoms. However, researches on optical manipulation of quantum dots are scarce. The difficulties arise from the relatively small polarizability, which normally tends to decrease with decreasing the particle's size in the Rayleigh regime. Here, we report on the optical trapping of a single quantum dot within the microdroplet in helium gas. The liquid droplet behaves as an optically-transparent container with a larger volume enabling the stable optical trapping. We detected bright single photon emission from the trapped quantum dot through the two photon excitation process. We also observed intensity and spectral fluctuation, which are well known features of a solid state quantum emitter. Our results can lead to the isolation of nanomaterials from their environment or substrates and provide unprecedented information on their intrinsic material properties which are obscured by the environmental fluctuation.

9548-18, Session 5

Steering a jet of particles into an x-ray beam with optically induced forces

Richard A. Kirian, Arizona State Univ. (United States); Niko Eckerskorn, The Australian National Univ. (Australia); Salah Awel, Max Wiedorn, Jochen Küpper, Henry N. Chapman, Ctr. for Free-Electron Laser Science (Germany); Andrei V. Rode, The Australian National Univ. (Australia)

Optical trapping of light-absorbing particles in a gas environment has shown to be governed by laser-induced thermal or photophoretic forces, which can be orders of magnitude higher than the force of the light-induced radiation pressure. Guiding of particles with photophoretic forces over large distances in open air was recently realised by an optical pipeline, formed by a vortex laser beam of doughnut-like intensity profile, with a high-intensity ring of light that surrounds a dark core. The exact formation mechanism of photophoretic force and the influence on the particle movement are still unclear. Here we report on our efforts to utilize the optical pipeline concept to guide particles into the focus of an x-ray free-electron laser (XFEL). XFELs produce coherent femtosecond-duration pulses of high-energy x-rays with immense brightness. In the "diffract-and-destroy" mode, such pulses destroy any illuminated target, but terminate prior to the onset of atomic motion and hence overcome fundamental problems associated with radiation damage. Through coherent diffractive imaging methods, one can form single-shot nanometer-resolution projection images of thick irreproducible targets such as cells, or Angstrom-resolution 3D electron density maps from reproducible macromolecules exposed in many orientations. The combination of a touch-free optical system for pin-point delivery of bioparticles to the focal spot of an XFEL would significantly enhance the efficiency of XFEL-based serial diffractive imaging experiments.

9548-20, Session 5

Bistable dynamics of a levitated nanoparticle

Francesco Ricci, ICFO - Institut de Ciències Fotòniques (Spain); M. Spasenovic, Univ. of Belgrade (Serbia) and ICFO - Institut de Ciències Fotòniques (Italy); Raúl A. Rica, ICFO - Institut de Ciències Fotòniques (Spain); Lukas Novotny, ETH Zürich (Switzerland); Romain Quidant, ICFO - Institut de Ciències Fotòniques (Spain)

Bistable systems are ubiquitous in nature. Classical examples in chemistry and biology include relaxation kinetics in chemical reactions [1] and stochastic resonance processes such as neuron firing [2,3]. Likewise, bistable systems play a key role in signal processing and information handling at the

nanoscale, giving rise to intriguing applications such as optical switches [4], coherent signal amplification [5,6] and weak forces detection [5].

The interest and applicability of bistable systems are intimately connected with the complexity of their dynamics, typically due to the presence of a large number of parameters and nonlinearities. Appropriate modeling is therefore challenging. Alternatively, the possibility to experimentally recreate bistable systems in a clean and controlled way has recently become very appealing, but elusive and complicated. With this aim, we combined optical tweezers with a novel active feedback-cooling scheme to develop a well-defined opto-mechanical platform reaching unprecedented performances in terms of Q-factor, frequency stability and force sensitivity [7,8]. Our experimental system consists of a single nanoparticle levitated in high vacuum with optical tweezers, which behaves as a non-linear (Duffing) oscillator under appropriate conditions. Here, we prove it to be an ideal tool for a deep study of bistability.

We demonstrate bistability of the nanoparticle by noise activated switching between two oscillation states, discussing our results in terms of a double-well potential model. We also show the flexibility of our system in shaping the potential at will, in order to meet the conditions prescribed by any bistable system that could therefore then be simulated with our setup.

Continuum electrodynamics and the Abraham-Minkowski controversy

Michael E. Crenshaw, U.S. Army Aviation & Missile Research, Development & Engineering Ctr. (United States)

The Abraham--Minkowski controversy refers to a long-standing inability to deal with issues involving the momentum of an electromagnetic field in a linear dielectric medium. In 1908, Minkowski derived a tensor energy--momentum continuity equation. Abraham subsequently argued that the Minkowski tensor violates conservation of angular momentum because the tensor is not symmetric. Based on the continuing work in the field, the resolutions that have been proposed over the last century have not been persuasive.

We treat continuum electrodynamics as an axiomatic formal theory based on the macroscopic Maxwell equations applied to a thermodynamically closed system consisting of an antireflection coated block of a linear dielectric situated in free-space that is illuminated by a quasimonochromatic field. We demonstrate that the Abraham and Minkowski formulations of the continuity of energy and momentum are valid theorems of the formal theory of continuum electrodynamics that are proven false by conservation laws. Furthermore, we show that another valid theorem of continuum electrodynamics is contradicted by special relativity. Our options are: 1) that the axioms of the formal theory, the macroscopic Maxwell equations, are proven false by conservation laws and relativity, 2) that conservation and relativity are proven false by continuum electrodynamics, or 3) all of the above. Electrodynamics, conservation, and relativity are fundamental principles of physics that are intrinsic to the vacuum in which the speed of light is c. The contradictions are resolved by a reformulation of physics for a region of space in which the speed of light is c/n.

9548-22, Session 6

Electromagnetic angular momentum

Masud Mansuripur, College of Optical Sciences, The Univ. of Arizona (United States)

In addition to energy and linear momentum, electromagnetic (EM) fields possess the capacity to carry spin and orbital angular momentum. With a view to Maxwell's macroscopic equations and the laws governing EM force and torque, we discuss the fundamental properties of EM angular momentum and point out several facts concerning the angular momentum content and behavior of static as well as dynamic fields. Certain paradoxes arise from the exchange of angular momentum between fields and material media, all involving the conservation of angular momentum, especially when the media are endowed with magnetic properties. We examine the origin of these paradoxes, discuss their connection to the Abraham-Minkowski controversy, and explain how the paradoxes can be resolved.

9548-23, Session 6

Physics of electromagnetic and material stresses in optical manipulation

Brandon A. Kemp, Cheyenne J. Sheppard, Arkansas State Univ. (United States)

Modeling the dynamics optical manipulation experiments relies upon a precise mathematical representation of electromagnetic fields and the interpretation of optical momentum and stresses in materials. However, the momentum of light within media has been an issue of debate over the past century. Multiple mathematically energy-momentum models have been advanced, each, under certain conditions, agreeing with experimental observation and mathematically consistent with classical electromagnetism.

The modern view is that the various formulations of electrodynamics represent different divisions of the total energy-momentum tensor, with the separation of field and matter being ambiguous. Recently, a proposed view of photon momentum identified two leading forms as the kinetic and canonical momenta. The Abraham momentum is responsible for the overall center-of-mass translation of a material, while the Minkowski momentum is responsible for translations with respect to the surrounding medium. However, the Abraham momentum corresponds to multiple, unique electromagnetic energy-momentum tensors that attempt to separate field from material responses (e.g. Abraham, Chu, and Einstein-Laub). However, only the form of the kinetic momentum density has been revealed, while the formulation that uniquely separates the kinetic stress tensor has remained ambiguous.

In this correspondence, multiple formulations are considered within the framework of relativistic electrodynamics. We apply various mathematical techniques to identify the kinetic subsystem of electrodynamics. While optical manipulation is usually modeled using a stationary medium approximation, the lessons from relativistic electrodynamics reveal a specific distribution of electromagnetic stress in media. The physics of optical and static manipulation of dielectric particles are described within this framework.

9548-24, Session 6

Discriminatory effects in the optical binding of chiral nanoparticles

Kayn A. Forbes, Univ. of East Anglia (United Kingdom); David S Bradshaw, David L Andrews, Univ of East Anglia (United Kingdom)

The laser-induced intermolecular force that exists between two or more particles subjected to a moderately intense laser beam is termed 'optical binding'. Completely distinct from the single-particle forces that give rise to optical trapping, the phenomenon of optical binding is a manifestation of the coupling between optically induced dipole moments in neutral particles. In conjunction with optical trapping, the optomechanical forces in optical binding afford means for the manipulation and fabrication of optically bound matter. The Casimir-Polder potential that is intrinsic to all matter can be overridden by the optical binding force in cases where the laser beam is of sufficient intensity. Chiral discrimination can arise when the laser input has a circular polarization, if the particles are themselves chiral. Then, it emerges that the interaction between particles with a particular handedness is responsive to the left- or right-handedness of the light. The present analysis, which expands upon previous studies of chiral discrimination in optical binding, identifies a novel mechanism that others have previously overlooked, signifying that the discriminatory effect is much more prominent than originally thought. The new theory leads to results for freely-tumbling chiral particles subjected to circularly polarized light. Rigorous conditions are established for the energy shifts to be non-zero and display discriminatory effects with respect to the handedness of the incident beam. Detailed calculations indicate that the energy shift is larger than those previously reported by three orders of magnitude.

9548-25, Session 6

1D problems of radiation pressure on elastic solids

Tomaz Pozar, Janez Mo?ina, Univ. of Ljubljana (Slovenia)

When light exerts pressure on elastic solids, the properties of both, light and matter change. In the simplest cases, the energy and momentum transferred between the light and matter can be solved in one dimension.

We treat the light-matter interaction solely due to radiation pressure using the fundamental nonrelativistic conservation principles of energy and momentum with the assumption that solids are considered as elastic objects. This optodynamic approach only assumes that the momentum of a light pulse propagating in vacuum equals its energy divided by the speed of light and that the speed of light is constant in any reference frame. The methodology intentionally avoids other known properties of light, such as the fact that light is an electromagnetic wave and that its energy is quantized. Since we handle solids as elastic objects, the results are consistent with the principles of causality and agree with recent experimental observations.

Employing the above mentioned assumptions, we shall tackle the problem of reflection of a laser pulse from a fully reflective mirror and show that its reflection gives rise to an elastic wave with measurable amplitude that propagates within the mirror and that our results predict a larger Doppler shift in the reflected pulse for the most common setting, when the mirror is initially at rest, compared to the results obtained when the mirror is treated as rigid.

Similarly, we will revisit the Balazs thought experiment. The final example will explain the infinite expansion of a fully reflective 1D resonator filled with light.

9548-26, Session 6

Optodynamic description of optical manipulation

Tomaz Pozar, Janez Mo?ina, Univ. of Ljubljana (Slovenia)

We treat optical manipulation of solid objects from the perspective of optodynamics, a research field which investigates light-induced motion of macroscopic matter. Contrary to general notion of optical manipulation which investigates the means to move an object as a whole, optodynamics also focuses on the redistribution of the acquired momentum from the initial, time-developing, extremely low-amplitude propagating mechanical waves to the final net motion of the object.

When a solid object is manipulated/propelled by a pulse of light, various types of mechanical waves are generated whenever and wherever light exchanges momentum with matter. In the case of opaque objects, the following elastic waves are launched from the illuminated surface towards the bulk of the solid: ablation-induced waves (AIWs) resulting from material recoil, thermoelastic waves (TEWs) caused by light absorption and the subsequent thermal expansion, and the light-pressure-induced waves (LIWs) emanating exclusively from the photon linear momentum transfer (radiation pressure). Even though the macroscopic motion of the object is the superposition of all these waves, only AIWs and the much weaker LIWs are involved in the translation of the object's center of mass.

In this contribution, we will present two unique measurements revealing AIWs and LIWs, and discuss the time-development of the transferred momentum. We shall report on the measurements that show how TEWs can be sufficiently suppressed in order to discern the presence of LIWs. The required experimental techniques will be reviewed. The Abraham-Minkowski debate and Balazs thought experiment shall also be theoretically expanded to include elastic wave motion.

9548-27, Session 7

A model for traumatic brain injury using laser induced shockwaves

Aaron R. Selfridge, Daryl C. Preece, Veronica Gomez, Linda Z. Shi, Univ. of California, San Diego (United States); Michael W. Berns, Univ. of California, Irvine (United States)

Traumatic brain injury (TBI) represents a major treatment challenge in both civilian and military medicine; on the cellular level, its mechanisms are poorly understood. As a method to study the dysfunctional repair mechanisms following injury, laser induced shockwaves (LIS) are a useful way to create highly precise, well characterized mechanical forces.

We present a simple model for TBI using laser induced shockwaves as a model for damage. Our objective is to develop an understanding of the processes responsible for neuronal death, the ways in which we can manipulate these processes to improve cell survival and repair, and the importance of these processes at different levels of organization.

The physics of shockwave creation has been modeled and can be used to calculate forces acting on individual neurons. By ensuring that the impulse is in the same regime as that occurring in practical TBI, the LIS model can ensure that in vitro conditions and damage are similar to those experienced in TBI. This model will allow for the study of the biochemical response of neurons to mechanical stresses, and can be combined with microfluidic systems for cell growth in order to better isolate areas of damage.

9548-28, Session 7

Periodic cavitation in an optical tweezer

Viridiana Carmona-Sosa, José E. Alba-Arroyo, Pedro A. Quinto-Su, Univ. Nacional Autónoma de México (Mexico)

We show that microscopic explosions (cavitation) can be generated periodically in an optical tweezer. An absorbing microparticle is attracted

to the trapping beam waist where it is superheated resulting in a cavitation bubble that impulsively pushes the particle close to the starting position where the cycle restarts.

We find that multiple microparticles can briefly coexist oscillating in asingle optical trap, increasing the frequency of microscopic explosions.

9548-29, Session 7

Interesting physics and applications using microbubbles in thermo-optic tweezers

Basudev Roy, Subhrokoli Ghosh, Soumyajit Roy, Ayan Banerjee, Indian Institute of Science Education and Research Kolkata (India)

We have developed a technique of generating a micro-bubble inside an optical trap by using a material (Mo-based Soft Oxometalate (SOM) compound) that absorbs at the trapping laser wavelength. A high concentration aqueous dispersion of the SOMs is taken in a sample chamber, and the trapping laser is focused on SOMs adsorbed on one of the surfaces of the chamber, so as to create a 'hot spot' due to which a microbubble is nucleated. Due to the temperature gradient on the bubble, a surface tension gradient results, which leads to Marangoni type flows around the bubble. The resultant Marangoni flow around the bubble causes self-assembly of material at its base, which undergoes a phase transition into a crystalline state when the laser spot is translated causing the bubble to follow due to convective effects [1]. We have used this technique to pattern materials ranging from dyes to carbon nano-tubes to conducting polymers which co-assemble in a mixture with the SOMs. The method is rather universal and has been used to develop catalytic chips [2] and solution processed printable electronics. The flow generated by the bubbles can be studied by mapping the trajectories of probe particles in the vicinity of the bubble. We show interesting self-assembly of the particles on the bubble surface, as well as manipulation of trajectories of the particles by multiple bubbles. The bubble can also be used to capture, transport, and release particles in a perfectly controlled manner.

9548-30, Session 8

Reactive oxygen species production in single cells following laser irradiation

Michelle L. Duquette, Justine Kim, Linda Z. Shi, Michael W. Berns, Univ. of California, San Diego (United States)

Region specific DNA breaks can be created in single cells using laser light that damages DNA but does not directly generate reactive oxygen species (ROS). We have examined the cellular response to directly generated DNA breaks in single cells. Using a combination of ROS specific dyes and oxidase inhibitors we have found that the oxidase and chromatin remodeling protein Lysine demethylase I (LSD1) generates detectable ROS as a byproduct of its chromatin remodeling activity during the initial DNA damage response. ROS is produced at detectable amounts primarily within the first 3 minutes post irradiation. LSD1 activity has been previously associated with transcriptional regulation therefore these findings have implications for regulation of gene expression following DNA damage particularly in cells with altered redox states.

9548-31, Session 8

Integrated 3D macro-trapping and light-sheet imaging system

Zhengyi Yang, Peeter Piksarv, David E. K. Ferrier, Frank J. Gunn-Moore, Kishan Dholakia, Univ. of St. Andrews (United Kingdom)

Light-sheet imaging technique is particular suitable for forming three-dimensional (3D) image of large samples. Construction of 3D image needs scanning sample along the detection axis, which is currently accomplished by moving the fixed sample in agent such as agarose. However, this fixing agent limits the development of the living sample, moreover the refractive-index mismatch between this agent and water introduces optical aberration which degrade the quality of image. Here we demonstrate a light-sheet imaging system integrated with dual-beam trap. The specimen was trapped by two counter-propagating beams and moved optically by a scanning mirror. Trapping and imaging of BY-2 cells and Pomatoceros lamarckii larva were successfully demonstrated.

9548-32, Session 8

Single-cell diffraction tomography with optofluidic rotation about a tilted axis

Paul Müller, Mirjam Schürmann, Jochen Guck, Technische Univ. Dresden (Germany)

The refractive index is an inherent property of every biological cell and its measurement does not require any markers. The knowledge of the three-dimensional refractive index distribution inside a cell helps to better characterize cell shape, dry mass, or volume. Its measurement thus complements techniques that investigate the inner structure of cells.

Optical diffraction tomography is a technique that produces refractive index maps with sub-cellular resolution. The refractive index can be inferred from quantitative phase maps which are recorded with imaging techniques such as digital holographic microscopy (DHM). We combine DHM with optical micromanipulation techniques to obtain tomographic projections of single biological cells in the visible spectrum of light. We employ optical diffraction tomography with the Rytov approximation to reconstruct the three-dimensional refractive index distribution of single cells from these projections. Optical diffraction tomography opens the possibility to monitor structural changes in cells, but also enables us to derive their optical properties which are of high interest for applications that involve optical forces.

9548-33, Session 9

Acoustic force spectroscopy *(Invited Paper)*

Iddo Heller, Vrije Univ. Amsterdam (Netherlands)

No Abstract Available

9548-34, Session 9

Structured interference force for enhanced optical trapping *(Invited Paper)*

Michael A. Taylor, The Univ. of Queensland (Australia) and Research Institute of Molecular Pathology (Austria); Muhammad Waleed, Alexander B. Stilgoe, Halina Rubinsztein-Dunlop, Warwick P. Bowen, The Univ. of Queensland (Australia)

Interferometry can completely redirect light, providing the potential for exceptionally strong and controllable optical forces. When a beamsplitter combines two fields, the output power is directed via the relative phase between the incident fields. Since the phase changes with beamsplitter displacement, the interference force can be used to stably trap; with displacements as small as (?/4n) able to completely redirect the light. The resulting change in optical momentum causes an opposing optical force. However, optical forces are most useful for trapping and manipulating small scattering particles. Optical scattering is not generally thought to allow efficient interference; essentially, it appears that small particles cannot act as beamsplitters. As such, optical traps have relied upon much weaker

deflection-based forces.

Here we show that efficient interference can be achieved by appropriately structuring the incident light. This relies on Mie scattering fringes to combine light which is incident from different incident angles. This results in a force, which we call the structured interference force, which offers order-of-magnitude higher trap stiffness over the usual Gaussian trap. We demonstrate structured interference force trapping (SIFT) of 10?m diameter silica spheres with a stiffness 20.1 times higher than is possible using Gaussian traps, while also increasing the measurement signal-to-noise ratio by two orders of magnitude. This is demonstrated using only phase control of the incident light, making the technique directly compatible with most existing holographic optical traps. These results are highly relevant to many applications, including cellular manipulation, fluid dynamics, micro-robotics, and tests of fundamental physics.

9548-35, Session 9

Mapping of independent force and position measurements for calibration of non-Hookean optical traps

Ann A. Bui, Alexander B. Stilgoe, Timo A. Nieminen, Halina Rubinsztein-Dunlop, The Univ. of Queensland (Australia)

Optical tweezers use highly focussed beams to trap microscopic particles in three dimensions. It is possible to carry out quantitative force measurements, on the order of piconewtons, if calibration of the system is done first. This requires finding the optical force for a given trapping power and position in the trap. Two tools commonly used for calibration are the camera and position-sensitive detector (PSD). Both are commonly used to track trapped particles, but they give complementary information. The camera gives the position of the particle. The PSD measures the defection of the beam, which is the force exerted on the particle. Since these data are obtained on different instruments, usually at vastly different rates, there is difficulty in synchronising the force and position data. Here we look at a force calibration method, without synchronising the data, by mapping force and position measurements. If the force-position relation is monotonic, then the median of the force distribution corresponds to the median of the position distribution; in general, the nth percentile of one corresponds to the (100-n)th percentile of the other. This intuitively works for traps whose force-position relations are monotonic, which includes Hookean traps like a single round symmetric trap. We discuss the limits at which this method can be applied to non-Hookean trapping arrangements, such as independent or coherent double-well traps.

9548-36, Session 9

A new method for calibrating the nonlinear range of a single-beam optical trap

Jamianne C. Wilcox, Benjamin J. Lopez, Otger Campas, Megan T. Valentine, Univ. of California, Santa Barbara (United States)

Optical traps allow for the precise application and measurement of pico-Newton forces in a wide variety of situations, and are particularly well suited for biophysical measurements of motor proteins and cells. Nearly all experiments exploit the linear regime of the optical trap, where force and displacement are related by a simple spring constant that does not depend on the trapped object's position. This typically limits the useful force range to < 100 pN for high-NA objective lenses and reasonable laser powers. Several biological studies require larger forces, which are not accessible in the linear regime of the trap. The best means to extend the maximum force is to make use of the entire nonlinear range; however, current techniques for calibrating the full nonlinear regime are limited. Here we report a new method for calibrating the nonlinear trap region that uses the fluctuations in the position of a trapped object when it is displaced from the center of a single gradient optical trap by controlled flow. From the position fluctuations, we measure the local trap stiffness, in both the linear and non-linear regimes. This approach requires only knowledge of the system temperature, and is especially useful for measurements involving trapped objects of unknown size, or objects in a fluid of unknown viscosity.

9548-37, Session 9

Measurement of radiation pressure in an ambient environment

Dakang Ma, Joseph L. Garrett, Jeremy N. Munday, Univ. of Maryland, College Park (United States)

Light reflected off a material or absorbed within it exerts radiation pressure through the transfer of momentum. Although this effect is small, microscale mechanical transducers have progressed to the point that radiation pressure can play an important role in these systems. Understanding these effects and distinguishing radiation pressure from photothermal effects is thus of great importance for future optomechanical devices. Here we discuss our recent measurements of radiation pressure on a silicon nitride microcantilever under ambient conditions. Using our technique, we are able to separately identify the radiation pressure and photothermal forces through an analysis of the cantilever's frequency response. Additionally, the radiation pressure is found to be much stronger than the effective photothermal forces when excitation occurs near the free end of the cantilever. In such a regime (where the photothermal forces make up less than 1% of the total cantilever amplitude at resonance), we measure the force resulting from the radiation pressure. Measured forces range from 1-10 pN for illumination powers of 1-9 mW at 660 nm. A model is used to calculate the radiation pressure, which is found to agree with experimental results within the measured and calculated uncertainties. We envision this method as a practical way to determine the response of optomechanical devices and as an alternative method for cantilever spring constant calibration. Further, we expect this technique to be an effective method for the study of optical forces on exotic metamaterials, which might be hindered by photothermal forces.

9548-38, Session 10

Photonic force microscopy of surface electromagnetic waves in a one-dimensional photonic crystal

Daniil Shilkin, Evgeny V. Lyubin, Lomonosov Moscow State Univ. (Russian Federation); Irina V. Soboleva, Lomonosov Moscow State Univ. (Russian Federation) and A.N. Frumkin Institute of Physical Chemistry and Electrochemistry (Russian Federation); Andrey A. Fedyanin, Lomonosov Moscow State Univ. (Russian Federation)

The Bloch Surface Electromagnetic Waves (SEWs) providing large field enhancement in all-dielectric structures are shown to be promising tool for optical manipulation of dielectric microparticles. In our work, momentum of the SEW at a one-dimensional photonic crystal/water interface is experimentally demonstrated to be transferred to a 1-?m polystyrene microsphere trapped by optical tweezers in the vicinity of the photonic crystal surface. By means of optical microscopy, the interaction force generated by the SEW evanescent field is shown to be large enough for particles localization near the surface and propulsion along the SEW propagating direction. Using photonic force microscopy, the force is measured quantitatively as a function of the exciting beam angle of incidence and the distance from the photonic crystal surface. The force is shown to decay exponentially with moving off the surface at large distances, but there is a surprising diminution of the force at surface/particle gaps less than 150 nm. The maximum force of 0.25 fN at the exciting radiation intensity of 1.6 kW/cm? is observed at the SEW excitation resonance. The SEW-induced gradient force was estimated in the dipole approximation. Because of the small width of the resonance (0.1° in our experiment), the angular divergence of the exciting radiation should be taken into account. The results are in a good agreement with the experimental data.

9548-39, Session 10

Optical epitaxial growth of gold nanoparticle arrays

Ningfeng Huang, The Univ. of Southern California (United States); Luis J. Martinez, The Univ. of Southern California (United States) and Ecole Normale Supérieure de Cachan (France); Eric Jaquay, Michelle L. Povinelli, The Univ. of Southern California (United States)

We demonstrate optical trapping of a periodic array of closely spaced gold nanoparticles. To achieve the experimental result, we considered competition between optical gradient forces and strong interparticle interactions. We achieve control of the gradient forces using a photonic-crystal template designed to create a periodic optical trapping potential. We modeled the interparticle interactions using a kinetic Monte Carlo approach. The results predict the formation of different particle superstructures (such as chains or filled-in arrays) depending on lattice constant and symmetry. Using the model prediction, we designed and demonstrated a template that allows trapping of a regular periodic array.

9548-40, Session 10

Submicron particle manipulation using slotted tapered optical fibers

Mark J. Daly, Viet Giang Truong, Síle Nic Chormaic, Okinawa Institute of Science and Technology Graduate Univ. (Japan)

Optical micro- and nanofibers (MNFs) have, in recent years, been used for trapping and manipulating micron, and even submicron scale particles with varying degrees of success. Despite their versatility, their applications to the trapping of submicron particles without a high refractive index have remained somewhat limited. To increase their performance in this regime, we demonstrate the use of a slotted tapered optical fiber (STOF), which was previously proposed in the context of cold atom trapping. This fiber has an increased evanescent field via nanostructuring, hence increasing the trapping strength for submicron particles. The structuring process consists of the removal of a rectangular section of the fiber with a focused ion beam, thus producing a region of increased electric field, when compared to that of an unstructured fiber. The STOF, with typical slot dimensions of 20 μm by 300 nm, can be used to propel and trap submicron particles. Using 1064 nm trapping beams, which are propagated through a STOF, particles can be localized to the slot region. We present the trapping and manipulation of submicron fluorescent particles, with diameters in the range of 100 – 300 nm, using this novel fiber design, alongside a brief presentation of the operational abilities and fabrication process of a STOF. The STOF's increased ability to trap submicron particles reliably within its evanescent field may lead to future applications in particle sorting, particle counting, and even opening up the possibility of performing in situ spectroscopic measurements on STOF trapped particles.

9548-41, Session 11

Optical manipulation of single microparticle for microfluidic flow rate sensing

Yuan Gong, Univ. of Electronic Science and Technology of China (China)

Sensitive flowmeter with large dynamic range is highly desirable for microfluidic applications. We developed an optofluidic flow rate sensor, with a dynamic range of 3 orders of magnitude and a minimum detectable flow rate change (MDFRC) as low as 5 nL/min, based on optical manipulation of a microparticle by a single mode fiber (SMF). A single polystyrene microsphere was trapped on the optical axis by the 980nm laser emitting from SMF and the force balance between optical force and flow force was used for sensing. The manipulation distance was detected as a function of the flow rate. The measurement range of the flow rate is 20 - 22000 nL/min with laser power of 11.43 mW to 146.31 mW. The maximum manipulation distance is about 715 ?m. The MDFRC can achieve 5nL/min at low rate range between 20 nL/min and 100nL/min which is 2 orders of magnitude better than the state-of-the-art microfluidic flowmeters. At other ranges, the MDFRC is around 5% of the measurand. The experimental results indicates that the sensor has a good repeatability for flow rate measurement. Theoretical analysis and numerical simulations were also provided and used for experimental discussion.

9548-42, Session 11

Optically-induced circulation of dielectric particles with fiber optic Bessel beam

Boram Joo, Sungrae Lee, Kyunghwan K. Oh, Yonsei Univ. (Korea, Republic of)

Bessel beams are important for applications in optical trapping because they have non-diffracting and self-reconstructing properties. Bessel beams are usually generated by bulk optic systems using ring apertures or axicons. We fabricated a fiber device to generate a Bessel-like beam that is significantly more compact than a conventional bulk-optic Bessel beam generation system. This Bessel beam generation(BBG) device is composed of two fiber segments: a single mode fiber section and a coreless silica fiber(CSF), both with diameter 125?m. The fundamental LP01 mode from the input SMF excites LP0m higher order modes in the CSF to form an interferometric concentric intensity distribution similar to a Bessel function. This alignment-free and micro-scale BBG device is well-suited for "Lab on a Chip" systems.

In this experiment, the BBG devices are connected to 980 nm He-Ne laser diodes. Three BBG devices are located inside a solution of polystyrene beads(n=1.55, D=15?m) and water to form a 3-beam array. The polystyrene beads are trapped by the beams and transported along the beam propagation direction. At the points where the Bessel-like beams are crossed, the bead changes its path from the initial trapping beam to the next beam. We were able to change the bead's path at a crossing of 120 degrees by utilizing the optical power difference between the beams. We set up a triangular beam route with three BBG devices. By controlling the speed and angular motion of the particles, we have demonstrated optically induced circulation of particles along triangular routes. This technique is applicable to the control of motion of living cells in a microscopic environment.

9548-43, Session 11

Ultrathin optical fibers for particle trapping and manipulation

Síle G. Nic Chormaic, Okinawa Institute of Science and Technology Graduate Univ. (Japan); Aili Maimaiti, Okinawa Institute of Science and Technology Graduate Univ. (Japan) and Univ. College Cork (Ireland); Marios Sergides, Ivan Gusachenko, Viet Giang Truong, Okinawa Institute of Science and Technology Graduate Univ. (Japan)

In recent years, optical micro- and nanofibres (MNF) have shown their potential as trapping devices across a range of particle size regimes, from atoms to microparticles. The fibers, with waist diameters close to or less than the wavelength of the guided light, have unique properties due to the strong evanescent field that extends from the waist region into the surrounding environment. This field can have very high intensities for very low guided light powers over the full length of the nanofiber, which is typically a few millimeters. This provides experimentalists with a relatively easy method of extending the interaction length between a tightly focused light beam and the surrounding environment. To date, most work on micron sized particles around optical MNFs has dealt with multiparticle trapping

and propulsion, and has been limited to fundamental mode propagation within the optical fiber. Research on higher order mode (HOM) particle trapping and manipulation was avoided due to the difficulties in fabricating MNFs that permit HOM propagation. Here, we report on HOM propagation in MNFs and the speed enhancement that can be achieved for dielectric particles moving under the influence of this mode. Optical binding using HOMs in MNFs has also been investigated. Detailed simulations support the experimental results and provide insight into the inter-dynamics of particle assembly within the multiparticle chains.

9548-44, Session 12

Stochastic thermodynamics with a Brownian particle in an optical trap *(Invited Paper)*

Ignacio A. Martinez, ICFO - Institut de Ciències Fotòniques (Spain) and Ecole Normale Supérieure de Lyon (France); Édgar Roldán, ICFO - Institut de Ciències Fotòniques (Spain) and Max-Planck-Institut für Physik komplexer Systeme (Germany) and Grupo Interdisciplinar de Sistemas Complejos (Spain); Luis Dinis, Grupo Interdisciplinar de Sistemas Complejos (Spain) and Univ. Complutense de Madrid (Spain); Pau Mestres, ICFO - Institut de Ciències Fotòniques (Spain); Juan M. R. Parrondo, Grupo Interdisciplinar de Sistemas Complejos (Spain) and Univ. Complutense de Madrid (Spain); Raúl A. Rica, ICFO - Institut de Ciències Fotòniques (Spain)

Stochastic thermodynamics [1,2] is a recently developed framework to deal with the thermodynamics at the microscope, where thermal fluctuations strongly influence their behaviour. Typical such systems are colloids and biomolecules or cells. These thermal fluctuations do not only lead to Brownian motion, but to a continuous and unavoidable heat exchange between the suspending medium and the particles, leading to a very interesting phenomenology. In order to explore such phenomenology and to test theoretical results obtained from stochastic thermodynamics, we developed an “experimental simulator” of thermodynamic devices in the microscale with an optically trapped bead that is subject to an external noise that mimics a controllable thermal bath. The noise is applied by means of electric fields acting on the charge of the trapped particle.

In this talk, I will present some of the results we obtained with this simulator, demonstrating excellent control over the effective temperature of the system and a control parameter. This allows us to perform a variety of equilibrium and non-equilibrium thermodynamic processes [3-5]. In particular, we were able to realize microadiabatic processes, where no heat is exchanged on average between the particle and the medium [6]. This achievement allowed us to implement a Carnot microengine as a concatenation of isothermal and adiabatic processes [7], whose theoretical study is playing a key role in the foundations of stochastic thermodynamics.

Auto correlation and relaxation time measurements on metal oxide core: dielectric shell beads in an optical trap

Shruthi S. Iyengar, Praveen Parthasarathi, Rekha Selvan, Sarbari Bhattacharya, Sharath Ananthamurthy, Bangalore Univ. (India)

Optical Tweezers are capable of trapping individual particles of sizes that range from sub micrometers to micrometers. By measuring the fluctuations in the position of the trapped particle with time, one can compute the trap strength experienced by the particle. It is reported that the trap strength of a dielectric bead, increases linearly with increase in the power of the trapping laser. The situation with metallic particles, however, is strongly dependent on the particle size. Available literature shows that metallic Rayleigh particles, despite having scattering no different from dielectric particles of similar sizes, experience enhanced trap strengths due to larger polarizability. On the contrary, micrometer sized metallic particles are poor candidates for trapping due to high reflectivity. We report here that core-shell (metal oxide-dielectric) micrometer sized beads are trapped like dielectric beads, but with reduced corner frequency compared to ordinary dielectric beads at the same laser power. We attribute this anomaly to an increase in the temperature of the surrounding of the bead due to an enhanced dissipation of the laser power as heat. The variation in the auto correlation coefficients and thereby relaxation times of such beads with laser power contrasted with that of ordinary dielectric beads supports our claim. We propose to extend this work towards extracting hydrodynamic correlations between beads where one is a heat source and study its variation as a function of the inter bead separation.

9548-46, Session 12

Tailoring defects in colloidal crystals using an external “non-affine” field

Saswati Ganguly, Indian Association for the Cultivation of Science (India); Surajit Sengupta, TIFR Ctr. for Interdisciplinary Sciences (India); Peter Sollich, King’s College London (United Kingdom)

Thermal fluctuations of displacements of particles within a small sub-volume in a two-dimensional colloidal crystal may be either affine or non-affine. Displacements are fully affine only if the instantaneous positions of all the particles in the sub-volume can be represented as an uniform deformation of the ideal reference configuration. Mostly however, these displacements are non-affine with the overall deviation from affine-ness being measured by a well defined non-affine parameter X. We show that X has all the characteristics of a thermodynamic variable and may be tuned using the conjugate non-affine field h_X. We show further that the largest contribution to X comes from displacements which are precursors to the creation of elementary dislocation dipoles. Hence, tuning X also automatically changes dislocation concentrations. Finally, we present a proposal for an experiment aiming to construct h_X using laser tweezer techniques. With presently available particle manipulation techniques one can only increase the defect concentration by introducing dislocation dipoles in colloidal crystals. Manipulating h_X , on the other hand, would allow one to both increase or decrease X and, therefore, the defect concentrations. Our method may find application in the study of the stability of crystals or in the manipulation of mechanical properties of colloidal crystals by external fields. A preprint presenting preliminary results from this work is available at http://arxiv.org/abs/1502.00042.

9548-47, Session 12

Plasticity avalanches for colloidal crystals in dynamical optical traps

Cynthia J. Reichhardt, Los Alamos National Lab. (United States); Danielle McDermott, Wabash College (United States); Charles M. Reichhardt, Los Alamos National Lab. (United States)

Colloidal assemblies are an ideal system in which to study general features of equilibrium and nonequilibrium phenomena since, due to their size scale, microscopic information about the particle configurations and dynamics can be accessed directly. Additionally, recent advances in optical trapping techniques permit the manipulation of colloidal particles at individual and collective levels. Here we numerically examine a collection of charge-stabilized colloids forming a triangular crystal that is placed in a quasi-one-dimensional confining potential which could be created using optical means. The potential depth is slowly increased to uniaxially compress the colloidal assembly. During the compression process, colloid motion occurs via both slow elastic distortions as well as short bursts or avalanches in which plastic rearrangements of the colloids occur. These rearrangements are associated with structural changes in the colloid lattice that make the configuration more isotropic and permit new triangular arrangements to fit in the trap. At high compression the avalanches are associated with row reduction events for the number of colloids that fit across the width of the confining potential. We also find that the colloid velocity distributions during the avalanches have power law tails with exponents close to those found for gliding dislocations. We also examine cases in which the colloidal interactions are more complex and consist of both attractive and repulsive components. Here we observe sharp transitions in which the entire structure of the lattice can change, producing sudden volume-collapse type events that result in the formation of a more compact colloidal lattice structure.

9548-48, Session 12

Combined magneto- and optofluidic assembly of colloidal chains of controllable length

Tao Yang, Ning Wu, David WM Marr, Colorado School of Mines (United States)

Because of their unique characteristics, colloids have been used to investigate the fundamental physics of soft materials including both equilibrium phase behavior and kinetic processes. Unlike atoms, colloidal sizes can be conveniently tailored and are typically large enough to be probed individually with interaction strengths and effective ranges that can be modulated over several orders of magnitude. Despite these significant advantages, only relatively simple colloidal models such as spheres have been created; such systems in turn assemble into crystals of fairly limited symmetry, precluding the study of problems associated with complex structure. To push towards the synthesis of more complicated colloidal molecules, we use combined applied magnetic and anisotropic optical fields to fabricate colloidal chains. By integrating these induced forces within microfluidic channels and in flow, we grow colloidal chains one particle at one time, mimicking step-growth polymerization. The key advantage of this method is the ability to precisely control chain length and sequence, both essential for studies of self-assembly. In this, chain length is determined by a balance between the hydrodynamic shear stress, applied magnetic field, and the optical forces applied. Once a desired chain length is achieved, we fix the assembly in situ via the use of thiol-functionalized magnetic beads and a functionalized polyethylene glycol crosslinker. With the ability to perform directed assembly and irreversible fixation in flow, a route to the high-throughput synthesis of colloidal molecules can be achieved.

9548-49, Session 13

Controlling hydrodynamic interactions in driven systems *(Invited Paper)*

David B. Phillips, Rebecca F. Hay, Graham Gibson, Univ. of Glasgow (United Kingdom); Stephen H. Simpson, Institute of Scientific Instruments of the ASCR, v.v.i. (Czech Republic); Miles J. Padgett, Univ. of Glasgow (United Kingdom)

Hydrodynamic interactions in low Reynolds number environments, where inertial forces are dominated by viscous ones, can give rise to some unusual effects.

At the micro-scale, particles continually undergo random walks due to the stochastic forces of Brownian motion. Nearby particles feel correlated Brownian forces, and so their motion is coupled.

The addition of external forces on such particles induces more coupling, as the flow-field generated around a moving particle in turn exerts hydrodynamic forces on surrounding objects. Although the underlying rules at play are well known, they can result in counter-intuitive behaviour, even in simple systems.

In this work we study two such systems. Firstly we show that an optically trapped microsphere in a time-reversible oscillating flow-field (created by a nearby optically trapped microsphere driven in an oscillatory manner) can exhibit a trajectory that breaks time-reversal symmetry. This is a consequence of the competition between the time-dependent hydrodynamic flow and the positiondependent optical force as the microsphere moves in the harmonic potential of the optical trap. We investigate the transfer of energy between the two hydrodynamically coupled particles, and describe how the topology of the resulting trajectories varies as the driven beads motion is altered.

Secondly, we study how such systems can exhibit yet more elaborate effects by moving the driving optical traps according to feedback on the positions of hydrodynamically interacting microspheres.

9548-50, Session 13

Hydrodynamic synchronisation in arrays of hollow beams

Luke J. Debono, Univ. of Bristol (United Kingdom); Stephen Simpson, Institute of Scientific Instruments of the ASCR, v.v.i. (Czech Republic); Simon Hanna, Univ. of Bristol (United Kingdom)

Hydrodynamic synchronisation has previously been observed in pairs of simple rotors controlled by optical tweezers. In one scenario, pairs of beads were driven on circular trajectories by moving Gaussian traps [Kotar et al, PRL 11,228103 (2013)]; in another, rigid spheroids were rotated by the angular momentum in vortex beams [Arzola et al, Opt. Exp. 22, 16207 (2014)]. In both cases, synchronised motion resulted from hydrodynamic interactions (HI). In the present computational study, we examine the stochastic behaviour of ensembles of microspheres trapped in the bright annuli of arrays of LG beams. In this model, the angular momentum of the beams provides the azimuthal driving force, while HI lead to synchronicity. The conditions for synchronisation are explored. Intriguingly, synchronisation is more difficult to achieve as the number of LG beams increases. This results from the long-range nature of HI in the low Reynolds number regime. In square arrays of rotors, the corner rotors are in substantially different environments from those on the edges and on the inside of the array, and experience correspondingly lower synchronisation forces and lower velocities. On the other hand, patches of rotors moving in concert tend to speed up, owing to the additive effects of the hydrodynamic forces. The net result, for large arrays of rotors, is a fragile synchrony; patches of synchronisation forming due to HI, are constantly moving, breaking up and re-forming due to stochastic forces. Learning to control the synchronised motion of large arrays of rotors is viewed as an important step in the development of micro-machines to deliver motion on the macroscopic scale.

9548-51, Session 13

Hydrodynamics of micro-objects near curved surfaces

Shu Zhang, David Carberry, Timo A. Nieminen, Halina Rubinsztein-Dunlop, The Univ. of Queensland (Australia)

Boundary walls have a strong influence on the drag force on optically trapped object near surface. Faxen's correction has shown how a flat surface modifies the hydrodynamic drag. However, to date, the effect of curved walls at microscopic scale on both translational and rotational movement of micro-objects has not been studied. Here we describe our experiments which aim to study the drag force on optically trapped particles moving near walls with different curvatures.

The curved walls were made using 3D laser nano-printing (Nanoscribe), and optical tweezers were used to trap micro-objects near the walls. The translational and rotational motion of the optically trapped particle is related to the drag coefficients. By monitoring the change in the motion of particle, we determined the increase in drag force for particles translating or rotating at different distances from surfaces with different curvatures.

These results are essential for calibrating the drag force on particles, and thus enable accurate rheology at the micron-scale. This opens the potential for microrheology under different conditions, such as within microdevices, biological cells and studies of biological processes

9548-52, Session 13

Boundary element method for optical force calibration in microfluidic dual-beam optical trap

Mehmet E. Solmaz, Izmir Katip Celebi Univ. (Turkey); Barbaros Cetin, Bilkent Univ. (Turkey); Besim Baranoglu, Atilim Üniv. (Turkey); Murat Serhatlioglu, Necmi Biyikli, Bilkent Univ. (Turkey)

The potential use of optical forces in microfluidics environment enables highly selective bioparticle manipulation [1, 2]. Manipulation could be accomplished via trapping or pushing a particle due to optical field. Empirical determination of optical force is often needed to ensure efficient operation of manipulation. The external force applied to a trapped particle in a microfluidic channel is a combination of optical and drag forces. The optical force can be found by measuring the particle velocity for a certain laser power level and the Faxen's law [3] is applied as the multiplicative correction factor for the proximity of the particle to the channel surface. This method is not accurate especially for small microfluidic geometries where the particle size is in Mie regime and is comparable to channel cross section. In this work, we propose to use Boundary Element Method (BEM) to simulate fluid flow within the microchannel with the presence of the particle to predict drag force on the particle. This way, the drag force on the particle will be determined accurately and the optical power will be calibrated. We will perform pushing experiments in a dual-beam optical trap and extracted the particle's position information. We will then obtain the drag force acting on the particle using BEM. We will also compare our results with the traditional drag force correction factor.

9548-53, Session 13

Rotational behavior of oblate spheroids in circularly polarized dual beam optical trap

Martin ?iler, Oto Brzobohat?, Institute of Scientific Instruments of the ASCR, v.v.i. (Czech Republic); Alejandro V. Arzola, Univ. Nacional Autónoma de México (Mexico); Luká? Chvátal, Petr Jákl, Stephen H. Simpson, Pavel Zemánek, Institute of Scientific Instruments of the ASCR, v.v.i. (Czech Republic)

We study the rotational dynamics of oblate spheroids in an optical trap which is based on interference of two counter-propagating Gaussian beams that are circularly polarized. Single spheroid may either rotate with a frequency determined by its size and aspect ratio or it may be oriented in a symmetric state where it is not rotating. The experimental results are supported by numerical calculations based on Finite elements method and T-matrix. Furthermore, a pair of spheroids display phase locking behavior and the introduction of additional particles leads to yet more complex behavior.

9548-54, Session 13

Spatial optical solitons in bidisperse fluorescent nanocolloids

M. Yadira Y. Salazar Romero, Instituto de Investigaciones en Materiales (Mexico); Juan Hernández-Cordero, Karen P. Volke-Sepúlveda, Alejandro V. Arzola, Univ. Nacional Autónoma de México (Mexico); Yareni Ayala, Univ Nacional Autónoma de México (Mexico)

We report on the nonlinear effects of light propagation through a fluorescent nanocolloid. The medium was formed by a bidisperse suspension of fluorescent and nonfluorescent nanospheres of similar diameters (60nm and 57nm, respectively) in distilled water. A CW laser beam (532 nm wavelength) was focused into the nano-suspension, generating a spatial optical soliton of a few millimeters in length as a result of the compensation between beam diffraction and the self-focusing nonlinearity. The threshold power and focusing conditions to create the soliton were analyzed as a function of the pump power and hysteresis effects were observed. We also varied the concentration of both types of particles and the size of the nonfluorescent nanospheres and studied their effect in the soliton formation. Thermal effects caused by the absorption of the fluorescent particles are discussed.

9548-55, Session 13

Spatio-temporal formation of amyloid aggregates by laser trapping of domain-swapped dimeric cytochrome c

Ken-ichi Yuyama, National Chiao Tung Univ. (Taiwan); Mariko Ueda, Satoshi Nagao, Shun Hirota, Nara Institute of Science and Technology (Japan); Teruki Sugiyama, National Applied Research Labs. (Taiwan); Hiroshi Masuhara, National Chiao Tung Univ. (Taiwan)

Laser trapping of a focused laser beam has been employed to gather molecules in solution spatio-temporally and realized the formation of a small molecular assembly in the focal volume. When the small molecular assembly evolves to a nucleus, it is grown outward from the focal spot, and eventually a crystal or a dense liquid droplet is generated under certain trapping conditions. In this paper, we present the spatio-temporal formation of protein amyloid aggregate by laser trapping in solution. Protein amyloids have recently attracted considerable interest because their accumulation in vivo is related to serious diseases and they have unique morphology of nanometer-scale fibrils. When a continuous-wave laser beam of 1064 nm was focused into a D2O solution of domain-swapped dimeric cytochrome c through an objective lens (100 magnification, NA = 1.4), the proteins were gathered at the focal spot, and a particle-like small assembly was formed in the focal volume. The small assembly greatly extended toward the outside of the focal spot after a certain lag time and eventually reached a diameter of over 10 ?m. Through a few kinds of analyses of the assembly, we confirmed that the large assembly resultant from dimeric cytochrome c consists of amyloid fibrils measuring several hundred nanometers in length and 5–10 nm in diameter. This spatio-temporal formation of amyloids by laser trapping is useful for fabricating and patterning amyloids as well as for elucidating the dynamics and mechanism of amyloid formation.

9548-56, Session 14

Behavior and applications of active Brownian particles in complex and crowded environments *(Invited Paper)*

Giovanni S. Volpe, Bilkent Univ. (Turkey)

Active Brownian particles, also know as microswimmers and nanoswimmers, have recently come under the spotlight, becoming the focus of the research of many groups around the world from the physical and biophysical communities alike. These swimmers are biological or manmade microscopic and nanoscopic particles that can propel themselves. Their behavior can therefore only be explained and understood within the framework of far-from-equilibrium physics. Several microscopic biological entities perform active Brownian motion, for example, when moving away from a poison or towards a source of food; a paradigmatic example is the swimming behavior of bacteria such as Escherichia coli. Inspired by these microorganisms, researchers around the world have been developing artificial active particles that can reproduce the swimming behavior of motile biological cells based on very different and varied physical mechanisms; the reason for this interest lies in the potential these manmade micro- and nanomachines hold as autonomous agents for healthcare, sustainability and security applications: for example, by enabling the targeted localization, pick-up and delivery of nanoscopic objects with applications including bioremediation, catalysis, chemical sensing and drug-delivery. In this talk I will review this field of research and present some of my latest results.

9548-57, Session 14

Pattern formation for active particles on optically created ordered and disordered substrates

Charles M. Reichhardt, Dipanjan Ray, Cynthia J. Reichhardt, Los Alamos National Lab. (United States)

There has been tremendous growth in the field of active matter, where the individual particles that comprise the system are self-driven. Examples of this class of system include biological systems such as swimming bacteria and crawling cells. More recently, non-biological swimmers have been created using colloidal Janus particles that undergo chemical reactions on one side to produce self-propulsion. These active matter systems exhibit a wide variety of behaviors that are absent in systems undergoing purely thermal fluctuations, such as transitions from uniform liquids to clusters or living crystals, pushing objects around, ratchet effects, and phase separation in mixtures of active and passive particles. Here we examine the collective effects of active matter disks in the presence of static or dynamic substrates. For colloids, such substrates could be created optically in the form of periodic, random, or quasiperiodic patterns. For thermal particles, increasing the temperature generally increases the diffusion or mobility of the particles when they move over a random or periodic substrates. We find that when the particles are active, increasing the activity can increase the mobility for smaller run lengths but decrease the mobility at large run lengths. Additionally we find that at large run lengths on a structured substrate, a variety of novel active crystalline states can form such as stripes, squares and triangular patterns.

9548-58, Session 14

Study of microparticles' anomalous diffusion in active bath using speckle light fields

Ercag Pince, Sabareesh K. P. Sabareesh, Bilkent Univ. (Turkey); Giorgio Volpe, Univ. College London (United Kingdom); Sylvain Gigan, Univ. Pierre et Marie Curie (France); Giovanni S. Volpe, Bilkent Univ. (Turkey)

Particles undergoing a stochastic motion within a disordered medium is a ubiquitous physical and biological phenomenon. Examples can be given from organelles as molecular machines of cells performing physical tasks in a populated cytoplasm to human mobility in patchy environment at larger scales. Our recent results showed that it is possible to use the disordered landscape generated by speckle light fields to perform advanced manipulation tasks at the microscale. Here, we use speckle light fields to study the anomalous diffusion of micron size silica particles (5 ?m) in the presence of active microswimmers. The microswimmers we used in the experiments are motile bacteria, Escherichia coli (E.coli). They constitute an active background constantly agitating passive silica particles within complex optical potentials. The speckle fields are generated by mode mixing inside a multimode optical fiber where a small amount of incident laser power (maximum power = 12 ?W/?m2) is needed to obtain an effective random landscape pattern for the purpose of optical manipulation. We experimentally show how complex potentials contribute to the anomalous diffusion of silica particles undergoing collisions with swimming bacteria. We observed an enhanced diffusion of particles interacting with the active bath of E.coli inside speckle light fields: this effect can be tuned and controlled by varying the intensity and the statistical properties of the speckle pattern. Potentially, these results could be of interest for many technological applications, such as the manipulation of microparticles inside optically disordered media of biological interests.

9548-59, Session 14

Noise, fluctuations, and nonlinear mechanical properties of living cells

H. Daniel Ou-Yang, Ming Tzo Wei, Dimitrios Vavylonis, Sabrina Jedlicka, Lehigh Univ. (United States)

Living cells are a non-equilibrium mechanical system, largely because intracellular molecular motors consume chemical energy to generate forces that reorganize and maintain cytoskeletal functions. Persistently under tension, the network of cytoskeletal proteins exhibits a nonlinear mechanical behavior where the network stiffness increases with intracellular tension. We examined the nonlinear mechanical properties of living cells by characterizing the differential stiffness of the cytoskeletal network for HeLa cells under different intracellular tensions. Combining optical tweezer-based active and passive microrheology methods, we measured non-thermal fluctuating forces and found them to be much larger than the thermal fluctuating force. From the variations of differential stiffness caused by the fluctuating non-thermal force for cells under different tension, we obtained a master curve describing the differential stiffness as a function of the intracellular tension. Varying the intracellular tension by treating cells with drugs that alter motor protein activities we found the differential stiffness follows the same master curve that describes intracellular stiffness as a function of intracellular tension. This observation suggests that cells can regulate their mechanical properties by adjusting intracellular tension.

9548-60, Session 15

Using optical tweezers to assess the role of inter-protein interactions in collagen self-assembly *(Invited Paper)*

Tuba Altindal, Marjan Shayegan, Evan Kiefl, Nancy R. Forde, Simon Fraser Univ. (Canada)

Collagen is a structural protein which is capable of self-assembling into hierarchical fibrillar structures. These structures form the basis of the extracellular scaffolding in the connective tissues of vertebrates. Further, collagen-based structures continuously remodel in a dynamic fashion. Collagen self-assembly into fibrils relies on specific interactions between these constituent proteins. Identification and characterization of these interactions is crucial for our understanding of the extracellular environment and cellular decisions prompted by this environment.

Here, we describe the results of the experiments where we probed the frequency-dependent viscoelasticity of collagen solutions with intact and

removed telopeptides using optical-tweezers-based passive microrheology. Telopeptides are short non-helical regions at the ends of triple helical collagen molecules, and their proteolytic removal results in a delay in the onset of fibril formation. We find that the removal of telopeptides significantly reduces elasticity of collagen solutions at timescales from ~10 msec to ~1 sec. By examining the loss modulus, we also find that increasing the concentration of telopeptide-intact collagen results in a growing non-Maxwellian behavior at low frequencies. Telopeptides have previously been postulated to bind transiently to specific sites on adjacent collagen triple helices in solution, and thus may facilitate the otherwise less probable alignment of two collagen molecules in proper register. Our microrheology experiments provide evidence of increased strength and duration of interprotein contact arising from the presence of telopeptides, critical in catalyzing self-assembly of fibrillar collagen systems.

9548-61, Session 15

Viscoelastic properties of subcellular structures measured by fluorescence correlation spectroscopy

Jens-Christian D. Meiners, Rudra P. Kafle, Molly R. Liebeskind, Univ. of Michigan (United States)

Mechanical quantities like the elasticity of cells are conventionally measured by directly probing them mechanically. This, however, is often impractical, and even impossible when subcellular structures inside living cells are concerned. We use a purely optical method instead; an adaptation of fluorescence correlation spectroscopy (FCS) to measure such mechanical quantities in chromosomal DNA in live E. Coli cells.

FCS is a fluorescence technique conventionally used to study the kinetics of fluorescent molecules in a dilute solution. Being a non-invasive technique, it is now drawing increasing interest for the study of more complex systems like the dynamics of DNA or proteins in living cells and cell membranes. Unlike an ordinary dye solution, the dynamics of macromolecules like proteins or entangled DNA in crowded environments is often slow and subdiffusive in nature. This in turn leads to longer residence times of the attached fluorophores in the excitation volume of the microscope and artifacts from photobleaching abound that can easily obscure the signature of the molecular dynamics of interest.

We present a method of calculating the intensity autocorrelation function from the arrival times of the photons on the detector that maximizes the information content while correcting for the effect of photobleaching to yield an autocorrelation function that reflects only the underlying dynamics of the sample. This autocorrelation function in turn is used to calculate the mean square displacement of the fluorophores attached to DNA. By using a suitable integral transform of the mean square displacement, we determine the viscoelastic moduli for lambda-DNA solution and the DNA in E. coli. We note that these mechanical quantities evaluated by an optical technique are in good agreement with similar quantities measured by completely different techniques.

9548-62, Session 15

Calibration of femtosecond optical tweezer as a sensitive thermometer

Dipankar Mondal, Debabrata Goswami, Indian Institute of Technology Kanpur (India)

We present the effects of a femtosecond perturbing heating source on an optical tweezer. Our experiments involve a unique combination of a non-heating femtosecond trapping laser at 780 nm with a femtosecond Infrared (1560 nm) laser at low power (100-800 μW) to cause heating in the trapped volume. We can control the temperature precisely around the optical trap center with such an experimental system. The 1560 nm high repetition rate laser acts as a resonant excitation source for the vibrational combination band of the hydroxyl group (OH) of water, which helps to create the local heating effortlessly within the trapping volume. We have observed for the first time direct effect of temperature on the corner frequency deduced from power spectrum. This observation leads us to calculate the viscosity as well as the temperature within the vicinity of the trapping zone. These experimental results also support the well-known fact that the behavior of Brownian motion is a response from optically trapped bead due to temperature change of surroundings. Temperature rise near the trapping zone can significantly change the viscosity of the medium. However, we notice that though the temperature and viscosity are changing as per our corner frequency calculations, the trap stiffness remains same throughout our experiments conducted within the temperature range of about 20 K.

9548-63, Session 16

Three dimensional living neural networks

Anna M. Linnenberger, Meadowlark Optics, Inc. (United States)

We investigate holographic optical tweezing combined with step-and-repeat maskless projection stereolithography for fine control of 3D position of living cells within a 3D microstructured hydrogel grid. PC12 cells were chosen as a demonstration platform because they can easily differentiate into neuron-like cells, exhibiting properties similar to neurons. PC12 cells are positioned in the monomer solution with optical tweezers at 1064 nm and then are encapsulated by photopolymerization of polyethylene glycol (PEG) hydrogels formed by thiol-ene photo-click chemistry via projection of a 512x512 spatial light modulator (SLM) illuminated at 405 nm. Fabricated samples are incubated in differentiation media containing nerve growth factor such that the PC12 cells cease to replicate and begin to form axon-like structures. By controlling the position and direction of channels between cells within the encapsulating hydrogel structure the formation of the neuron-like circuits is controlled. The samples fabricated with this system are a useful model for future studies of neural circuit formation, neurological disease, cellular communication, plasticity, and repair mechanisms.

9548-64, Session 16

Multi-point optical manipulation and simultaneous imaging of neural circuits through wavefront phase modulation

Samira Aghayee, Dan Winkowski, Patrick Kanold, Wolfgang Losert, Univ. of Maryland, College Park (United States)

The spatial connectivity of neural circuits and the various activity patterns they exert is what forms the brain function. How these patterns link to a certain perception or a behavior is a key question in neuroscience. Recording the activity of neural circuits while manipulating arbitrary neurons leads to answering this question. That is why acquiring a fast and reliable method of stimulation and imaging a population of neurons at a single cell resolution is of great importance. Owing to the recent advancements in calcium imaging and optogenetics, tens to hundreds of neurons in a living system can be imaged and manipulated optically. We describe the adaptation of a multi-point optical method that can be used to address the specific challenges faced in the in-vivo study of neuronal networks in the cerebral cortex. One specific challenge in the cerebral cortex is that the information flows perpendicular to the surface. Therefore, addressing multiple points in a three dimensional space simultaneously is of great interest. Using a liquid crystal spatial light modulator, the wavefront of the input laser beam is modified to produce multiple focal points at different depths of the sample for true multipoint two-photon excitation.

9548-65, Session 16

Trapping and manipulation of bacteria with circular Airy beams

Drew Bischel, Anna S. Bezryadina, Joseph C. Chen, Zhigang Chen, San Francisco State Univ. (United States)

In micromanipulation and optical trapping, rod-shaped objects have a tendency to align along the propagation direction of the beam, which limits simultaneous trapping and observation of the entire cellular structure. We utilize a circular Airy beam (CAB) to optically trap rod-shaped and multi-pronged bacteria in the observation plane and controllably stretch in transverse direction. This is achieved by exploiting the outward transverse acceleration of the autofocusing Airy beam, which acts as a radially outward force along the poles of a bacterium in the sample plane. This beam can be used to trap a multi-pronged bacterium by applying an evenly distributed tunable lateral force to the parts of the cell caught within the adjustable optical ring. We demonstrate that the CAB can be used as a tool to stretch symmetric and asymmetrically mutated S. meliloti cells, as well as bacterial clusters via its radial profile. This approach explores the use of the CAB as a tool for micromanipulation and for studying cellular clustering and aggregation, intercellular interactions, and viscoelasticity of cells with nontrivial morphologies.

9548-66, Session 16

Label-free dynamic optical chromatography for laser analysis of biological samples

Alex V. Terray, U.S. Naval Research Lab. (United States)

Label-free Optical Chromatography is a transformative NRL grown technology that is transitioning to industry. Over the last 12 years, this NRL basic research program has matured from a simple experiment to push a plastic particle with a laser against flow to a fully capable analytical measurement and sorting instrument that measures the subtle optical forces on micron sized particles and cells. This technology has been used to distinguish the optical forces of Bacillus anthracis Sterne spores for biological warfare agent detection and the optical forces of blood components in the body. Recently, we have used this sensitive analysis techniques to identify the host response in macrophage cells exposed to Bacillus anthracis Sterne spores. Through a collaboration with our industry partner LumaCyte, an NRL built prototype sits in UVA's Flow Cytometry Core Facility. Researchers are using it to study cancer, infectious diseases, drug development and more. Because the technology is based on a completely label-free method, the information revealed has the potential to identify previously unknown changes in cells during infection or injury.

9548-67, Session 17

Listening to proteins and viruses with nanoaperture optical tweezers *(Invited Paper)*

Reuven Gordon, Univ. of Victoria (Canada)

This talk will present a nanoaperture tweezer approach to measure the acoustic spectra of viruses and single proteins. The approach, termed extraordinary optical Raman (EAR), shows promise for uncovering the structure and mechanical properties of nanoparticles as well as the effects of their interactions.

9548-69, Session 17

Characterization of periodic plasmonic nanoring devices for nanomanipulation

Marios Sergides, Viet Giang Truong, James R. Schloss, Bishwajeet S. Bhardwaj, Síle G. Nic Chormaic, Okinawa Institute of Science and Technology Graduate Univ. (Japan)

We study the optical properties of hybrid gold nanodisk and nanohole arrays and present experimental evidence of nanoparticle trapping using these devices. The fabrication procedure using electron beam lithography (EBL) is also discussed. This hybrid design exhibits a splitting of the resonance modes (low and high energy modes) due to the coupling of the electromagnetic interaction between nanohole and nanodisk plasmons. The devices demonstrate high plasmon resonance tunabilities from the visible to the near-infrared region (NIR) by varying the periodicity, dimension of the disks, and holes of the arrays. This enhancement in the NIR is highly desirable for the purposes of biological sample manipulation where photo damage is low. The characterization of the devices is achieved by excitation using evanescent fields via the Kretschmann configuration. The spectrometric measurements are conducted by monitoring the reflected light at the prism-water interface and the dependency of the plasmon resonance frequency on the incident angle and polarization is investigated. Additionally, these devices consist of grooves connecting the hybrid structures to each other. These regions provide further enhancement of the local electric fields and play the role of the trapping sites. We demonstrate multiple fluorescent dielectric nanoparticle trapping in these grooves. The incident angle and polarization dependency is also considered in the trapping experiments. The results provide good evidence of the potential of this design to be used for the manipulation of biological samples with sub-diffraction limit sizes.

9548-70, Session 17

Optical trapping of nanoparticles with significantly reduced laser powers by using counter-propagating beams

Chenglong Zhao, Thomas W. LeBrun, National Institute of Standards and Technology (United States)

Gold nanoparticles (GNP) have wide applications ranging from nanoscale heating to cancer therapy and biological sensing. Optical trapping of GNPs as small as 18 nm has been successfully achieved with laser power as high as 855 mW, but such high powers can damage trapped particles (particularly biological systems) as well heat the fluid, thereby destabilizing the trap.

In this article, we show that counter propagating beams (CPB) can successfully trap GNP with laser powers reduced by a factor of 50 compared to that with a single beam. The trapping position of a GNP inside a counter-propagating trap can be easily modulated by either changing the relative power or position of the two beams. Furthermore, we find that under our conditions while a single-beam most stably traps a single particle, the counter-propagating beam can more easily trap multiple particles. This (CPB) trap is compatible with the feedback control system we recently demonstrated to increase the trapping lifetimes of nanoparticles by more than an order of magnitude. Thus, we believe that the future development of advanced trapping techniques combining counter-propagating traps together with control systems should significantly extend the capabilities of optical manipulation of nanoparticles for prototyping and testing 3D nanodevices and bio-sensing.

9548-71, Session 17

Plasmonic hybridization induced trapping and manipulation of metallic nano-objects

Changjun Min, Shenzhen Univ. (China); Yuquan Zhang, Nankai Univ. (China); Lichao Zhang, Xiaocong Yuan, Shenzhen Univ. (China)

Hybridization in the narrow gaps between the surface plasmon polaritons (SPP) along a metal surface and the localized surface plasmons (LSP) on metallic nano-objects strongly enhance the electromagnetic field. Here, we employ plasmonic hybridization to achieve dynamic trapping and manipulation of metallic nano-objects (particle, nanowire, nanorod, etc.) on a flat metal surface. We first reveal that metallic particles of nanometer to micrometer sizes can be attracted and steadily trapped due to the plasmonic hybridization in a plasmonic tweezers excited by a highly focused radially polarized beam, instead of being repulsed by a conventional optical tweezers due to high scattering force. Next we

demonstrate that trapping and manipulating various metallic nano-objects can be achieved by modifying the property of incident beam. We show that plasmonic hybridization achieved by exciting plasmonic tweezers with a linearly polarized laser beam could induce strong trapping forces and large rotational torques on a single metallic nanowire. The position and orientation of the nanowire could dynamically be controlled by the hybridization-enhanced nonisotropic electric field in the gap. Based on this technique, a plasmonic swallow tail structure is built to demonstrate its potential in the fabrication of lab-on-a-chip plasmonic devices. This work could provide a profound influence on manipulating various metallic nano-objects and have an important contribution to plasmonic lab-on-a-chip devices for quantum optics, optical characterization, spectroscopy, and sensing applications.

9548-72, Session 17

Aggregation of gold nanorods by optical forces for SERS biosensing in liquid environment

Barbara Fazio, Antonino Foti, Cristiano D'Andrea, Elena Messina, Valentina Villari, Onofrio M. Maragó, Norberto Micali, Istituto per i Processi Chimico-Fisici (Italy); Pietro G. Gucciardi, Consiglio Nazionale delle Ricerche (Italy)

Here we report on a novel concept of label-free, all-optical SERS biosensor for proteins detection in liquid, based on the laser-induced aggregation of gold nanorods (NRs) in proteins buffered solution. Commercial gold NRs dispersed in deionized water and capped with CTAB molecules are mixed with the target proteins dissolved in PBS in a glass microcell. A laser beam is then focused on a micron scale spot inside the liquid solution. Due to radiation pressure, NRs-protein complexes thermally drifting through the laser spot are pushed towards the bottom of the glass microcell. Here they stick and accumulate, forming SERS-active aggregates. BSA has been used as a model protein to test the sensor performances. We reach sensitivities down to 10-7 M, whereas solution phase Raman spectroscopy of BSA is already impossible at concentrations of 10-4 M. This methodology paves the way to a new generation lab-on-chip sensors that implies user-friendly experimental set up allowing for highly sensitive vibrational spectroscopy of biomolecules in their natural habitat.

9548-73, Session 18

Tilted optical trapping of anisotropic single crystal nanorod

Paul Brule-Bareil, Yunlong Sheng, Univ. Laval (Canada)

When a nanorod of typically d=100's nm diameter and h=1-3 micrometers length trapped in the optical tweezers, its orientation is along the trapping beam axis for h/d > 2 and is normal to beam axis for h/d < 2. We report the preliminary experimental observation that some anisotropic single crystal nanorod was stably trapped at a tiled angle to the beam axis. We explain the observation with the T-matrix calculation. In the anisotropic media, as the divergence of is non zero, the conventional vector spherical wave functions (VSWFs) do not individually satisfy the anisotropic vector wave equation. Some new bases, such as the modified VSWFS and qVSWF, have been proposed. Notice that the anisotropic nanorod is floating in the aquatic isotropic medium, we make the VSWF expansions of the incident and scattered fields in terms of , and the VSWF expansion of internal field in the anisotropic nanorod in terms of . Both expansions are therefore legitimate. The boundary condition was chosen as for the normal components of . The internal field is represented as a sum of a set of compoment VSWF expansions to gave better description with more expansion coefficients and to help the convergence of the T-matrix solver. Our calculation showed that when the optical axes of an anisotropic nanorod are not aligned to the nanorod axis, the nanorod may be trapped at a tilted angle position where the lateral torque is zero and its derivative is negative.

9548-74, Session 18

Studies on shape anisotropy in red blood cells

Argha Mondal, Basudev Roy, Sudipta Bera, Ayan Banerjee, Indian Institute of Science Education and Research Kolkata (India)

Red blood cells often demonstrate rotational motion (spin) inside optical tweezers – a phenomenon that has been attributed to both shape anisotropy and form birefringence induced due to the asymmetric shape, resulting in a degree of ambiguity about the cause of such rotation. We show by numerical simulations for a structure similar to RBCs' having large shape anisotropy, that the torque resulting from an imbalance in scattering forces due to shape anisotropy is almost an order of magnitude higher than that due to form birefringence. We also measure the entire Mueller Matrix for a trapped RBC and observe that the measured retardance due to form birefringence is similar to that numerically obtained in our model. In addition, we probe an important signature of shape anisotropy – that of a coupling between translational and rotational motion under the action of the trapping force. We introduce a coupling term as a measure of the shape anisotropy in the coupled Langevin equations, and numerically demonstrate that the cross correlation would indeed depend significantly on the value of the coupling term. We verify this experimentally by measuring the translational and rotational Brownian motion simultaneously using a quadrant photodiode. By trapping single RBCs' of different degrees of shape anisotropy, we demonstrate that the cross-correlation is indeed dependent on the shape anisotropy and fits very well to the solution obtained for the coupled Langevin equation numerically. Indeed, this could be a general technique to determine the presence of any anisotropy in trapped objects.

Low frequency dynamical stabilisation in optical tweezers

Christopher J. Richards, Thomas J. Smart, Univ. College London (United Kingdom); David Cubero, Univ. de Sevilla (Spain); Philip H. Jones, Univ. College London (United Kingdom)

It is well known that a rigid pendulum with minimal friction will occupy a stable equilibrium position vertically upwards when its suspension point is oscillated at high frequency. The phenomenon of the inverted pendulum was explained by Kapitza by invoking a separation of timescales between the high frequency modulation and the much lower frequency pendulum motion, resulting in an effective potential with a minimum in the inverted position.

We present here a study of an optical analogue of Kapitza's pendulum that operates in different regimes of both friction and driving frequency. The pendulum is realised using a microscopic particle held in a scanning optical tweezers and subject to a viscous drag force. The motion of the optical pendulum is recorded and analysed by digital video microscopy and particle tracking to extract the trajectory and stable orientation of the particle. In these experiments we enter the regime of low driving frequency, where the period of driving is comparable to, or greater than the characteristic relaxation time of the radial motion of the pendulum with finite stiffness.

In this regime we find stabilisation of the pendulum at angles other than the vertical (downwards) is possible for modulation amplitudes exceeding a threshold value where, unlike the truly high frequency case studied previously, both the threshold amplitude and equilibrium position are found to be functions of friction. Experimental results are complemented by analytical theory and Brownian motion simulations.

Laser trapping and assembling of nanoparticles at solution surface studied by reflection micro-spectroscopy

Shun-Fa Wang, Ken-ichi Yuyama, National Chiao Tung Univ. (Taiwan); Teruki Sugiyama, National Applied Research Labs. (Taiwan); Hiroshi Masuhara, National Chiao Tung Univ. (Taiwan)

Nanometer-sized objects like nanoparticles, polymers, and amino acids can be confined in the focal volume by conventional laser trapping in solution. Interestingly, the trapping behavior at a solution surface is different from that inside the solution, namely we have demonstrated laser trapping-induced crystallization of amino acids at a solution surface. In this paper, we present laser trapping dynamics of 200 nm polystyrene nanoparticles at a solution surface studied by reflection micro-spectroscopy. When a CW laser beam of 1064 nm was focused into a surface layer of the colloidal D2O solution through an objective lens (60 magnification, NA = 0.9), nanoparticle were gathered at and around the focal spot, and eventually a nanoparticle assembly with a size much larger than the focal volume was formed. The resultant assembly showed structural color in transmission and backscattering images, meaning that constituent nanoparticles are periodically packed in the assembly. The reflection micro-spectroscopy revealed that the nanoparticle assembly has a reflection band in visible region and the peak position is shifted to shorter wavelength with the narrowing of band width during the assembly growth. This result indicates that the nanoparticle packing structure in the assembly becomes homogeneous with the decrease in inter-particle distance under the laser irradiation. Turing off the laser led to the diffusion of constituent nanoparticles, meaning that the assembly is temporarily formed under dynamic force balance between optical trapping and inter-particle force. Reflection spectra of the nanoparticle assembly were measured under various laser trapping conditions, and we discuss the trapping and assembly dynamics of nanoparticles based on the spectral change.

Magnon-like properties of spin-3/2 chains

Jhon James J. Hernández Sarria Sr., Univ. del Valle (Colombia) and Ctr. for Bioinformatics and Photonics (Colombia); Karem Cecilia C. Rodríguez Ramírez, Univ. del Valle (Colombia)

Ultracold gases is optical lattices constitute an extraordinary tool for the analysis of strongly-correlated gases under extremely well-controlled condition. In this work, we study the magnon-like properties of repulsively interacting spin-3/2 fermions in one-dimensional optical lattices. For large-enough interactions, the system enters into the Mott-insulator regime with maximally one fermion per site.

We perform the Holstein-Primakoff transformation to the fermionic system. This is a useful technique based on the expansion of the spin operators in terms of the creation and annihilation operators of the harmonic oscillator, i.e. magnon-like position-operators. In this way, we obtain a spinless bosons system described by an extended Bose-Hubbard model with a hole-like lowest band. The magnon-like model involves single, pair and correlated nearest neighbors hopping terms beside the on-site and nearest neighbor interactions.

The magnetic phases present in the Mott-insulator of the spin-3/2 lattice fermions namely the gapless spin liquid and the gapped spin Peierls quantum phases, previously studied, are analyzed in the mirror frame of their bosonic counterpart. Since the transformation is not linear and the coupling between the oscillators has important consequences for many properties of ordered systems, we perform the ground-state characterization as a function of the spin-changing collision strength including the calculation of several observables such as the magnetization and spin-spin and dimer-dimer correlations in the magnon-like frame-work.

This kind of work pave the path of revealing magnetic phases signatures in the state-of-the-art spinless boson experiments. The many-body numerical calculations are performed using the Matrix Product State formalism.

Correlated fluctuations of optically trapped particles

Thomas J. Smart, Christopher J. Richards, Univ. College London (United Kingdom); Xian Han, National Univ. of Defense Technology (China); Stefan Siwiak-Jaszek, Philip H. Jones, Univ. College London (United Kingdom)

We present a study of correlated Brownian fluctuations between optically confined particles in a number of different configurations. First we study colloidal particles held in separate optical tweezers. In this configuration the particles are known to interact through their hydrodynamic coupling, leading to a pronounced anti-correlation in their position fluctuations at short times. We study this system and the behaviour of the correlated motion when the trapped particles are subject to an external force such as viscous drag. The experiments are complemented by Brownian motion simulations.

The second system considered is a chain of optically bound particles in an evanescent wave surface trap. In this configuration the particles interact both through hydrodynamic and optical coupling. Using digital video microscopy and subsequent particle tracking analysis we study the thermal motion of the chain and map the variation in fluctuation correlation amplitude between pairs of particles. We further analyse the dynamics by constructing the normal modes of the particle chain, extracting the mode amplitudes and autocorrelation decay times.

Finally we examine the potential of these systems for probing fluctuation theorems of thermodynamics when applied to systems of coupled or interacting particles. In these systems with well-controlled coupling of a well-defined number of particles we calculate the distribution of the dissipation function (entropy production) in the system when one particle is subject to an external driving force.

Three-dimensional thermal noise imaging of collagen networks

Tobias F. Bartsch, The Rockefeller Univ. (United States); Martin D. Kochanczyk, Emanuel N. Lissek, The Univ. of Texas at Austin (United States); Janina Lange, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); Ernst-Ludwig Florin, The Univ. of Texas at Austin (United States)

Extracellular biopolymer networks show interesting mechanical properties that are essential for living organisms. In particular, a highly nonlinear elastic response to strain is seen, which gives biopolymer networks the ability to comply with small stresses but resist to large ones. The macroscopic mechanical properties have their origin in the properties of the individual filaments and the properties of the network that they form, like cross-linking geometry and pore size distribution. While the macroscopic properties of biopolymer networks have been extensively studied, there has been a lack of experimental techniques that can simultaneously determine mechanical and architectural properties of the network in situ with single filament resolution. Thermal Noise Imaging (TNI) is a novel scanning probe technique that utilizes the confined thermal motion of an optically trapped particle as a three-dimensional, noninvasive scanner for soft, biological material. It achieves nanometer precision in probe position detection with MHz bandwidth. Using feedback control we have recorded thermal noise images on the micrometer scale inside a collagen I network for the first time, extracting quantitative information about cross-linking geometry and network architecture from the data. We are also able to quantify filament fluctuations by monitoring the forward scattered light from the collagen network structure. We find that the transverse fibril fluctuations are negligible compared to their diameter, and cannot account for strain

stiffening behavior. This is in agreement with recent models of stiff filament networks and points towards elastic deformations and structural changes as the origin of the nonlinear response to force. Thermal Noise imaging will allow us to study network deformations and force distribution on the single filament level under local and global stresses.

A study of red blood cell deformability in diabetic retinopathy using optical tweezers

Thomas J. Smart, Christopher J. Richards, Rhythm Bhatnagar, Univ. College London (United Kingdom); Carlos Pavesio, Moorfields Eye Hospital NHS Foundation Trust (United Kingdom) and Univ. College London (United Kingdom); Philip H. Jones, Univ. College London (United Kingdom); Rupesh Agrawal, Moorfields Eye Hospital NHS Foundation Trust (United Kingdom) and Univ. College London (United Kingdom) and Tan Tock Seng Hospital (Singapore)

Red blood cells (RBCs) possess an ability to undergo significant cellular deformation, allowing them to pass through capillaries in the human microcirculation system whose diameters are smaller than their own. There is evidence that diabetes mellitus impairs RBC deformability and it has been suggested that this may be part of the cause of microangiopathy. A common complication of diabetes mellitus, microangiopathy is a disease that can cause capillaries to bleed, leak protein and slow the flow of blood. In the eye, this may lead to diabetic retinopathy - microangiopathy in the retina caused by high blood sugar levels, which can cause blindness.

Here we present an investigation into the deformability of RBCs in patients with diabetic retinopathy using optical tweezers. We compare the deformability with those of RBCs in healthy patients as well as to those with other retinal vascular disorders: Behçet's disease and birdshot chorioretinopathy.

To extract a value for the deformability of RBCs we use a dual-trap optical tweezers set-up to stretch individual RBCs. RBCs are trapped directly (i.e. without micro-bead handles), so rotate to assume a 'side-on' orientation. Video microscopy is used to record the deformation events and shape analysis software is used to determine parameters such as maximum RBC length. 3D imaging of individual RBCs is also performed using defocusing microscopy to ascertain the radius, volume, surface area and sphericity index to test the hypothesis that it is increased volume and sphericity index of RBCs that leads to the decreased deformability of the pathological cells.

9548-83, Session PWed

Absortion model of different fluids in an optical fiber trap using CFD

Jenny Emmanuelle Hernández Zavala, Univ. Veracruzana (Mexico); Hector H. Cerecedo, Univ. Autonoma Veracruzana (Mexico)

It is important to determine the heat absorption of a fluid where a micro-particle is merge in an optical fiber trap and to be capable to predict the impact in the particle movement. In this sense, this document presents a first approach to study the thermal behavior of an initially static fluid radiated by infrared light (980nm, 100mW) transmitted by a single-mode optical fiber, for this simulation temperature and radiation pressure are calculated based on the intensity delivered by a laser diode.

With the help of Computing Fluid Dynamics (CFD) it is possible to study the absorption of heat of a specific fluid due to thermal radiation. Experiments show that as the particle moves along the axis, temperature decreases, having the points of mayor temperature around the axis, with a different thermal spectrum depending on the substance and heat model used.

Noticeable nonlinear optical effect in plasmon-assisted radiation force

Masayuki Hoshina, Osaka Prefecture Univ. (Jordan); Nobuhiko Yokoshi, Hajime Ishihara, Osaka Prefecture Univ. (Japan)

For the optical manipulation of nanoparticles, the light of extremely high intensity is required in order to gain the radiation force overwhelming the effects of fluctuating environment. One of the ways to produce such a high intensity field is to utilize localized surface plasmons (LSP) induced on the metallic nanostructures [1]. Although there exist many works to investigate and demonstrate the LSP-assisted optical manipulation [2], theoretical analyses have been limited within the linear response theory. However, the recent works of our group have revealed essential roles of optical nonlinearity in resonant molecular trapping by the conventional method [3]. Thus, considering the great enhancement of the field intensity by LSP, a theoretical method incorporating the optical nonlinearity is also desired for the system including arbitrary-shaped metallic structures.

In this work, we develop a new calculation method for the LSP-assisted optical manipulation based on the quantum master equation combined with the discrete dipole approximation method. This method enables us to investigate the radiation force including the strong nonlinear optical effect such as absorption saturation of the excited states. Our demonstration reveals that the consideration of optical nonlinearity leads to significantly different behavior of molecules near the resonant region even for the incident intensity around a few kW/cm2.

Three-dimensional trapping with a focused Bessel beam

Yareni Ayala, Karen P. Volke-Sepúlveda, Alejandro V. Arzola, Univ. Nacional Autónoma de México (Mexico)

A Bessel beam generated with an axicon lens is focused by a low numerical aperture objective lens to create an optical levitation trap. This configuration allows a full three dimensional trapping of solid glass spheres of few microns in diameter immerse in water. We establish a comparison with an optical levitation trap generated with a Gaussian beam under the same focusing conditions. In both cases the particles are lifted up in an axial position above the focal region that depends on the incident power. The spatial stability is investigated in both cases as a function of axial position, which in turn depends on the input optical power.

9548-86, Session PWed

Non-radially symmetric dark-hollow optical beams for manipulation elongated microobjects

Aleksey P. Porfirev, Samara State Aerospace Univ. (Russian Federation); Roman V. Skidanov, Image Processing Systems Institute (Russian Federation)

We theoretically and experimentally investigate shaping of non-radially symmetric dark-hollow optical beams (DHOBs) generated by superimposed non-coaxial Bessel beams. Transverse dimensions of the traps can be changed by varying a number of Bessel beams. Thus it is possible to adjust the size of the trap to the size of the captured objects. We used scalar theory diffraction to theoretically investigate shaping of DHOBs. Also the generation of non-radially symmetric DHOBs, especially by using the

laser radiation with different wavelengths (from 400 to 1000 microns), is experimentally investigated. In this experiments, we used EKSPLA NT200 series tunable laser systems (output wavelength range from 335 nm to 12 000 nm, Lithuania). We used diffractive optical elements and a spatial light modulator PLUTO VIS (Holoeye Pluto-Vis, Germany) to demonstrate experimentally the generation of DHOBs. Dynamically forming by a spatial light modulator non-radially symmetric DHOBs can create a device to manipulate elongated microobjects. Trapping of non-spherical particles is essential for microassembling and driving microstructures in optofluidic systems and for manipulating of biological microobjects, that are mostly non-spherical.

Creation of three-dimensional volume chain under high numerical aperture illumination

Jiming Wang, Nanjing Univ. of Aeronautics and Astronautics (China)

Recently, the beams with unconventional polarization states have attracted increasing interests in their generation, manipulation, and focusing. The polarizations of this vector beams are spatially inhomogeneous in the transverse cross-section. Generalized vector beams can be obtained through engineering the phase, polarization and amplitude of the incoming beams. For their unique properties, the beams meet potential applications in many fields. As a new way to explore phenomenon and physics on nano-scale, the focused field with desired intensity shaping and polarization structuring in the focal volume has been investigated in a high-numerical-aperture (NA) imaging system. In this paper, we attempt to construct a focused field with a shape of complex chain. Here the three-dimensional uniform optical chain consists of arrayed bubbles with high radial barrier and quasi-periodic location. Except for this bubbles array along the optical axis, the dark fields exist in the focused field. In the rz plane, the focused field presents a volume feature of chain, so-called volume chain. Ten holes appear and six of them exist beside the z-axis at r=0.42?. The six formed holes is located at the cross section of the dark fields at r=0.42? and the other four arrange along z-axis at r=0. This focused field as a tool can provide effective optical manipulation. Optical bubbles generated by the vectorial beam have the trapping capability of the low-refractive-index particles. The constructed optical chain may be used as an effective tool for multiple particles trapping, delivering and self-assembling.

Single-shot multiphoton fabrication of polygonized structures by a novel fresnel zone lens via spatial light modulator

Chenchu Zhang, Dong Wu, Yanlei Hu, Jiawen Li, Zhaoxin Lao, Bin Xu, Jiaru Chu, Wenhao Huang, Univ. of Science and Technology of China (China)

Recently, annular beams has been developed to rapidly fabricate microscope tubular structures via two-photon polymerization, but the distribution of light field is limited to ring pattern. Here a novel Fresnel lens is designed and applied to modulate the light field into a uniform quadrangle or hexagon shape with controllable diameters. By applying spatial light modulator to load the phase information of Fresnel lens, quadrangle and hexagon structures are achieved through single exposure of a femtosecond laser. A 3?6 array of structures is made within 9 seconds. Comparing with the conventional holographic processing, this method shows higher uniformity, high efficiency, better flexibility, and easy-operation. The novel approach exhibited the promising prospect in rapidly fabricating structures such as tissue engineering scaffolds and various shape tubular arrays.

Analysis of the phage lambda DNA packaging motor by optical tweezers measurements and site-directed mutagenesis of residues involved in ATP binding

Mariam Ordyan, Damian J. Deltoro, Douglas E. Smith, Univ. of California, San Diego (United States)

We use optical tweezers to measure molecular-motor driven packaging of single DNA molecules into single viral proheads. Analysis of the sequence of the lambda gpA motor protein suggests it contains a “Walker A”-like ATP binding region spanning amino acids K76 to S83 that is essential for motor function. Systematic alteration of the amino acids in this region by genetic mutations causes moderate to nearly complete impairment of viral replicationOptical tweezers measurements of mutants exhibiting moderate impairment in viral productionreveal clear impairments in DNA translocation in every case. We characterize the impairments by determining motor velocity distributions from ensembles of single-molecule packaging events. Our findings support the hypothesis that this region corresponds to a Walker A motif and shed light on the relative importance of different amino acids within this region for DNA translocation. Relationships between the functional roles and positions of specific amino acids in the protein structure are explored via the use of a structural model based on homology with other ATP binding proteins.

Single-molecule mechanics of the molecular spring that underlies hearing

Tobias F. Bartsch, Albert J. Hudpeth, The Rockefeller Univ. (United States)

The astounding sensitivity, frequency selectivity, and dynamic range of mammalian hearing result from the ear’s sensory receptors, the hair cells of the inner ear. Atop each hair cell stands a hair bundle, a cluster of stiff stereocilia, whose deflection causes mechanically gated ion channels to open. One candidate for the mechanical element that converts bundle deflection to a force capable of opening the channels is the tip link, a biopolymer of cadherin molecules that connects pairs of adjacent stereocilia. The link’s elasticity results both from the extensibility of individual cadherin domains, which was recently explored by molecular-dynamics simulations, and from the rearrangement of the domains relative to each other, which is stabilized by Ca2+ binding and remains unexplored.

We show that the elasticity of the tip link’s constituents can be measured in the physiologically relevant low-force regime by a single-molecule experiment with a custom-built photonic force microscope. In our assay thermal forces are exploited to sample the proteins’ energy landscapes. A single protein molecule is positioned between a fixed glass substrate and a probe nanoparticle held in a weak optical trap. The three-dimensional spatial probability distribution of the probe’s thermal motion is measured with nanometer precision and megahertz bandwidth by interfering on a quadrant-photodiode the unscattered trapping beam with light scattered forward by the probe. The protein’s energy landscape can be computed directly from the measured spatial probability distribution.

We next intend to investigate the effects on the proteins’ energy landscapes, and thus on their mechanical properties, of varying the Ca2+ concentration and of pathologically relevant mutations.

Conference 9549: Physical Chemistry of Interfaces and Nanomaterials XIV

SPIE. OPTICS+ PHOTONICS NANOSCIENCE+ ENGINEERING

Sunday - Wednesday 9–12 August 2015

Part of Proceedings of SPIE Vol. 9549 Physical Chemistry of Interfaces and Nanomaterials XIV

9549-1, Session 1

Interface design principles for high efficiency organic semiconductor devices *(Invited Paper)*

Adiitya D. Mohite, Los Alamos National Lab. (United States)

Present day electronic devices are enabled by design and implementation of precise interfaces that control the flow of charge carriers. However, unlike the well-controlled interfaces in conventional electronics based on silicon and other inorganic materials, organic semiconductor interfaces are relatively poorly characterized and understood. Here, we describe how precise manipulation and control of organic-organic interfaces using interface modification strategies can overcome a long-standing bottleneck of interface recombination at the donor-acceptor interface in an organic photovoltaic device. These strategies lead to a dramatic increase in the average power conversion efficiency by 2-5 times in a model bilayer system and when applied to practical architectures like the bulk heterojunction result in a dramatic increase in the overall efficiency from 4.1% to ~8.0 %. Moreover, these interface strategies are applicable to a wide variety of donor-acceptor systems,, making them both fundamentally interesting and technologically relevant for achieving high efficiency organic electronic devices.

In addition, I will also briefly describe our most recent work on organic-inorganic perovskite solar cells. We have developed a new solution-based hot-casting technique to grow continuous, pin-hole free thin-films of organometallic perovskites with millimeter-scale crystalline grains. Photovoltaic devices show hysteresis-free response, which had been a fundamental bottleneck for stable operation of perovskite devices. Characterization and modeling attribute the improved performance to reduced bulk defects and improved charge-carrier mobility in large-grain devices.

9549-3, Session 1

In situ transient optical studies of bulk and interfacial recombination processes in nanostructured photocatalytic materials *(Invited Paper)*

Matthew Y. Sfeir, Kannatassen Appavoo, Mingzhao Liu, Brookhaven National Lab. (United States)

Generating hydrogen-fuel by photoelectrochemical (PEC) water splitting is a promising renewable energy technology and also a complex and fascinating mesoscale science problem. Efficient photocatalytic water splitting requires both a high quantum yield for transport of charge carriers to the reactive interface (occurring on ps timescales) and for charge transfer (occurring on ns and longer time scales). Using in situ ultrafast optical methods, we have developed an experimental framework to separately measure recombination losses during charge separation and interfacial charge transfer in nanostructured semiconductor photocatalysts. This approach allows us to quantify and understand the origins of differences in performance between different materials through concurrent electrical characterization and in situ optical studies carried out in a customized PEC cell. Using a transient emission technique with sub-ps resolution, we preferentially probes the photogenerated excitons and directly monitor parasitic recombination processes that occur on timescales shorter than interfacial charge transfer. Performing these measurements at various applied potential, we tune the depletion region to direct the flow of photogenerated minority carriers and to correlate the measured carrier dynamics to the electrical properties of the photoelectrochemical device. Losses occurring on picosecond timescales are found to represent a major loss channel in heavily doped nanostructured photocatalytic materials, even when the size of the nanostructure is below its carrier diffusion length. Furthermore, this approach allows us to evaluate the role of ultrathin (~ 1 nm) surface layers, which, in our model system, provides enhanced chemical activity in addition to reducing corrosion.

9549-4, Session 1

Avoding the kinetics of the bulk heterojunction: self-assembled materials and sequential processing for organic photovoltaics *(Invited Paper)*

Benjamin Schwartz, Univ. of California, Los Angeles (United States)

One of the key issues with improving the efficiency of conjugated polymer-based phovoltaics is controlling the nm-scale morphology of the two active components. Typically, efficiency is optimized by trial-and-error: component weight ratios, solvent additives, post-processing thermal annealing, etc. are all used to attempt to obtain the desired bulk heterojunction (BHJ) interpenetrating network. In this talk, we discuss some of our recent work aimed at using alternate, more reproducible methods for controlling BHJ morphology. We present results showing new amphiphilic semiconducting polymers and fullerenes that spontaneously selfassembly into co-axial cylindrical micelles in solution, and thus provide a built-in connected network when cast into gels that form thin films. Photoexcitation of the polymer in these systems produces separated charges on sub-ps time scales, and the separated charges are stable for weeks to months in air-free environments. The stability of the charge-separated pair can be controlled by changing the gel morphology. We also show that sequential processing of the polymer and fullerene components can provide an exquisite degree of control of the nm-scale morphology of a BHJ, and that the degree of crystallinity of the polymer controls both the amount of intercalated fullerene and the geometry of the interpenetrating network.

9549-5, Session 2

Interfacial considerations in organo-halide perovskite optoelectronics *(Invited Paper)*

Paul Meredith, Qianqian Lin, Ardalan Armin, Dani Lyons, Ravi Nagiri, Paul L. Burn, The Univ. of Queensland (Australia)

The organo-halides perovskites have recently emerged as one of the leading candidates for low cost, next generation thin film photovoltaics [1]. The working principles of CH3NH3PbI3-based homojunction solar cells were recently disclosed by Lin et al. [2] who proposed the material to be non-excitonic with high static dielectric constant. Lin et al. also discussed the origin of the cell Voc, suggesting that it arises directly from the difference in work functions between the anode and cathode consistent with minimal chemical potential loss across the perovskite homojunction. In this regard the interface between the active layer and both electrodes is critical, and this was demonstrated using a range of semiconducting polymers to modify the anode electronics.

In our paper we will discuss these interfacial considerations, and also highlight the differences between solution processed and evaporated perovskites on various work function modified anodes. In principle, the cell Voc could be optimised by increasing the electrode work function difference, but in practise this is very difficult due to surface energy considerations which control the morphology and quality of the subsequent perovskite active layer. These principles are not only relevant to solar cells but organo-halide perovskite optoelectronics in general.

[1] Liu et al., Nature 501, 395-398 (2013).

9549-6, Session 2

Investigation on the initial photophysics in hybrid perovskite-polymer solar cells

Jan C. Brauer, Univ. de Fribourg (Switzerland); Arianna Marchioro, Univ. of Washington (United States); Yong Hui Lee, Mohammad K. Nazeeruddin, Jacques-Edouard Moser, Ecole Polytechnique Fédérale de Lausanne (Switzerland); Natalie Banerji, Univ. de Fribourg (Switzerland)

Perovskite solar cells based on alkali-metal halides represent an emerging photovoltaic technology that has attracted a lot of attention in the scientific community due to an incredible increase in efficiency over the last years starting from 3-4 % in 2009 to a certified efficiency over 20% in 2015. These performances rivaling the best thin-film photovoltaic devices in combination with their ease of fabrication present a major breakthrough in the quest for renewable energy devices. A variety of cell architecture including the use of a mesopourous TiO2 or Al2O3 scaffolds, planar TiO2/perovskite heterojunctions as well as architectures using purely organic charge transport layers sandwiching the central perovskite layer have been investigated in literature. While a lot of effort has been invested in order to improve device performance, the fundamental understanding of the involved mechanisms and material-properties is lagging behind.

In this work we investigate the early photophysics of hybrid perovskite-polymer solar cells by means of ultrafast transient absorption spectroscopy and THz spectroscopy. We were particularly interested in the charge transfer reactions at the perovskite-TiO2 and perovskite-polymer interfaces since theses reactions are crucial for the proper functioning of the cell. In this regards we investigated the influence of the choice of the organic hole-conductor with respect to the early time dynamics of the charge transfer reaction as well as the quenching efficiency in comparison to the standard organic hole-conductor spiro-MeOTAD.

9549-7, Session 2

Mapping the electrical properties of methylammonium lead triodide perovskite films using conductive tip atomic force microscopy for photovoltaic applications

James G. Stanfill, R. Clayton Shallcross, Neal R. Armstrong, The Univ. of Arizona (United States)

This paper focuses on our recent studies of the mapping of the electrical properties of ultrathin methylammonium lead triodide (MAPbI3) perovskite (PVSK) films on bare and chemically modified metal oxide surfaces through conductive tip atom force microscopy (cAFM). Despite the impressive growth in PV efficiencies using PVSK active layers, we hypothesize that the charge harvesting efficiencies in fully optimized PV platforms using these active layers, especially those obtained by massively scalable processing approaches, will be dependent upon PVSK crystal morphologies, orientations, and energetic heterogeneity in ways that can be uniquely probed by cAFM. Our approach has been to control nucleation free energy of either the stoichiometric PVSK film (direct deposition), or the PbI2 precursor (two-step deposition) using surface modifiers which vary in polarity and functional groups that might incorporate into the PbI2 or PVSK during the initial 1-2 nm of film growth. Correlations will be shown between differences in crystalline morphology, which low-index faces are exposed, and the long range order in the PVSK lattice, with dark J/V behavior, on substrates and with cAFM tips designed to produce either rectifying behavior or a purely ohmic contact. These dark electrical properties are correlated with band edge energetics and density-of-states observed above the valence band edge, out to the Fermi energy, obtained with high sensitivity UV-photoemission spectroscopies and finally to differences in PV device performance.

9549-8, Session 2

Induction of photocurrent by the hole transporting layer to adjacent photoactive perovskite sensitized TiO2 thin film for the solar cell application

Sadia Ameen, Mohammed Nazim, Hyung-Kee Seo, Hyung-Shik Shin, Chonbuk National Univ. (Korea, Republic of)

The high performance perovskite solar cell is fabricated using unique and well-defined morphology of polyaniline nanoparticles (PANI-NPs) as efficient hole transporting layer (HTL) with methyl ammonium lead iodide perovskite (CH3NH3PbI3) as sensitizer to fabricate the high performance perovskite solar cell. PANI NPs are simply synthesized by the oxidative chemical polymerization of aniline monomer at 0-5 oC. The reasonable solar-to-electricity conversion efficiency of ~6.29 % with high short circuit current (JSC) of ~17.97 mA/cm2 and open circuit voltage (VOC) of ~0.877 V are accomplished by Ag/PANI-NPs/CH3NH3PbI3/mp-TiO2/bl-TiO2/FTO perovskite solar cell. The IPCE measurement reveals that the fabricated Ag/PANI-NPs/CH3NH3PbI3/mp-TiO2/bl-TiO2/FTO perovskite solar cell presents the maximum value of ~51% in the wavelength range of ~450-700 nm and drops at longer wavelengths. The transient photocurrent and photovoltage studies reveal that the fabricated solar cell shows better charge transport time, diffusion coefficient, diffusion length and the charge collection efficiency. Herein, the use of PANI NPs as HTL improves the charge carrier generation and the charge collection efficiency of the fabricated solar cell.

9549-9, Session 3

Linking molecular features of conjugated polymers, acceptors, and additives to the blend morphology for organic electronics applications *(Invited Paper)*

Arthi Jayaraman, Univ. of Delaware (United States)

Organic solar cells consist of an active layer made of an electron donating species (e.g. conjugated polymer) and an electron accepting species (e.g. fullerene derivative). The efficiency of a solar cell is dependent on the spatial organization or morphology of the donor and acceptor materials. The donor-acceptor blend morphology is dependent on the chemistry and architecture of the conjugated polymer and its interactions with the acceptor material (fullerene derivatives), and other additive material. This talk will present our recent work using theory and simulation techniques to connect molecular features of polymers and nanoscale additives to the blend/composite morphology, thereby guiding synthesis of new materials for organic photovoltaic applications.

9549-10, Session 3

Describing and quantifying tightly packed molecular aggregate properties using innovative electronic structure methods *(Invited Paper)*

Clémence Corminboeuf, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Improving the performance of organic materials (e.g., charge-carrier mobility in field-effect transistors) relies upon the adjustment of the ϖ-conjugated molecules or chains at the molecular level. A relevant and efficient strategy consists in fine-tuning specific non-covalent interactions, which dictate the lateral displacements, intermolecular distances and relative orientation of the ϖ-conjugated moieties. The use of efficient computational schemes can be very useful to identify promising structural patterns and analyze their electronic structure properties. This talk will discuss novel electronic structure approaches capable of modeling and

analyzing the structures, energies and properties of molecular assemblies relevant to the field of organic electronics. Special emphasis will be placed on molecular architectures designed to feature unusually close ϖ-stacking interactions. The proposed electronic structure approaches will range from the DORI (i.e., density overlap region indicator) molecular descriptor capable of visualizing and comparing the "electronic compactness" of quatertiophene-based crystals and up to recently introduced density functional-based schemes aiming at improving the electronic structure description of large-sale systems and overcoming the obvious failures of standard DFT methods. In this context, we will also address lingering difficulties associated with the accurate description of ground and excited state properties of molecular aggregates using standard density functionals and post-Hartree-Fock approaches.

Diffusion, recombination, and photon emission properties of interacting excitons in semiconductor carbon nanotubes *(Invited Paper)*

Andrei Piryatinski, Los Alamos National Lab. (United States); David H. Dunlap, The Univ. of New Mexico (United States); Oleksiy Roslyak, Fordham Univ. (United States); Han Htoon, Los Alamos National Lab. (United States)

Semiconductor single-walled carbon nanotubes (SWCNTs) are near-perfect 1D materials with great potential for applications in opto-electronic and photonic devices. Their unique optical properties are determined by highly mobile interacting excitons. Motivated by recent experimental studies, we examine competition between exciton diffusion dynamics and their local interactions resulting in the exciton-exciton annihilation (EEA). Treating the EEA as the exciton coalescence reaction, we propose a mean field model based on non-linear diffusion equation for exciton density with generalized time-dependent EEA coefficient. This model interpolates between short-time Auger recombination and long-time diffusion-limited recombination dynamics. While exciton key model parameters such as diffusion and Auger recombination constants are physically independent quantity, we demonstrate that environment disorder perturbing the exciton energy landscape gives rise to their correlation. Our model based simulations reveal important dependence of the exciton emission profile on exciton population prepared by optical pule. These results are rationalized by partitioning exciton density into spatial diffusion length segments that are identify as independent quantum emitters. This coarse-grained model is further applied to interpret the photon counting statistics available from 2nd order photon correlation measurements. Provided exciton density is prepared on the scale larger than exciton diffusion length (i.e., case of multiple independent emitters), our calculations show strong photon bunching. Reduction of the exciton density spread to the diffusion lengthscale causes photon anti-bunching whose degree is limited by the strength of the EEA processes. These findings have strong implications toward development of SWCNT-based room-temperature single photon sources.

9549-12, Session 3

Impact of mesoscale order on open-circuit voltage in organic solar cells

Carl Poelking, Max-Planck-Institut für Polymerforschung (Germany); Max L. Tietze, Chris Elschner, Technische Univ. Dresden (Germany); Selina Olthof, Dirk Hertel, Univ. zu Köln (Germany); Björn Baumeier, Max-Planck-Institut für Polymerforschung (Germany); Frank Würthner, Julius-Maximilians-Univ. Würzburg (Germany); Klaus Meerholz, Univ. zu Köln (Germany); Karl Leo, Technische Univ. Dresden (Germany); Denis Andrienko, Max-Planck-Institut für Polymerforschung (Germany)

Structural order in organic solar cells is paramount: it reduces energetic disorder, boosts charge and exciton mobilities, and assists exciton splitting. Owing to spatial localization of electronic states, microscopic descriptions of photovoltaic processes tend to overlook the influence of structural features at the mesoscale. Long-range electrostatic interactions nevertheless probe this ordering, making local properties depend on the mesoscopic order. Using a technique developed to address spatially aperiodic excitations in thin films and in bulk, we show how inclusion of mesoscale order resolves the controversy between experimental and theoretical results for the energy-level profile and alignment in a variety of photovoltaic systems, with direct experimental validation. Optimal use of long-range ordering also rationalizes the acceptor–donor–acceptor paradigm for molecular design of donor dyes. We predict open-circuit voltages of planar heterojunction solar cells in excellent agreement with experimental data, based only on crystal structures and interfacial orientation.

9549-13, Session 3

Modeling electric field-induced quenching in conjugated polymers and oligomers

Christian M. Legaspi, Linda A. Peteanu, David J. Yaron, Carnegie Mellon Univ. (United States)

The phenomenon of electric field-induced emission quenching is important in organic light-emitting diodes which require the application of large electric fields for their function. Past experimental work on light-emitting polymers and oligomers showed that field-induced quenching (FIQ) efficiencies are higher in non-rigid molecules such as poly(p-phenylene vinylene) or PPV, than in similar, more planar molecules.(ref 1) Based on this relationship, we proposed that the applied field enhances internal conversion decay channels.(refs 2,3) The current study builds on this idea by examining FIQ in PPV oligomers of varying length using computational methods. Calculations performed at the INDO/S-CI level show the presence of free electron-hole pair (FEHP) states which are stabilized by the uniform external electric field. These FEHP states undergo an avoided crossing with the fluorescent 1Bu bound exciton state at sufficiently high field magnitudes. The magnitude of the electronic coupling between the FEHP and 1Bu state, determined from these avoided crossings, is found to be a function of the field at which these states cross. This function is universal in that it applies across different length oligomers and across different FEHP states on the same oligomer. A model for FIQ is developed by combining this electronic-coupling function with Marcus theory and a simple model for the surrounding dielectric medium. To better reproduce the gradual increase of quenching with field seen in experiment (ref 3), inhomogeneous broadening of state energies is also included. The resulting model yields reasonable quantitative agreement with FIQ magnitudes, dependence on oligomer length, and threshold field strengths at which quenching is observed.

Singlet, triplet, electron and hole transport along single polymer chains *(Invited Paper)*

Matthew Bird, Brookhaven National Lab. (United States);

Gina Mauro, Brookhaven National Lab. (United States) and Dowling College (United States); Xiang Li, Brookhaven National Lab. (United States); Lori Zaikowski, Brianne Karten, Dowling College (United States); Sada Asauoka, Kyoto Institute of Technology (Japan); Qin Wu, Hung-Cheng Chen, Andrew Cook, John Miller, Brookhaven National Lab. (United States)

The diffusion of singlet and triplet excitons along single polyfluorene chains in solution has been studied by monitoring their transport to end traps. Time-resolved transient absorption and steady state fluorescence were used to determine fractions of excitons that reach the end caps. In order to accurately determine the singlet diffusion coefficient, the fraction of polymer ends that have end traps was determined through a combination of NMR and triplet quenching experiments. The distributions of polymer lengths were also taken into account and the resulting analysis points to a surprisingly long singlet diffusion length of 34nm. Experiments on triplet transport also suggest that the entire 100nm+ chain is accessible to the triplet during its lifetime suggesting a lack of hindrance by defects or traps on this timescale.

Pulse radiolysis microwave conductivity measurements were performed on single chains of homo polymers and alternating donor-acceptor copolymers. Through the careful addition of electron or hole scavengers, the electron and hole mobilities could be independently extracted for a series of common OPV polymers. A surprising result has been the similarity of electron and hole mobility in polymers where quantum chemical calculations would suggest large asymmetries in the localization of their respective wavefunctions.

9549-16, Session 4

Cross-linking high-k fluoropolymer gate dielectrics enhances the charge mobility in rubrene field effect transistors

Jwala M. Adhikari, Enrique D. Gomez, Matthew R. Gadinski, Qing Wang, The Pennsylvania State Univ. (United States)

Polymer dielectrics have the potential to incorporate the chemical and mechanical flexibility of polymers into gate insulators. For example, polymers can be functionalized with polar groups to enhance the dielectric constant. Nevertheless, fluctuations in chain conformations at the semiconductor-dielectric interface can introduce energetic disorder and limit charge mobilities in organic thin-film transistors. Here we demonstrate a photopatternable high-K fluoropolymer, poly(vinylidene fluoride-bromotrifluoroethylene) P(VDF-BTFE), with a dielectric constant between 8 and 11. The bromotrifluoroethylene moiety enables photo-crosslinking and stabilization of gate insulator films while also significantly enhancing the population of trans torsional conformations in the chain backbones. Using rubrene single crystals as the active layer, charge mobilities exceeding 10 cm2/Vs are achieved in thin film transistors with cross-linked P(VDF-BTFE) gate dielectrics, in contrast to 4 cm2/Vs without crosslinking. We hypothesize that crosslinking reduces energetic disorder at the dielectric-semiconductor interface by suppressing segmental motion and controlling chain conformations of P(VDF-BTFE), thereby leading to approximately a three-fold enhancement in the charge mobility of rubrene thin-film transistors over devices incorporating uncross-linked dielectrics or silicon oxide.

9549-17, Session 4

The deactivation of a conducting polymer

Ricardo I. Tucceri, Univ. Nacional de la Plata (Argentina)

The aim of this work was to study the effect of prolonged potentiodynamic cycling (PPC) on the conducting properties of poly(o-aminophenol) (POAP) film electrodes. PPC reduces strongly the electron transport rate at POAP films. This effect is called here deactivation. Cyclic Voltammetry (CV) and Rotating Disc Electrode Voltammetry (RDEV) were employed in this study. The attenuation of the voltammetric response of the polymer with the increase in the number of oxidation-reduction cycles allowed one to define a degree of deactivation. RDEV was employed to obtain the dependence of the electron-transport rate on the degree of deactivation of the polymer. RDEV data were interpreted in terms of the electron hopping model. POAP films maintain their conducting properties almost unaltered for about 500 potential cycles at a scan rate of 0.010 V s-1. However, a loss of conductivity was observed as the number of potential cycles was extended beyond 500. The slower electron transport with the increase in the degree of deactivation was attributed to the increase of the electron hopping distance between redox sites.

9549-18, Session 5

Excited state dynamics in next-generation photovoltaic materials *(Invited Paper)*

Cody W. Schlenker, Univ. of Washington (United States)

Interface states and defect states are often responsible for some of the most interesting processes observed in next-generation solid-state optical devices such as organic and hybrid photovoltaics. We explore these states in a range of organic and hybrid materials by using transient optical absorption spectroscopy and field-dependent excited state spectroscopy. In all-organic systems, we find evidence for a connection between nanostructure and charge recombination mechanisms that appears to be correlated with the susceptibility of different interfacial spin states to be influenced by an electric field. We will also discuss our recent work focused on using transient optical spectroscopy to understand the role of photon energy and flux in determining excited state population kinetics in hybrid systems.

9549-19, Session 5

Photo-induced electron transfer processes in doped conjugated polymer films *(Invited Paper)*

Garry Rumbles, National Renewable Energy Lab. (United States) and Univ. of Colorado (United States); Obadiah G. Reid, Univ. of Colorado at Boulder (United States) and National Renewable Energy Lab. (United States); Jaehong Park, National Renewable Energy Lab. (United States); Jessica Ramirez, Hilary Marsh, Univ. of Colorado at Boulder (United States); Tyler T. Clikeman, Colorado State Univ. (United States)

With increasing knowledge of the role of the different phases in the bulk heterojunction organic solar cell, the primary site for charge generation is now considered to be the mixed phase, and not the clean interface between neat polymer and neat fullerene. To gain a better understanding of the primary charge generating and recombination steps in this region of the system, we focus our studies on the role of the solid-state microstructure of neat polymers and light-doping of these polymers with a variety of electron-accepting dopants at low concentration.

This presentation will describe some recent work on the doping of polythiophene and polyfluorene derivatives with fullerenes, phthalocyanines and perylenes, which provide a range of reduction potentials that serve to control the driving force for electron transfer processes. Results from flash photolysis, time-resolved microwave conductivity (fp-TRMC), femtosecond transient absorption spectroscopy (fTA) and photoluminescence spectroscopy will be presented.

9549-20, Session 5

Using the Stark effect to understand charge generation in organic solar cells

Natalie Banerji, Univ. de Fribourg (Switzerland)

The photoactive material of organic solar cells commonly consists of a conjugated polymer blended with a fullerene derivative, yielding a complex network of intermixed and phase-pure domains. The charges that are photo-generated in the blend create an electric field in their vicinity, which can affect neighboring molecules and shift their absorption spectrum (Stark effect). The corresponding electro-absorption signature is a powerful tool to understand charge generation in the organic materials. We have investigated pBTTT:PCBM samples with a variety of well-defined microstructures, exploiting the Stark effect in two complementary ways. First, we have studied the evolution of the electro-absorption signal present in ultrafast transient absorption data (no external bias). This has allowed for the first time to directly visualize the migration of charges from intermixed to phase-pure regions, leading to significant insight to the still poorly understood mechanism by which the neat domains favour spatial separation of charges. Second, we have looked at the field-dependent generation and transport of charges in full solar cell devices with externally applied reverse bias, where the photo-generated charged cause a time-resolved reduction of the electro-absorption induced by the external field.

9549-21, Session 5

Exciton dissociation at organic small molecule donor-acceptor interfaces

Steven W. Robey, National Institute of Standards and Technology (United States)

Exciton dissociation at organic semiconductor donor-acceptor (D-A) heterojunctions is critical for the performance of organic photovoltaic (OPV) structures. Interfacial charge separation and recombination processes control device efficiency. We have investigated these fundamental interfacial issues using time-resolved two-photon photoemission (TR-2PPE), coupled with the formation of well-controlled D-A structures by organic molecular beam epitaxy. The interfacial electronic and molecular structure of these model interfaces was well-characterized using scanning tunneling microscopy and ultraviolet photoemission. Exciton dissociation dynamics were investigated by using a sub-picosecond pump pulse to create Pc ϖ?ϖ* transitions, producing a population of singlet (S1) Pc excitons. The subsequent decay dynamics of this population was monitored via photoemission with a time-delayed UV pulse. For CuPcC60 interfaces, S1 exciton population decay in the interfacial CuPc layer was much faster than decay in the bulk due to interfacial charge separation. The rate constant for exciton dissociation was found to be ≈ 7 x 10 12 sec-1 (≈ 140 fs). Excitons that lose energy via intersystem crossing (ISC) to triplet levels dissociate approximately 500 to 1000 times slower. The dependence of exciton dissociation on separation was also studied. Exciton dissociation falls of rapidly with distance from the interface. Dissociation from the 2nd, and subsequent, layers of H2Pc is reduced by at least a factor of 10 from that in the interfacial layer. Finally, investigations of the relative efficiency for interfacial exciton dissociation by alternative acceptors based on perylene cores, (perylene tetracarboxylic dianhydride, or PTCDA) compared to fullerene-based acceptors such as C60 will also be discussed.

9549-22, Session 5

Fluorescence and UV/VIS absorption spectroscopy studies on polymer blend films for photovoltaics

Jan van Stam, Camilla Lindqvist, Rickard Hansson, Leif K. E. Ericsson, Ellen Moons, Karlstad Univ. (Sweden)

The quinoxaline-based polymer TQ1 (poly[2,3-bis-(3-octyloxyphenyl) quinoxaline-5,8-diyl-alt-thiophene-2,5- diyl]) [1] is a promising candidate as electron donor in organic solar cells. In combination with the electron acceptor [6,6]- phenyl-C71-butyric acid methyl ester (PC70BM), TQ1 has resulted in solar cells with power conversion efficiencies of 7 % [2].

We have studied TQ1 films, with and without PC70BM, spin-casted from different solvents, by fluorescence spectroscopy and UV/VIS absorption spectroscopy. We used chloroform (CF), chlorobenzene (CB), and o-dichlorobenzene (o-DCB) as solvents for the coating solutions and 1-chloronaphthalene (1-CN) as solvent additive. 1-CN addition has been shown to enhance photo-conversion efficiency of these solar cells [2,3]. Phase-separation causes lateral domain formation in the films and the domain size depends on the solvent [2,3]. These morphological differences coincide with changes in the spectroscopic patterns of the films.

From a spectroscopic point of view, TQ1 acts as fluorescent probe and PC70BM as quencher. The degree of fluorescence quenching is coupled to the morphology through the distance between TQ1 and PC70BM. Furthermore, if using a bad solvent for PC70BM, morphological regions rich in the fullerene yield emission characteristic for aggregated PC70BM [4]. Clear differences were found, comparing the TQ1:PC70BM blend films casted from different solvents and at different ratios between the donor and acceptor. The morphology also influences the UV/VIS absorption spectra, yielding further information on the composition.

The results show that fluorescence and UV/VIS absorption spectroscopy can be used to detect aggregation in blended films and that these methods extend the morphological information beyond the scale accessible with microscopy.

9549-2, Session 6

Electronic coupling at hybrid organic/inorganic interfaces *(Invited Paper)*

Oliver L. A. Monti, The Univ. of Arizona (United States)

Hybrid organic / inorganic interfaces play a central role in organic optoelectronics as charge harvesting layers or charge-recombination layers. The properties that determine electronic structure, dynamics and charge collection efficiencies are however at present poorly understood. I will discuss recent results for the paradigmatic interface of organic semiconductors with highly conductive ZnO films. Using a wide range of steady-state and time-resolved spectroscopic approaches, I will show how defect-driven strong electronic interactions determine interfacial energy-level alignment, carrier dynamics on the sub-fs time-scale and device function. These interactions can be controlled by judicious preparation of the interface, with immediate consequences for carrier-harvesting efficiencies.

9549-23, Session 6

Ultrafast excited-state dynamics at interfaces: fluorescent DNA probes at the dodecane/water interface *(Invited Paper)*

Giuseppe Licari, Eric Vauthey, Univ. de Genève (Switzerland)

Although liquid/liquid interfaces play a key role in many area of science and technology, their properties are only partially understood. Our strategy to obtain an insight into these properties is to investigate the ultrafast excited-state dynamics of environment-sensitive molecular probes at liquid interfaces using time-resolved surface second harmonic generation (SSHG), and to compare it with the dynamics of the same molecules in bulk solutions. This approach gives additionally rich information on how the

chemical reactivity may change when going from the bulk liquid phase to the interface.

This will be illustrated by several examples, concentrating on results obtained with several fluorescent DNA probes, such as YO (oxazol yellow) and the homodimeric probe YOYO, as well as with chiral helicenium dyes. Stationary and time-resolved SSHG measurements reveal substantial differences in the structure and the excited-state lifetime of these DNA probes at the interface compared to bulk water. For example, whereas some of these dyes form H aggregates in aqueous solution, J aggregation is observed at the alkane/water interface. Similarly, the excited-state lifetime of these flexible molecules increase substantially when going from the bulk phase to the interface, pointing to higher friction.

The sensitivity of SSHG to the chirality of the interface has been used to observe the intercalation of these dyes in B-DNA. Our effort to exploit this sensitivity to measure temporal photoinduced changes of optical activity and hence to monitor structural dynamics will be illustrated with results obtained with helicenium dyes.

9549-24, Session 6

Absolute polaron yield generated in donor-acceptor P3HT:fullerene bulk heterojunction composites *(Invited Paper)*

Saptaparna Das, Alia A. Latif, William Thornbury, Barry C. Thompson, Stephen E. Bradforth, The Univ. of Southern California (United States)

Broadband pump-probe spectroscopy over the entire time range (200 fs to 500 ns) relevant to monitor the polaron generation and recombination dynamics were performed on the bulk heterojunction composites of poly (3-hexylthiophene) (P3HT) and poly(3-hexylthiophene-thiophene-diketopyrrolopyrrole) (P3HTT-DPP-10%) with [6,6]-phenyl-C61-butyric acid methyl ester (PCBM) as the acceptor. The modeling of the polaron dynamics with the Debye-Smoluchowski diffusion model provides the charge separation length at the polymer:fullerene interface. Using the polaron cross-section obtained from the chemical doping measurements, the computed polaron yield over the entire time range reveals how many photo-generated charges are created and survive in P3HT:PCBM and P3HTT-DPP-10%:PCBM bulk-heterojunction thin films.

9549-25, Session 6

Photoinduced carrier generation and recombination dynamics of a trilayer cascade heterojunction composed of poly(3-hexylthiophene), titanyl phthalocyanine, and C60

Jaehong Park, Obadiah G. Reid, Garry Rumbles, National Renewable Energy Lab. (United States)

We demonstrated that the combination of flash-photolysis time-resolved microwave conductivity experiments (fp-TRMC) and classic fs-ns pump-probe transient absorption spectroscopy can serve to complement each other and can be utilized to elaborate photoinduced carrier generation and recombination dynamics for more complicated trilayer cascade heterojunction system (P3HT/TiOPc/C60) composed of poly(3-hexylthiophene) (P3HT), titanyl phthalocyanine (TiOPc), and C60. Carrier generation following selective photoexcitation of TiOPc is independently observed at both the P3HT/TiOPc and TiOPc/C60 interfaces. Moreover, fp-TRMC results show that the yield-mobility product (???) of the trilayer (P3HT/TiOPc/C60) exceeds the sum of ??? each bilayer (P3HT/TiOPc and TiOPc/C60), suggesting that carriers generated at one interface undergo a second charge transfer step at the other interface. Pump-probe transient absorption spectroscopic studies probe carrier generation through hole and electron transfer processes at the interfaces of P3HT/TiOPc and TiOPc/C60, respectively. Each bilayer (P3HT/TiOPc) and (TiOPc/C60) exhibited ultrafast electron/hole transfer as well as exciton-diffusion limited processes. These transient absorption results indicates that following initial charge generation processes to produce P3HT•+/TiOPc—• and TiOPc•+/C60—• at each interface from (P3HT/TiOPc*/C60) via electron transfer and hole transfer processes, the final charge separated product of (P3HT•+/TiOPc/C60—•) is responsible for the long-lived photoconductance signals in fp-TRMC.

9549-26, Session 6

Cause of absorption band shift of disperse red-13 attached on silica spheres

Byoung-Ju Kim, Hyung-Deok Kim, Na-Rae Kim, Byeong-Gyu Bang, Eun-Hye Park, Tea Wuk Kang, Kwang-Sun Kang, Kyungil Univ. (Korea, Republic of)

A reversible color change and large absorption band shift have been observed for the disperse red-13 (DR-13) attached on the surface of the monodisperse silica spheres. Two step synthetic processes including urethane bond formation and hydrolysis-condensation reactions were used to attach the DR-13 on the surface of the silica spheres. After the reaction, the characteristic absorption peak at 2270 cm-1 representing the –N=C=O asymmetric stretching vibration disappeared, and the a new absorption peak at 1700 cm-1 corresponding the C=O stretching vibration appeared. A visual and reversible color change was observed before and after wetting in alcohol. Although the absorption peak of DR-13 in alcohol is at 510 nm, the absorption peak shifts to 788 nm when it is dried. The absorption peak shifts to 718 nm when it is wetted in alcohol. This result can be explained by the formation of intramolecular charge transfer band.

Nano-optical spectroscopic imaging of MoS2: probing 2D materials at the length scales that matter *(Invited Paper)*

James P. Schuck, The Molecular Foundry (United States)

No Abstract Available

9549-28, Session 7

Surface-enhanced, multi-dimensional attenuated total reflectance spectroscopy *(Invited Paper)*

Jan Philip Kraack, Univ. of Zürich (Switzerland); Davide Lotti, Univ. of Zurich (Switzerland); Peter Hamm, Univ. of Zürich (Switzerland)

Vibrational dynamics of molecules at solid-liquid interfaces attract attention due to their involvement in heterogeneous catalysis.1 This includes simple samples like small molecules (e.g., CO) and large organic molecules (e.g., self-assembled monolayers) on metallic substrates. It is therefore desirable to develop spectroscopic techniques for obtaining surface-sensitive molecular information.

We present a new method for delivering coherent, time-resolved two-dimensional (2D) infrared (IR) spectra from adsorbates on metallic thin films.2,3 The technique is based on reflection absorption spectra obtained under total reflection conditions at interfaces of different refractive index materials. Details of femtosecond 2D ATR IR spectroscopy are presented along with benefits and challenges. 2D ATR IR spectroscopy is used to resolve ultrafast interfacial dynamics of molecules on metallic thin films. We characterize surface-enhancement effects due to the presence of the metal. The experiments focus on the impact of different chemical environments on samples vibrational dynamics. The technique is capable for a surface-sensitive characterization of vibrational lifetimes, dephasing, spectral diffusion and sample inhomogeneity. Finally, we discuss the future scope

of 2D ATR IR spectroscopy regarding its applicability on more complex samples such as heterogeneous photocatalysts or transient intermediates in spectro-electrochemistry.

Ultrafast carrier photogeneration dynamics in polymer: fullerene solar cells probed by photocurrent-detected two-dimensional coherence spectroscopy *(Invited Paper)*

Carlos Silva, Univ. de Montréal (Canada)

In solar cells that incorporate semiconductor polymers as electron donors and fullerene derivatives as acceptors, a number of reports based on ultrafast optical probes reveal that charges can be generated on timescales significantly faster than ~100 fs in certain solid-state microstructures. Techniques that have been applied in these studies include variants of visible transient absorption and photoluminescence spectroscopy, terahertz spectroscopy, time-resolved infrared spectroscopy, and femtosecond stimulated Raman spectroscopy. These probes allow measurement of population dynamics of relevant photoexcitations (excitons, polarons) but do not reveal directly how these interact to produce photocarriers. Here, we present a non-linear coherent spectroscopy, photocurrent-detected two-dimensional spectroscopy (2DPC), which is an ultrafast optical thechnique belonging to a family of 2D Fourier- domain spectroscopies that allows measurement of correlations between optical transitions induced by short optical pulses. In our implementation, spectral correlations are detected via the time-integrated photocurrent produced in a photovoltaic diode. Four collinear ultrashort laser pulses (10 fs, centered at 600 nm in our experimental setup) excite the semiconductor polymer in the solar cell, with a variable delay that is independently controlled between each pulse in the sequence. Each pulse separately excites a quantum wavepacket with spectral phase and amplitude imparted by that pulse, while the effect of the pulse sequence is to collectively excite multiple quantum coherences. Interferences between the various combinations of the wavepackets determine linear and non-linear contributions to the material optical response. The fourth-order signal terms of the detected photocurrent are read using phase-sensitive detection schemes with reference waveforms corresponding to a modulation of specific phase combinations of the four femtosecond excitation pulses. By scanning the time delay between the pulses 1 and 2, as well as that between pulses 3 and 4 (coherence times), at a fixed delay between pulses 2 and 3 (population waiting time), one measures a two-dimensional coherence decay function that is Fourier transformed to produce a 2D photocurrent correlation excitation spectrum. Measurement of such spectra at different population waiting times provides insight into the role of spectral correlations and state coherence in photocurrent generation in such complex functional materials. We focus on solar cells produced by blends of a common carbazole-thiophene-benzothiadiazole polymer, PCDTBT (the donor polymer), and PCBM (the fullerene acceptor), in which we analyse the dynamics of total photocurrent generation via the time evolution of diagonal and off-diagonal spectral correlations. We address the role of vibronic coherence as well as resonant tunneling in charge separation pathways on ultrashort timescales.

Controlling electron transfer in condensed phase with bond specific Infrared excitation *(Invited Paper)*

Milan Delor, Paul A. Scattergood, The Univ. of Sheffield (United Kingdom); Igor V. Sazanovich, Gregory M. Greetham, STFC Rutherford Appleton Lab. (United Kingdom); Anthony J. H. M. Meijer, The Univ. of Sheffield (United Kingdom); Anthony W. Parker, Michael Towrie, STFC Rutherford Appleton Lab. (United Kingdom); Julia A. Weinstein, The Univ. of Sheffield (United Kingdom)

The ability to direct chemical change by targeted external perturbation is a long sought after gateway to controllable reactivity. Photochemically driven electron transfer (ET), one of the few elementary processes, is a particularly attractive target for such optical control. A key but elusive factor that often determines the mechanism of ET is nuclear-electronic (vibronic) coupling, known to considerably affect ultrafast photoinduced ET in a vast range of biochemical systems. Vibronic effects are particularly difficult to probe in condensed phase due to the convolution of multiple electronic and structural processes occurring on ultrafast timescales. We use the frequency-domain Transient 2-Dimensional Infrared (T-2DIR) pulse sequence (UV pump, narrowband IR pump, broadband IR probe) to elucidate the interplay between vibrational and electronic processes in charge transfer complexes. We demonstrate the application of this technique to covalent Donor-Bridge-Acceptor systems, where the Donor and Acceptor are tethered together by a strongly IR-active Pt-acetylide bridge which is the target for the IR pulse.

Using 400 - 470 nm excitation, we optically populate a gateway state [D-B-A]*, which branches over separate pathways, and then introduce a ~2-ps, ~15 cm(-1) IR-pulse to selectively perturb IR-vibrations coupled to a charge-separation pathway. e show that vibrationally exciting intramolecular bridge vibrations during visible-light induced ET between donor and acceptor can result in substantial modulation of ET rates and photoproduct yields, and in some cases, completely switches off charge-separation.

9549-31, Session 8

Exciton and polaron interactions in self-assembled conjugated polymer aggregates *(Invited Paper)*

John K. Grey, The Univ. of New Mexico (United States); Jian Gao, Lawrence Berkeley National Lab. (United States); Alan Thomas, The Univ. of New Mexico (United States)

We study exciton coupling and interconversion between neutral and charged states of different spin in pi-stacked conjugated polymer aggregates. Rigorous self-assembly approaches are used to prepare aggregate nanofibers that permit reliable control of polymer chain conformational and packing (intra- and interchain) order within these structures. Exciton coupling can be tuned between the H- and J-aggregate limits which has important implications for determining the fates of excitons and polarons. Single molecule intensity modulation spectroscopy was performed on individual nanofibers and large quenching depths of emissive singlet excitons by triplets are found in J-aggregate type structures. We propose that high intrachain order leads to exciton delocalization that effectively lowers singlet-triplet energy splittings thus increasing triplet yields. Exciton-polaron and polaron-polaron interactions are next investigated in both H- and J-type nanofibers where polarons are injected by charge transfer doping. We find that the enhanced intrachain order of J-aggregates enables efficient intrachain polaron transport and leads to significantly larger doping efficiencies than less ordered H-aggregates. As polaron densities increase, signatures of spin-spin interactions between polarons on adjacent chains become appreciable leading to the formation of a spinless bipolaron. Overall, these studies demonstrate the potential for controlling and directing exciton and polaron interactions via tuning of subtle intra- and interchain ordering characteristics of aggregates, which could benefit various polymeric optoelectronic applications.

9549-32, Session 8

Controllable supramolecular architectures for modulating the optical properties

Yongjun Li, Runsheng Jiang, Institute of Chemistry (China)

There is growing interest in the design of pi-conjugated systems that

can self-assemble into uniform aggregates with specific shape and novel functionalities. Indeed, an effective way to shape supramolecular architectures is through molecular self-assembly technology based on intramolecular, intermolecular, and molecule-substrate interactions. The optical properties of the conjugated molecules can also be influenced by different conformations and spatial arrangements, such as observed in conformation-dependent fluorescent enhancement induced by laser irradiation.

A thiophene-substituted perylene bisimide has been synthesized and used to demonstrate a relatively simple associated approach to the construction of nano- and microstructures with zero and two dimensions. The thiophene substituted perylene bisimide showed conformation-dependent hypochromatic shift and fluorescent enhancement behavior in the solid state, which is induced by tuning the intramolecular charge transfer from the trithiophene unit to the perylene bisimide through light-induced conformation changes of the trithiophenes. The mechanism differs from the fluorescent bleaching of normal solid-state fluorescent materials, and suggests potentially important applications in optical devices. This work demonstrates the importance of controlling molecular conformation in molecular aggregation systems to modulate optical properties.

9549-33, Session 8

Characterization of nano-sized iron particle layers spin coated on glass substrate

Sunil Dehipawala, Queensborough Community College (United States); Pubudu Samarasekara, Rasika Dahanayake, Univ. of Peradeniya (Sri Lanka); George Tremberger Jr., Tak D. Cheung, Queensborough Community College (United States); Harry D. Gafney, Queens College (United States)

Nanometer scale iron particles have a variety of technological applications. They are vastly utilized in optical and microwave devices. Thin films with various compositions of iron (III) nitrate and ethylene glycol were deposited on glass substrate using the spin coating technique. The micro structures of iron particles in films prepared under different conditions were investigated using X-ray Absorption spectroscopy and Mossbauer spectroscopy.

9549-34, Session 8

Influence of the molecular orientation on the optical properties and photomodification of cyanine thin film

Anton A Starovoytov, ITMO University (Russian Federation); Elena N. Kaliteevskaya, Valentina P. Krutyakova, Tatiana K. Razumova, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

Cyanine dyes have a good ability to form layers from solutions of organic solvents. Due to the high polarizability of the electron cloud in the conjugation chain, the cyanines are optical materials with large nonlinear susceptibility. The photorecording cyanine layers are widely used in optical discs. Photochemical switches with subpicosecond response time are developed based on cyanine films. Ionic cyanines are used in light-emitting electrochemical cells.

The structural photomodification of the multicomponent cyanine thin films was studied. Samples were prepared by spin-coating of the ethanol solution of cyanine dye on the glass substrate. The spectrum of the film shows different bands of components, formed by dye molecules. Optical properties of the films were determined by the relative concentrations of the components and their orientation angles, which depend on the temperature of the substrate during coating of the layer.

Photoinduced modification of the film structure was provided by laser pulses (duration of 10 ns). Laser irradiation carried out in the absorption range of different monomer and aggregate components of the films. Photoinduced changes in the absorption spectra of film associated with the variation of the relative concentrations of the components and their orientation angles. The dependences of angle on the total photoexcitation energy, which was determined by the number of laser pulses, had the form of saturating functions. With increasing pulse energy, the limiting angles grow. The limiting angle vs. pulse energy dependences are the saturating functions. Maximum limiting angles depend on the initial orientation angles of the component.

9549-60, Session 8

SHG techniques to investigate the surface and the bulk of aqueous solutions

Anthony Maurice, Institut Lumière Matière (France); Q. Ma, Institut Lumière Matière (France) and Commissariat à l'Énergie Atomique (France); Fabrice Canto, Laurent Couston, Commissariat à l'Énergie Atomique (France); Olivier Diat, Institut de Chimie Séparative de Marcoule (France); Emmanuel Benichou, Pierre-François Brevet, Institut Lumière Matière (France)

During the last years, ion extraction processes were widely used in industry to separate and concentrate ionic species in solutions. These processes are of considerable interest both from the fundamental and the industrial point of view, particularly in the fields of ore extraction or nuclear waste treatment. In all cases, the region of interest is the interface between the two media, where the structure and the dynamics remain elusive. In order to access the interface and the bulk solution at the same time with a high contrast, we have developed a method based on second harmonic generation, namely the conversion of two photons into a single one at the sum energy

We will present our recent results obtained for simple multivalent cations and different counter-anions, standard organic dye molecules and metallic nanoparticles. SHG profiles of these species at air-liquid and liquid-liquid interfaces exhibit two distinct regions. The first one corresponds to the interface where the bulk centrosymmetry is broken whereas the second one corresponds to the bulk volume of the phases where incoherent second harmonic is generated. A general framework to describe these data sets will be provided and the structure of the interface discussed in light of these results.

9549-35, Session 9

Mapping optoelectronic processes at their native length scale in perovskite PV materials *(Invited Paper)*

Alexander Weber-Bargioni, The Molecular Foundry (United States)

No Abstract Available

9549-36, Session 9

Interfacial energy landscapes of organic semiconductors probed on the sub-molecular scale by STM *(Invited Paper)*

Sarah A. Burke, Agustin E. Schiffrin, Katherine Cochrane, Martina Capsoni, Tanya Roussy, The Univ. of British Columbia (Canada)

The inter- and intra- molecular energy transfer underlying applications in electronics, optoelectronics and catalysis relies on both the spatial distribution of electronic states and their energy level alignment across interfaces. As models for organic photovoltaic and catalytic materials, we are investigating well-controlled nanostructures of the organic semiconductor PTCDA, and an iron-terpyridine coordination polymer. Scanning tunneling microscopy and spectroscopy, operated in a spectroscopic mapping mode, allows us to visualize position and orientation of molecules alongside the spatial distribution of states and shifts in the energy level alignments across these organic nanostructures. In small clusters of PTCDA, we have found a pronounced shift in the energy level alignment and change in the semiconducting gap of up to 0.5eV, likely due to the abrupt change in the local polarization environment. This interfacial energy level shift has potential consequences for electronic devices and organic heterostructures for photovoltaics where the distinct local environment of the interface would need to be considered. On-surface coordination of iron-terpyridine chains was used to generate well-controlled and clean metal-ligand complexes as a model for dyes and catalytic systems. Taking inspiration for existing molecular complexes, this surface-bound macromolecular system exhibits spatial and energetic characteristics that mimic the molecular complexes, most notably showing a metal-centered HOMO and ligand-centered LUMO that indicates a low-lying MLCT optical excitation exploited in related photoactive dyes. In each of these examples, the sub-molecular resolution spectroscopy yields high resolution energetic and spatial information that can be used to understand the local electronic landscape.

9549-37, Session 9

Super-resolution imaging with mid-IR photothermal microscopy on the single particle level

Zhongming Li, Gregory V. Hartland, Univ. of Notre Dame (United States)

Photothermal microscopy, as a label-free imaging technique, has achieved single molecule sensitivity. However, the analytes are usually restricted to be natural absorbers in the visible light region. Mid-IR imaging, on the other hand, encounters difficulties of diffraction-limited spatial resolution and scarcity of ideal detectors. Here we present Mid-IR photothermal heterodyne imaging (MIR-PHI) microscopy, which overcomes the diffraction limit and is universally applicable to any analyte. It can also provide spectroscopic information for further identification. In MIR-PHI, a tunable Mid-IR pulsed laser at 150 kHz is used as a heating beam to transmit thermal energy to an analyte particle. Energy relaxation creates a temperature gradient, changing the refractive index of the surrounding solvent and creating a thermal lens around this particle. A collinear counter propagating probe beam (a 532 nm CW laser) is modified by the thermal lens and generates a super-resolution photothermal image. We studied 1.1 μm polystyrene beads on the single particle level using this technique. Images were recorded at 3030 cm-1, which corresponds to the strong absorption from aromatic C-H stretches. Various solvents with different heat capacities and refractive indices are tested for the best image contrast. Spectra were recorded in the 2.5 to 3.7 μm and 5.4 to 9.6 μm regions, which cover the majority of both of the functional group frequency region and the fingerprint region. The spectra obtained can be used to distinguish different materials. The wide applicability and high sensitivity of this technique make it promising for biological imaging and identification.

9549-38, Session 10

Emergence of collective luminescence in mesoscopic conjugated polymer aggregates by coherent and incoherent processes *(Invited Paper)*

Jan Vogelsang, Thomas Stangl, Philipp Wilhelm, Univ. Regensburg (Germany); Klaas Remmerssen, Sigurd Höger, Univ. Bonn (Germany); John Lupton, Univ. Regensburg (Germany)

Many applications of conjugated polymers depend critically on the nature of excitation energy transport in these materials. Bulk measurements regarding these processes have the inherent disadvantage that an average physical or chemical mechanism is probed, which can mask important microscopic mechanisms, taking place on smaller subunits. An example of this problem is coherent coupling between multiple chromophores, which leads to efficient energy transport and is therefore masked by photoluminescence quenching in the bulk.

By employing single molecule and aggregate spectroscopy on well-defined conjugated polymer chains and differently sized aggregates composed of multiple chains, we unravel the following non-intuitive behaviour in the material poly(phenylene-ethynylene): (i) aggregation by solvent vapour annealing [1] of multiple chains leads to coherent coupling between chromophores, best described in the context of H-aggregation [2] or excimer-like states [3] and resulting in a ~10-fold increase in the excited state lifetime. (ii) This coupling between chromophores in aggregates is so efficient that photon anti-bunching occurs in aggregates consisting of up to ~20 chains, even though single chains do not show such an effect. (iii) Quenching, due to photochemical quenchers, becomes increasingly dominant with increasing aggregate size, resulting in a strong blinking behaviour of the photoluminescence. These incoherent quenching processes, mediated by FRET, lead to a decrease of the excited state lifetime in the aggregate and also to a decrease in the fidelity of photon anti-bunching. Our results demonstrate that important intermolecular processes take place in the mesoscopic size regime, which do not exist on the single chain and are masked in the bulk, but influence the bulk properties.

Transient absorption microscopy studies of single metal and semiconductor nanostructures *(Invited Paper)*

Paul Johns, Mary Sajini-Devadas, Gregory V. Hartland, Univ. of Notre Dame (United States)

Single particle spectroscopy is capable of providing detailed information about how differences in size, shape and environment affect the properties of nanomaterials. In this talk results from transient absorption experiments performed with diffraction limited spatial resolution will be presented. This technique allows us to perform ultrafast measurements on single nanostructures, and provides information about their dynamics that is washed out in ensemble experiments. The systems that have been examined to date include metal nanoparticles and nanowires, carbon nanotubes, and semiconductor nanowires. The time scales of interest range from a few hundred fs to several ns, and the results provide detailed information about how nanomaterials interact with their environment. In particular, recent results on the damping of the breathing modes of Au nanowires will be described. These modes are impulsively excited by rapid heating from the pump laser. Their damping strongly depends on the viscosity of the surrounding medium. Analysis of the results for viscous to moderately viscous solvents shows that viscoelastic effects have to be included to properly describe the experiments. Viscoelasticity is normally only

important in complex fluids, such as concentrated colloidal dispersions. It appears here because of the high frequencies inherent to the vibrational modes of nanomaterials. Imaging experiments that provide information about the propagation of surface plasmon polaritons (SPPs) in metal nanowires will also be described. These measurements have been used to determine how the SPPs couple between nanostructures. This was achieved by investigating Au nanowires with gaps that were created by focused ion-beam milling.

9549-40, Session 10

Single-molecule methods to quantify adsorptive separations *(Invited Paper)*

Christy Landes, Rice Univ. (United States)

Interfacial adsorption and transport are the chemical and physical processes that underlie separations. Although separations technology accounts for hundreds of billions of dollars in the global economy, the process is not well-understood at the mechanistic level and instead is almost always optimized empirically. One of the reasons is that access to the underlying molecular phenomena has only been available recently via single-molecule methods. There are still interesting challenges because adsorption, desorption, and transport are all dynamic processes, whereas much of the advances in super-resolution imaging have focused on imaging static materials. Our lab has focused in recent years on developing and optimizing data analysis methods for quantifying the dynamics of adsorption and transport in porous materials at nanometer-resolution spatial scales. Our methods include maximizing information content in dynamic single-molecule data and developing methods to detect change-points in binned data. My talk will outline these methods, and will address how and when they can be applied to extract dynamic details in heterogeneous materials such as porous membranes.

9549-42, Session 10

Stability studies on promethazine unexposed and exposed to UV laser radiation

Agota Simon, Adriana Loredana Smarandache, Tatiana Tozar, Viorel V. Nastasa, National Institute for Laser, Plasma and Radiation Physics (Romania) and Univ. of Bucharest (Romania); Ruxandra Pirvulescu, Univ. of Medicine and Pharmacy Carol Davila (Romania); Mihail Lucian Pascu, National Institute for Laser, Plasma and Radiation Physics (Romania) and Univ. of Bucharest (Romania)

Since multiple drug resistance evolved, it became crucial to develop new medicines and to improve the action of the existing ones. A method to cope with these requirements consists in the generation of new photoproducts with possible bactericide, fungicidal effects, by modifying the parental compound at the molecular level by exposure to UV laser beam. This is particularly applied on phenothiazines which are photosensitive non-antibiotics.

The phenothiazine derivative Promethazine (PMZ), was investigated from the point of view of its stability before and after exposure to UV laser radiation. PMZ is a neuroleptic drug with antihistaminic, antiemetic and anticholinergic properties.

Stability studies of samples are imperative prior to be used in preclinical applications. PMZ solutions have been studied by pH measurements, absoption spectroscopy, laser induced fluorescence and FTIR before and after irradiation. Samples (exposed and unexposed to UV laser beam) of different concentrations have been prepared, to examine their time stability while kept in different conditions: laboratory temperature and exposed to white light, laboratory temperature in the dark, fridge in the dark. This study involved the exposure of solutions utilizing the 4th harmonic (266nm) of a Nd:YAG pulsed laser beam. Stability measurements have been performed monitoring samples evolution for long time intervals after exposure. First results about applications of irradiated phenothiazines samples on infected rabbit eyes are reported.

Effect of surface stoichiometry and interfacial interactions on ultrafast carrier dynamics of crystalline CdTe *(Invited Paper)*

Xing He, Napat Punpongjareorn, Chengyi Wu, Karjini Rajagopal, Ding-Shyue Yang, Univ. of Houston (United States)

To improve the efficiency of optoelectronic devices, it is critical to understand the carrier dynamics of photoactive materials and the mechanisms involved, including those effects caused by different surface stoichiometry and/or interfacial interactions. A good example is CdTe, which exhibits cost-effective high performance in thin-film photovoltaic cells; it is also known to show surface oxidation, which may affect device efficiency and hence limit the production methods used. In this contribution, we present ultrafast carrier dynamics of crystalline CdTe specimens with different surface conditions using transient reflectivity measurements, following a femtosecond above-gap excitation. The distinct differences observed in the dynamics and the time constants for oxidized and stoichiometrically restored specimens indicate the major role of surface tellurium oxide on the relaxation of photoinduced carriers. The much slower recovery observed on oxidized surfaces is attributed to a transfer (and trapping) of electrons to the tellurium atoms with a high oxidation state, which signifies a charge separation near the surface. To distinguish the effect caused by oxygen adsorption, we also examined the carrier dynamics of CdTe surfaces covered by a thin layer of water molecules for comparison. These results, which show clear interfacial effects, may have broader implications for the understanding of carrier dynamics in nanostructured and polycrystalline specimens under different chemical environments, as such materials exhibit a high surface-to-volume ratio.

9549-44, Session 11

Quadratic nonlinear optics of liquids: from bulk to surfaces and interfaces *(Invited Paper)*

Anthony Maurice, Isabelle Russier-Antoine, Christian Jonin, Emmanuel Benichou, Pierre-François Brevet, Institut Lumière Matière (France)

Quadratic nonlinear optical processes entailing the conversion of two photons at a fundamental energy into one photon with the sum energy are gaining a wider interest over the years, fueled by the development of highly spatially resolved microscopy techniques. These processes obey strict parity rules in order to occur. They are for instance forbidden in media possessing inversion symmetry like liquids. However this constraint may be turned into a benefit when used in special cases where it is broken by a small amount. One of these processes, second harmonic generation, namely the degenerate process of photon addition, can thus be used to investigate liquids on short scales, within the bulk or at the interface. This property will be illustrated through several examples of nanoscale molecular organization.

9549-45, Session 11

High resolution patterning electronic polymers using dopant induced solubility control *(Invited Paper)*

Adam J. Moule, Ian E. Jacobs, Jun Li, Stephanie L. Burg, David J. Bilsky, Brandon T. Rotondo, Pieter Stroeve, Univ. of California, Davis (United States)

Organic electronics promise to provide flexible, large-area circuitry such as photovoltaics, displays, and light emitting diodes that can be fabricated inexpensively from solutions. A major obstacle to this vision is that most conjugated organic materials are miscible, making solution-based fabrication of multilayer or micro- to nanoscale patterned films problematic. Here we demonstrate that the solubility of prototypical conductive polymer poly(3-hexylthiophene) (P3HT) can be reversibly "switched off" using high electron affinity molecular dopants, then later recovered with light or a suitable dedoping solution. Using this technique, we are able to stack mutually soluble materials and laterally pattern polymer films using evaporation of dopants through a shadow mask or with light, achieving sub-micrometer, optically limited feature sizes. After forming these structures, the films can be dedoped without disrupting the patterned features; dedoped films have identical optical characteristics, charge carrier mobilities, and NMR spectra as as-cast P3HT films. This method greatly simplifies solution-based device fabrication, is easily adaptable to current manufacturing workflows, and is potentially generalizable to other classes of materials.

9549-46, Session 11

Effect of substrate on Scanning Kelvin Probe Microscopy (SKPM) of interface polarity at carbon nanotube/fullerene junctions

Olivia Alley, Johns Hopkins Univ. (United States); Meng-Yin Wu, Univ. of Wisconsin-Madison (United States); Josue F. Martinez Hardigree, Johns Hopkins Univ. (United States); Michael S. Arnold, Univ. of Wisconsin-Madison (United States); Howard E. Katz, Johns Hopkins Univ. (United States)

Using our method of SKPM of lateral junctions, we have observed the interfacial potential between semiconducting carbon nanotubes and phenyl-C61 butyric acid methyl ester (PCBM). The lateral junctions are made using a fluoro-polymer based lithography and dry etching technique. We determined that the polarity of this potential is reversed when the lateral junction is made on Al2O3 compared to when it is made on SiO2. We did not observe this reversal for a polyemer/PCBM junctions made on these two substrates. There are several possible reasons behind this difference. First, the carbon nanotube layer is thinner and more conductive than the polymer layer, so the substrate will have more of an effect on the potential at the surface. Additionally, others have found that insulators with larger dielectric constants, such as Al2O3, alter the electronic states of adjacent organic semiconductors (OSCs). This is both from greater dipolar disorder in the insulator, and a greater degree of polaron formation in the OSC. We think these effects extend to this situation, and lead to greater charge trapping near the dielectric interface. It is only evident in the nanotube/PCBM system because the effects only extend a few nm beyond the interface with the insulator. The surface of the thicker polymer film therefore is not affected.

9549-47, Session 12

Interface engineering to eliminate bias-stress effect in quantum dot transistors *(Invited Paper)*

Matt Law, Univ. of California, Irvine (United States)

Colloidal quantum dot (QD) solids are the subject of active research with applications emerging in light-emitting diodes, field-effect transistors, and solar cells. In this talk, I describe the use of atomic layer deposition (ALD) infilling to engineer the surfaces and interfaces of PbSe QD films in order to produce high-performance QD field-effect transistors (FETs) that completely lack bias-stress effect (i.e., drain current transients caused by charge trapping near the dielectric/channel interface). This ALD "matrix engineering" approach includes steps designed to manage ligand concentrations, passivate surface states, and arrest ionic motion within the films, resulting in the first high-mobility (~14 cm V-1 s-1), environmentally stable, and transient-free PbX QD transistors. Two bias-stress mechanisms in QD FETs are identified and discussed. The implications of these mechanisms for the operation of QD solar cells is highlighted.

9549-48, Session 12

Exciton formation dynamics in Si quantum dots and functionalized CdSe nanorods studied with time-resolved THz spectroscopy

Matthew C. Beard, National Renewable Energy Lab. (United States)

Time-resolved THz spectroscopy is typically used to probe the complex photoconductivity in a non-contact fashion with sub-picosecond temporal resolution. As such the THz spectra is sensitive to the nature of carriers within nanostructures. We show that the THz probe can distinguish between free-carriers and excitons. The THz probe therefore distinguishes the initially produced hot-carriers from excitons that are formed on a longer timescale. We report size-dependent exciton formation dynamics within colloidal silicon quantum dots. We find that the exciton formation time increases from ~600 fs - 1 ps, as the size of the QD is reduced. At longer delay times we extract the exciton-polarizability, which follows an ~r^4 dependence, consistent with previous reports for quantum-confined excitons. The ability to differentiate between excitons and free carriers makes time-resolved terahertz spectroscopy a powerful technique for understanding the complex carrier relaxation processes that can occur in semiconductor nanocrystals.

We studied the exciton formation dynamics within methylene blue (MB) sensitized CdSe nanorods (NRs). In the absence of MB, free charge-carriers are initially produced that then form excitons within the CdSe NRs within ~ 2 ps. In the presence of MB, photoexcited electrons reduce the MB within ~ 3 ps and the hole remains delocalized. In the subsequent 17 ps the hole becomes localized on the reduced MB as it is trapped by the Coulomb potential that arises from the reduced MB. Our results explain why dot-in-rod systems work better than NRs in photocatalytic systems and should allow for designing a better photocatalytic system based on CdSe NRs.

9549-49, Session 12

Tunable emission properties of Au nanoclusters

Woong Young So, Anindita Das, Hee Young Byun, Carnegie Mellon Univ. (United States); Santosh Kumar, Henkel Corp. (United States); Rongchao Jin, Linda A. Peteanu, Carnegie Mellon Univ. (United States)

Despite the significant interest in the fluorescence properties of gold nanoclusters, the emission mechanism remains unclear. This study reports

the fluorescence properties of two structural forms of Au25, a nano-sphere (Au25PET18) and a nano-rod ([Au25(PPh3)10(PET)5Cl2]2+) in several different solvent environments. For both materials, the strongest emission is observed for excitation at energies higher than the HOMO-LUMO gap of the material with the nano-rod form being significantly more emissive than the nano-sphere. Increasing the polarity of the solvent results in a substantial enhancement of the emission intensity of the nano-rod which is evident in both bulk studies and at the single-molecule level. This enhancement effect requires the presence of the solvent and does not persist in the solid state. In addition, the fluorescence maximum is strongly red shifted in more polar solvents which suggest that the emitting state has a highly dipolar character. Similar to what has been previously reported for CdSe quantum dots and silver nanoparticles[1,2], the emission intensity of the nano-rod in solution increased by up to 250% after illumination for several minutes at relatively low laser powers. Implications of these observations for the emission mechanism of gold nanoclusters will be discussed.

Electronic logic gates from three-segment nanowires featuring two P-N heterojunctions

Huibiao Liu, Yuliang Li, Chinese Academy of Sciences (China)

We have fabricated a novel heterojunction structure combining one inorganic and two organic semiconductors. The different segments exhibited distinct self–assembly behavior, allowing us to control the production of 1D three–segment nanowires featuring two diodes in series on two interfaces; the isolated organic/inorganic semiconductor wires displayed the novel properties of a two–input OR logic gate. We suspect that these devices might have applicability for fundamental research in the field of nanoscience and to applications in the field of nanotechnology, with great potential to produce new molecular electronic devices.

9549-51, Session 13

Photophysical versus structural properties in hybrid lead-halide perovskites *(Invited Paper)*

Annamaria Petrozza, Istituto Italiano di Tecnologia (Italy)

Hybrid perovskites represent a new, disruptive, technology in the field of optoelectronics. They have the potential to overcome the performance limits of current technologies and achieving low cost and high integrability. Hybrid halide perovskite, e.g. CH3NH3PbX3 [X = Cl, Br, or I], are usually deposited as polycrystalline thin-films with variable mesoscale morphology depending on the growth conditions. The obtained grain size ranges from tens to thousands of nm. Over the last two years the impressive improvement of photovoltaic performance has been driven by radical empirical evolution of the device architecture and processing methodologies. However, there is a considerable lack of understanding of material properties, both as pristine films and their embodiment in a device.

Here we demonstrate that the electron-hole interaction is sensitive to the microstructure of the material. We find that by control of the material processing during fabrication both free carrier and Wannier excitonic regimes are accessible, with strong implications for optoelectronic devices. The long-range order of the organic cation dipole field is disrupted by polycrystalline disorder introducing domain walls where dipole twinning breaks down. The variations in electrostatic potential found for smaller crystallites suppress exciton formation, while larger crystals of the same composition demonstrate an unambiguous excitonic state1,2. In addition, we demonstrate that it is also possible to design the emissive properties for a single material composition by designing the processing routs3. By simply tuning the average crystallite dimension in the film from tens of nanometers to a few micrometers, it is possible to tune the optical band gap of the material along with its photoluminescence lifetime. We demonstrate that larger crystallites present smaller bandgap and longer lifetime which correlates to a smaller rediative bimolecular recombination coefficient. We also show that they present a higher optical gain, becoming preferred candidates for the realization of lasing devices.

Effect of substrate surface free energy on the optoelectronic and morphological properties of organolead halide perovskite solar cell materials

R. Clayton Shallcross, James G. Stanfill, Neal R. Armstrong, The Univ. of Arizona (United States)

Here, we show how the surface free energy of the electron-collecting oxide contact has a very pronounced effect on the nucleation free energy of solution-processed organolead halide perovskite thin films, which influences the crystal size/orientation, band-edge energies, conductivity and, ultimately, the performance of solar cell devices. While a great deal of the research community's attention has been focused on the perovskite deposition methodology (e.g., starting precursors, annealing conditions, etc.), we demonstrate how the surface free energy of the oxide contact itself can be modified to control morphology and optoelectronic properties of the resulting hybrid perovskite thin films. The surface free energy of high-quality oxide contacts deposited by chemical vapor deposition (CVD) and atomic layer deposition (ALD) is modified by functionalization with a variety of self-assembled monolayers. We explore a number of deposition methodologies (e.g., a variety of single step and sequential step approaches) and their effect on the morphological and electronic properties of the resulting perovskite thin films deposited on these modified oxide contacts. Standard atomic force microscopy (AFM) and its conductive analog (cAFM) show how the oxide surface free energy ultimately affects the nanoscale morphology and charge transport characteristics of these semiconductor films. Photoelectron spectroscopy is used to elucidate the chemical composition (e.g., X-ray photoelectron spectroscopy ? XPS), band edge energies (e.g., ultraviolet photoelectron spectroscopy ? UPS), and the presence of gap states above the valence band (high sensitivity UPS measurements near the Fermi energy) of the hybrid perovskite materials as a function of the oxide surface free energy.

9549-53, Session 14

Optical processes in molecular junctions *(Invited Paper)*

Abraham Nitzan, Tel Aviv Univ. (Israel); Michael Galperin, Univ. of California, San Diego (United States); Maxim Sukharev, Arizona State Univ. (United States)

The interaction of light with molecular conduction junction is attracting growing interest as a challenging experimental and theoretical problem on one hand, and because of its potential application as a characterization and control tool on the other. From both its scientific aspect and technological potential it stands at the interface of two important fields: molecular electronics and molecular plasmonics. I shall review the present state of the art of this field and our work on optical response, Raman scattering, temperature measurements, light generation and photovoltaics in such systems.

9549-54, Session 14

Site models for including effects of torsions and disorder on charge and energy transport in organic semiconductors *(Invited Paper)*

David J. Yaron, Nicolae M. Albu, Christopher R. Collins, Christian M. Legaspi, Carnegie Mellon Univ. (United States)

In organic molecules with extensive pi conjugation, the motion of charge and energy is strongly influenced by disorder and motion in the torsional degrees of freedom. Site models provide a computationally efficient description and make it possible to carry out the ensemble and time averaging needed to gain insight into the phenomena. The development of site models from quantum chemical calculations on a large set of representative oligomers will be discussed. An important feature of conjugated polymers, that is well described by site models, is an increase in the torsional barrier in the vicinity of an exciton or charge. This leads, for instance, to rapid planarization of the excited state following photoexcitation. A Brownian dynamics model of this excited-state relaxation reveals universal behaviors that apply across a wide range of polymer systems. Among these universal features is the prediction of two timescales for the relaxation such that short-time and longer-time dynamics differ substantially. Similar to the planarization associated with photoexcitation, oxidation or reduction to form a charge on the polymer increases the torsional potential and so leads to self-trapping of the charge on a planarized region of the polymer. Our models suggest that the solution-phase charge mobility, as measured by microwave reflectivity, is established by the stochastic motion of this planarized, charged region along the polymer chain.

Size-dependent Hamaker constants for silver and gold nanoparticles

Pavlo Pinchuk, Ke Jiang, Univ. of Colorado at Colorado Springs (United States)

Hamaker-Lifshitz constants are material specific constants that are used to calculate van der Waals forces between colloidal particles. Typically, these constants do not depend on the size of the interacting particles in the colloids. According to the Lifshitz theory, the Hamaker-Lifshitz constants can be calculated by taking integrals that include dielectric permittivity of the interacting particles as a function of the frequency. The complex dielectric permittivity of the interacting metal nanoparticles can be calculated by using the Drude model that describes the response of free conducting electrons to the external excitations. Usually, the complex dielectric permittivity of bulk metals does not depend on the size of the interacting objects. However, metal nanoparticles with sizes smaller than the mean free path of the electrons in the bulk metals exhibit size-dependent dielectric complex permittivity. The size dependence of the complex dielectric permittivity is the result of the scattering of the free conduction electrons from the surface of the nanoparticles. This leads to the size dependence of the Hamaker-Lifshitz constants for metal nanoparticles. In this work we show theoretically that scattering of the free conducting electrons inside silver and gold nanoparticles with the size of 1 – 50 nm leads to their size-dependent Hamaker-Lifshitz constants. We calculate numerically the Hamaker-Lifshitz constants for silver nanoparticles with different diameters. The results of the study might be of interests for understanding colloidal stability of metal nanoparticles.

9549-56, Session 14

Effect of excess charge on metallic nanoclusters

Shideh Ahmadi, Nanyang Technological Univ. (Singapore); Xi Zhang, Shenzhen Univ. (China); Yinyan Gong, China Jiliang Univ. (China); Changqing Sun, Nanyang Technological Univ. (Singapore)

Charged Ag, Cu, Pt, and Rh nanostructures have attracted enormous research interest recently due to their unique properties comparison with their bulk counterparts. The effect of excess charge on metallic nanoclusters with Cuboctahedral and Marks decahedral structures has been studied using density functional theory (DFT) calculations, bond order-length-strength correlation (BOLS) [1] and nonbonding electron polarization (NEP) [2] theories. Our calculations are consistent, in trend, with experimental observations such as X-ray-absorption fine structure, scanning tunneling microscope/spectroscopy, X-ray photoelectron differential spectroscopy, photoelectron spectroscopy, and ultraviolet photoelectron spectra. The agreement confirmed the predications based on BOLS-NEP notation, suggesting that the bonds between under-coordinated atoms in the surface skin of nanostructures become shorter and stronger, inducing entrapment and polarization, which give rise to observed unique catalytic and magnetic behaviors.

9549-57, Session 14

Multiscale molecular modeling of tertiary supported lipid bilayers *(Invited Paper)*

Holden T. Ranz, Roland Faller, Univ. of California, Davis (United States)

Lipid bilayer structures supported on solid substrates are highly important experimental analogs for understanding cell membranes. We use and adapt different variations of the Martini model to study the differences in phase behavior between supported and free bilayers and to explain observed experimental discrepancies. The same phases are found in both cases but the phase boundaries are different both in temperature and concentration. We study the impact of the surface and the effect of the water layer between surface and membrane. We also find differences in the structure of the membranes. We particularly study for the first time computationally the effect of cholesterol in supported bilayers.

9549-58, Session PWed

Electronic and optical properties of novel carbazole-based donor-acceptor compounds for applications in blue-emitting organic light-emitting devices

Christian M. Legaspi, Regan E. Stubbs, Linda A. Peteanu, David J. Yaron, Carnegie Mellon Univ. (United States); Abraham Kemboi, Jesse Picker, Eric Fossum, Wright State Univ. (United States)

The optical and electronic properties of polythiophenes and other poly(heterocycles) have received extensive study due to their applications in photovoltaic devices and organic transistors. Several short oligometric thiophenes are highly emissive making them promising materials for organic lighting and displays. This study focuses on the effect of steric hindrance on the electronic spectroscopy of a series of bithiophenes with emphasis on identifying those structural properties that give rise to high emission yields. The simplest member of this series is 2,2'-bithiophene (2T), which computations have shown to have a highly twisted ground state.1-4 Substitution in the inner ring positions (3 and 3') with bromo (33'Br2T) and methyl (33'Me2T) substituents show distinctly different optical properties from 2T or 55'Br2T, a derivative brominated in the outer ring positions (5 and 5'). 33'Br2T and 33'Me2T exhibit very large Stokes shifts compared to 2T and 55'Br2T. Perhaps most interestingly, the excitation spectra of 33'Br2T

and 33'Me2T do not overlap their respective absorption spectra except in a low-absorbing red tail not present in 2T or 55'Br2T. Excitation in the red tail shows a greater than ten-fold increase in the quantum yield as compared to excitation at the absorption maxima. This study explores this unusual behavior by use of ultrafast spectroscopy to probe excited state dynamics and theoretical calculations of the torsional energy surfaces and excited-state structure. We theorize the mechanism is related to the presence of small populations of highly-emissive conformers and that torsion about inter-ring angle greatly influences the electronic properties of these thiophene oligomers.

9549-59, Session PWed

Growth of axial nested P-N heterojunction nanowires for high performance diode

Huibiao Liu, Chinese Academy of Sciences (China)

Heterojunction nanomaterials have attracted the interests of a broad range of scientists and engineers to explore fundamental scientific understanding the formation of heterojunction nanostructure, special properties with enhanced electrical and optical performance and the relationship between functionality and molecule structures. In this work, we synthesized a novel axial nested P-N heterojunction nanowire combined inorganic semiconductor PbS and organic conjugated polymers polypyrrole (PPy). The nested P-N heterojunction nanowires (NWs) show higher rectification ratio (exceeded 100), long-term stability and high unilateral conductivity due to the producing bigger area of junction.

9550-1, Session 1

Semiconductor quantum dots as delivery and imaging platforms for intracellular assembly

Lauren D. Field, James B. Delehanty, Igor L. Medintz, U.S. Naval Research Lab. (United States)

The efficient and specific intracellular delivery of nanoparticle-based drug formulations is a critical area of research which can allow for further understanding of cellular processes and increased efficacy of therapeutic treatments. The visualization of these delivery mechanisms is often achieved using florescent molecules, some of which are bulky and can interfere with the processes being studied. Alternatively, semiconductor nanocrystals or quantum dots (QDs) are nanoscale particles that provide a scaffold for both drugs and targeting moieties while providing superior optical properties that include size-tunable photoluminescence and resistance to photobleaching. Utilizing this nanoparticle platform, delivery methods and intracellular assembly can be studied. Potential delivery mechanisms include either specific delivery using targeting ligands or direct cytosolic administration through microinjection or electroporation. Once within the cytosol, the QDs can assemble to targeted proteins, a process that can be visualized through the use of Förster resonance energy transfer (FRET). Here, we characterize the effectiveness of various delivery methods and the role of QD surface chemistry in mediating intracellular QD delivery and assembly to targeted proteins.

9550-2, Session 1

Using a narrow linewidth spectral filter for calibration of the spectrometer in spectral domain optical coherence tomography

Tong Wu, Nanjing Univ. of Aeronautics and Astronautics (China)

Calibration of the pixel-wavelength relationship is necessary for a custom-built spectrometer in a spectral domain optical coherence tomography (SDOCT) system. A calibration method based on a narrow linewidth spectral filter (NLSF) is proposed and presented in this paper. Through detecting the narrow linewidth spectral light generated by the NLSF with the spectrometer and a commercial optical spectrum analyzer (OSA) simultaneously, the absolute wavelength corresponding to each pixel can be measured accurately. The wavelength filtering performance and the spectral resolution of the NLSF is theoretically modeled, and the generated narrow linewidth spectral signal can be covering the whole bandwidth of the light source with a measured linewidth of 0.2 nm. The proposed method may be applied to the general calibration process for the various type of spectrometer.

9550-3, Session 1

Biodegradable bisphosphonate nanoparticles for imaging and therapeutic applications in osteosarcoma

Safra Rudnick-Glick, Enav Corem-Salkmon, Igor Grinberg, Eran Gluz, Shlomo Margel, Bar-Ilan Univ. (Israel)

Osteosarcoma (OS) is amongst the most commonly diagnosed bone tumors occurring in adolescence, young adults and adults over the age of 65. Current treatment is based on a combination of surgery and chemotherapy. Chemotherapy has improved the survival rate, however it is associated with severe side effects due to the use of high dosages, nonspecific uptake and poor bone blood supply. At present bisphosphonates (BP) are widely used in the treatment of bone disorders including OS. We have engineered a unique biodegradable BP nanoparticle that possesses a dual functionality: 1) covalent attachment of a dye (e.g., NIR dye) or drug to the nanoparticles through the primary amine groups on the surface of the nanoparticle; 2) chelation to the bone mineral hydroxyapatite through the BP on the surface of the nanoparticle. Due to a high concentration of PEG in the BP nanoparticles they possess a relatively long plasma half-life time. Therefore, the nanoparticle has potential for use both in diagnosis and therapy of OS. Doxorubicin was conjugated to the free amine on the surface of the BP nanoparticles, in vitro experiments on osteosarcoma cells demonstrated that the doxorubicin-conjugated BP nanoparticles possess a higher efficacy than the free doxorubicin. Further investigation in vivo confirmed that both in chicken embryo and mouse models the doxorubicin-conjugated nanoparticle was significantly more effective in inhibiting tumor growth compared to free doxorubicin at a similar concentration. Additionally, we have shown that these BP nanoparticles preferentially target OS tumor tissue, thus increasing anti-cancer drug bioavailability at targeted site.

9550-4, Session 1

Enhanced in-vivo optical coherence tomography of live mouse brain by the use of implanted micro-lens *(Invited Paper)*

Iman Hassani Nia, Daniel Dombeck, Hooman Mohseni, Northwestern Univ. (United States)

Near-infrared optical coherence tomography (OCT) has gained a lot of attention due to the fact that it is relatively cheap, non-invasive and provides high resolution and fast method of imaging. However the main challenge of this technique is the poor signal to noise ratio of the images of the tissue at large depths due to optical scattering. The signal to noise ratio can be improved by increasing the source power, however the laser safety standards (ANSI Z136.1) restricts the maximum amount of power that can be used safely to characterize the biological tissue. In this talk, we discuss the advantage of implanting a micro-lens inside the tissue to have a higher signal to noise ratio for confocal and OCT measurements. We explain the theoretical background, experimental setup and the method of implanting the micro lens at arbitrary depths within a live mouse brain. The in-vivo 3D OCT and two-photon microscopy images of live mouse with implanted micro-lens are presented and significant enhancement of signal to noise ratio is observed. The confocal and OCT measurements have been performed with super-luminescent LEDs emitting at 1300 nm. We believe that the high resolution and high sensitivity of this technique is of fundamental importance for characterization of neural activity, monitoring the hemodynamic responses, tumors and for performing image guided surgeries.

9550-5, Session 1

Probing cellular forces with an elastic optical micro-cavity

Nils M. Kronenberg, Philipp Liehm, Anja Steude, Malte C. Gather, Univ. of St. Andrews (United Kingdom)

Mechanical forces at the cellular level are increasingly recognized as an important factor in numerous biological processes. Here, we present a completely new approach to measure cellular forces which overcomes limitations of existing methods such as traction force microscopy (TFM). The centerpiece of our innovation is a novel optical micro-cavity sensor that enables fast force mapping across a large field of view by analyzing changes in resonance wavelength. Our approach avoids phototoxic effects and therefore allows the measurement of cellular forces at high frame rates over hours or days. Being based on wide-field imaging, the method measures

deformation at each point of the image simultaneously and with diffraction limited lateral resolution. Vertical displacements are detected with accuracy far beyond conventional confocal microscopy (5 nm or better). Force maps can be recorded without the need for zero-force images, increasing throughput, eliminating the need to detach non-migrating cells after force mapping and allowing measurements of multiple cells on one substrate. Additionally, the optics needed for the readout of the new biosensor can be readily integrated with a conventional inverted microscope. In this presentation, we will discuss the fabrication of our micro-cavity sensors and provide detailed investigations of force and spatial resolution of the device by means of AFM indentation analysis. Cell mechanical measurements of different cell lines will be presented and links between recorded force patterns and subcellular structures labelled by fluorescence staining will be discussed.

9550-6, Session 1

Beta-cyclodextrin functionalized gold nanoparticles for trace cancer biomarker quantification

Jian Wu, Fraser Hof, Reuven Gordon, Univ. of Victoria (Canada)

We demonstrate the application of beta-cyclodextrin (?-CD) functionalized gold nanoparticles (AuNPs) as a platform for surface enhanced Raman scattering (SERS) quantification of the exogenous cancer biomarker Acetyl Amantadine (AcAm). We utilize the ?-CD encapsulation to capture the hydrophobic AcAm from solution, followed by drying and detection using SERS. We achieve a detection limit of 0.6 ng/mL using this platform. Compared with our previous ?-CD functionalized Klarite [1] and polystyrene functionalized gold nanorods [2], this platform shows better sensitivity and lower cost, which is promising for clinical adoption for early cancer detection.

9550-7, Session 1

A three-camera imaging microscope for high-speed single-molecule tracking and super-resolution imaging in living cells *(Invited Paper)*

Brian P. English, Timothée Lionnet, Robert H. Singer, Howard Hughes Medical Institute (United States)

Most cellular processes are the result of multiple factors coming together at precise subcellular locations to form complexes. Our aim is to develop quantitative single-molecule assays to study when and where molecules are interacting inside living cells and where enzymes are active. To this end we present a three-camera imaging microscope for fast tracking of multiple interacting molecules simultaneously, with high spatiotemporal resolution. The system was designed around an ASI RAMM frame using three separate tube lenses and custom multi-band dichroics to allow for enhanced detection efficiency. The frame times of the three Andor iXon Ultra EMCCD cameras were hardware synchronized to the laser excitation pulses of the three excitation lasers, such that the fluorophores are effectively immobile during imaging and do not yield blurred-out views of the diffraction-limited spots. Stroboscopic illumination allows robust detection from even rapidly moving objects, and since snapshots can be spaced out with varying time intervals, stroboscopic illumination enables a direct comparison to be made between fast and slow molecules under identical light dosage. We developed algorithms that accurately track and co-localize multiple interacting biomolecules. The three-color microscope combined with our co-movement algorithms have made it possible to simultaneously image and track when mRNA may be translated by ribosomes, how the chromosome environment affects diffusion kinetics as well as other systems. Such multiplexed single-molecule measurements at a high spatiotemporal resolution inside living cells will provide a major tool for testing models relating molecular architecture and biological dynamics.

9550-8, Session 1

Nanostructured silicon biosensors *(Invited Paper)*

Sharon M. Weiss, Vanderbilt Univ. (United States)

Optical biosensors based on nanostructured silicon hold great promise as low-cost, lab-on-chip sensor array elements due to their compatibility with both standard microelectronics processing and standard surface functionalization techniques. The sensitivity of these optical biosensors is fundamentally derived from the level of interaction between light and the target molecules to be detected. This light-matter interaction can be strengthened by either designing the sensor structure in such a way as to promote strongly confined fields in selected regions where molecules can attach or by increasing the number of target molecules that are captured in regions where light is localized. The former approach can be achieved through modifications to the nanostructured silicon photonic sensor geometry while the latter approach is achieved through modifications to the surface chemistry of the sensor. This talk will discuss both approaches to increasing light-matter interaction, and hence sensitivity, of nanostructured silicon photonic biosensors. In particular, several biosensor designs, including photonic crystals with multiple defect holes, suspended ring resonators, and Bloch surface wave structures will be described in the silicon-on-insulator and porous silicon materials systems. A method of in-situ bioreceptor synthesis will also be discussed as a means of increasing bioreceptor density. Several illustrative examples of specific molecular detection using nanostructured silicon optical biosensors will be presented.

9550-9, Session 2

Detection of cancerous biological tissue areas by means of infrared absorption and SERS spectroscopy of intercellular fluid

Martynas Velicka, Vidita Urboniene, Justinas Ceponkus, Milda Pucetaite, Feliksas Jankevicius M.D., Valdas Sablinskas, Vilnius Univ. (Lithuania)

Precise identification of cancerous biological tissue areas during the surgical segmental resection has high importance since information about location of borders between normal and cancerous tissues is needed. Most of the identification methods used nowadays are based on histopathology, which is time consuming procedure and cannot be performed directly in the operating room during the surgery.

We present a novel approach for the detection of cancerous kidney tissue areas by measuring surface-enhanced Raman (SERS) spectrum of its intercellular fluid taken from the tissue. Thickness of the dried film of the fluid on optical substrate is in nanometric scale and conventional Raman spectroscopy cannot be used unless some enhancement of the Raman signal is applied. Determination of cancerous and normal kidney tissue areas was performed by using differences in the SERS spectra of the fluid taken from the corresponding tissue areas.

The samples were prepared by sliding the kidney tissue over the calcium fluoride optical substrate and covering the dried fluid film by silver nanoparticle colloidal solution. In order to suppress fluorescence background the measurements were performed in NIR region with the excitation wavelength of 1064 nm and 785 nm. The most significant spectral differences were found in the region between 400-1300 cm-1, where spectral bands related to various vibrations of fatty acids, glycolipids and carbohydrates are located. We found for the first time that SERS spectra of

intercellular fluid can be used for detection of cancerous areas of biological tissue and the method has potential to be used directly during the surgery.

9550-10, Session 2

Colloidal assembly of surface enhanced Raman scattering sensors for monitoring airway infections *(Invited Paper)*

Regina Ragan, Nicholas Sharac, Univ. of California, Irvine (United States); Salvatore Campione, Sandia National Labs. (United States); Katrine Whiteson, Filippo Capolino, Univ. of California, Irvine (United States)

Since doctors first used flies to detect glucose in the urine of diabetic patients, the biomarkers primarily used in medical diagnostics and disease monitoring have been small molecule metabolites. Current tools such as clinical culturing take days to obtain results, leaving physicians to choose antibiotic treatment based on trial and error. Pilot breath and sputum metabolite profile studies using Gas chromatography-Mass spectroscopy (GC-MS) paired with microbial DNA sequencing, establishing that fermentation products such as 2,3-butanedione are present in the ppb range in cystic fibrosis patients. Though single molecule detection limits have been demonstrated using nanostructured surfaces previously, issues of cost, shelf life, reproducibility in detection response, and integration have limited technological impact. We have created and developed a low-cost colloidal assembly process using covalent nanoparticle-substrate interactions to produce arrays of ad hoc clusters of nanoparticles. Full-wave simulations show the dependence of electric field enhancements on geometric arrangement of and gap spacing between nanoparticles in clusters. Transmission electron microscopy data shows that by varying driving forces for assembly, diffusion versus electrophoresis, nanoparticle clusters with gaps between nanoparticles of 4 nm down to 1 nm, respectively, are obtained. SERS characterization measurements demonstrate robust SERS sensors reaching ppb detection limits for small volatile molecules reproducibly over large areas. Samples have a tested shelf life of two years indicating that materials, chosen for integration in micro-optofluidic chips, do not degrade over time. Our platform aims to achieve the elusive goal of providing easy to use technology alongside ppb detection for patient diagnosis and treatment.

9550-11, Session 2

Detection of p17-1 peptide (HIV) based in surface enhanced Raman scattering (SERS)

Leandro de B. Carneiro, Chemistry Institute (Brazil) and Univ. of Victoria (Canada); Alexandre Brolo, Univ. of Victoria (Canada); Sidney Ribeiro, Univ. Estadual Paulista “Júlio de Mesquita Filho” (Brazil)

SERS offers great promises for simplified and sensitive detection of biomolecular interactions that are relevant for early disease diagnostics.

Human immunodeficiency virus (HIV) has been a problem for decades. There are several methods of diagnostics based on antibodies specific reactions, such as Western blotting and enzyme-linked immunosorbent assays (ELISAs). However, new strategies have been developed for rapid HIV diagnostics and, as a proof-of-concept, peptide p17-1 was considered here.

The matrix protein p17 is a structural protein that is essential in the life cycle of the retrovirus . The early stages of the virus replication involve the pre integration of the DNA complex into the nucleus. P17 plays a role in RNA viral binding and transport to the membrane

The fabrication and characterization of a new SERS platform for HIV detection based on peptide p17-1 is described. Self-Assembled monolayers (SAM) were obtained by immersion of the gold surface into ethanolic solution of 11-Mercaptoundecanoic acid (MUA). To activate the COOH functional group at the gold surface EDC/NHS (1-ethyl-3-(-3-dimethylaminopropyl) carbodiimid/ N-hydroxysuccinimide) was used. The prepared substrates were immersed in a solution containing of the anti-p17 (100μg/ml). Gold substrates were immobilization with the peptide p17-1 (0.1μM sequence LSGGELDRWEKIRLPGG). SERS probes were prepared with gold nanoparticles and are coated with a Raman reporter molecule (Nile Blue A) and, functionalized with an anti-p17. These structures (SERS probe and Au substrate) allow for a sandwich assay, a strategy regularly used for high-sensitivity detection . Spectral variations were analysed through a statistical approach and also considering false positive possibility. Statistical distribution shows high intensity for surface exposed to solution containing the peptide p17-1 when compared with negative controls. The suggest approach to detect peptide p17 is promising and could be further tested using real blood.

Using Raman spectroscopy and SERS for in-situ studies of rhizosphere bacteria

Sneha Polisetti, Nameera Baig, Univ. of Notre Dame (United States); Amber Bible, Jennifer Morrell-Falvey, Mitchel Doktycz, Oak Ridge National Lab. (United States); Paul W. Bohn, Univ. of Notre Dame (United States)

Bacteria colonize plant roots to form a symbiotic relationship with the plant and can play an important role in promoting plant growth. Raman spectroscopy is a useful technique to study these bacterial systems and the chemical signals they utilize to interact with the plant. We present a Raman study of Pantoea sp. YR343 that was isolated from the rhizosphere of Populus deltoides (Eastern Cottonwood). Pantoea sp. YR343 produces yellowish carotenoid pigments that play a role in protection against UV radiation, in the anti-oxidative pathways and in membrane fluidity. Raman spectroscopy is used to non-invasively characterize the membrane bound carotenoids. The spectra collected from a mutant strain created by knocking out the crtB gene that encodes a phytoene synthase responsible for early stage of carotenoid biosynthesis, lack the carotenoid peaks. Surface Enhanced Raman Spectroscopy is being employed to detect the plant phytoharmone indoleacetic acid that is synthesized by the bacteria. This work describes how Raman spectroscopy is utilized as a label free, non-destructive method of studying plant-bacteria interactions in the rhizosphere.

9550-13, Session 3

Advances in macromolecular data storage *(Keynote Presentation)*

Masud Mansuripur, College of Optical Sciences, The Univ. of Arizona (United States)

Many of the traditional problems in disk and tape data storage can be overcome if data-blocks were to be released from the confines of a disk (or tape) and allowed to float freely between read/write stations (i.e., heads) and permanent “parking spots.” The heads and parking spots thus become fixed structures within an integrated chip, while the macromolecular data blocks themselves become the (mobile) storage media. In this scheme, a large number of read/write heads could operate in parallel, the heads and parking spots would be constructed (layer upon layer) in a truly 3-dimensional fashion, and individual nanometer sized molecules—strung together in a flexible macromolecular chain—would be used to represent the zeros (0s) and ones (1s) of binary information. We discuss the potential advantages of this alternative scheme for secondary data storage and, to demonstrate the feasibility of the concept, present results of experiments

based on DNA molecules that travel within micro-fluidic chambers. Since our first proposals to develop macromolecular data storage systems, other groups have contributed to developments in DNA-based techniques for information storage and processing. In this presentation we will discuss the latest developments reported by other groups as well.

9550-14, Session 3

Mid-Infrared (~2.8 μm to ~7.1 μm) interband cascade lasers *(Keynote Presentation)*

Sven Höfling, Univ. of St. Andrews (United Kingdom); Robert Weih, Matthias Dallner, Julius-Maximilians-Univ. Würzburg (Germany); Julian Scheuermann, Lars Nähle, Marc Fischer, Johannes Koeth, nanoplus GmbH (Germany); Martin Kamp, Julius-Maximilians-Univ. Würzburg (Germany)

20 years after their first reference [1] interband cascade lasers (ICLs) have become a mature and competitive semiconductor laser source in the mid-infrared region. The carrier rebalancing concept that was introduced in 2011 [2] drastically improved the performance. As a consequence the wavelength window that is accessible for ICLs operating at ambient temperatures could be extended. For GaSb based ICLs cw-emission at room temperature could be achieved up to a wavelength of 5.6 μm [3]. As the need for thicker claddings at longer wavelengths makes the growth of the superlattice claddings increasingly difficult and limits the heat dissipation, a plasmon waveguide structure with highly doped InAs-layers grown on InAs-substrates is typically used for ICLs emitting up to ~7 μm in pulsed mode at room temperature [4]. With regard to the short wavelength limit of ICLs, we present cw emission of a GaSb based ICL emitting at 2.8 μm and with regard to the long wavelength limit we present room temperature pulsed operation of an InAs based plasmonic waveguide ICL up to 7.1 μm. Furthermore, we show single mode emitting ICLs with distributed feedback gratings emitting between 2.8 and 5.2 μm.

Towards novel compact laser sources for non-invasive diagnostics and treatment *(Keynote Presentation)*

Edik U. Rafailov, Aston Univ. (United Kingdom)

In the past decades, progress in compact semiconductor based laser technologies has brought to science and industry an enormous number of new applications. Such laser systems which were mostly utilised in the communication and other industries are now becoming adopted in biology and medicine. In this talk we would like to discuss and review some of the most promising biomedical applications where novel compact lasers are being used. Particularly we are focussing on the development of compact non-invasive diagnostics system for monitoring main body parameters in parallel, like blood perfusion, blood and tissue oxygen saturation based on Doppler Flowmetry, tissue oximetry and fluorescent spectroscopy techniques.

9550-16, Session 4

Switchable bioelectronics on graphene interface *(Invited Paper)*

Onur Parlak, Linköping Univ. (Sweden); Ashutosh Tiwari, Linköping Univ (Sweden); Anthony P. F. Turner, Linköping Univ. (Sweden)

Smart and flexible bioelectronics on graphene have emerged as a new frontier in the field of biosensors and bioelectronics. Graphene has begun to be seen as an ideal signal transducer and a promising alternative for the production of low-cost bioelectronic devices.1-2 However, biological systems used in these devices suffer from a lack of control and regulation. There is an obvious need to develop “switchable” and “smart” interfaces for both fundamental and applied studies. Here, we report the fabrication of a stimuli-responsive graphene interface, which is used to regulate biomolecular reactions.

The present study aims to address the design and development of a novel auto-switchable graphene bio-interface that is capable of positively responding, by creating smart nanoarchitectures. By changing the external conditions such as temperature, light and pH of the medium, we acheived control of the biochemical interactions. In the negative mode, access of an associated enzyme to its substrate is largely restricted, resulting in a decrease in the diffusion of reactants and the consequent activity of the system. In contrast, the biosubstrate could freely access the enzyme facilitating bioelectrocatalysis in a positive response.

Using electrochemical techniques, we demonstrated that interfacial bio-electrochemical properties can be tuned by modest changes in conditions. Such an ability to independently regulate the behaviour of the interface has important implications for the design of novel bioreactors, biofuel cells and biosensors with inbuilt self-control features.

9550-17, Session 4

Evaluating cells and protocells as therapeutic vehicles *(Invited Paper)*

Natalie Adolphi, The Univ. of New Mexico (United States); Jaclyn Murton, Sandia National Labs. (United States); Helen Hathaway, The Univ. of New Mexico (United States); Yu-Shen Lin, Jason Townson, Oncothyreon (United States); Jeff Norenberg, The Univ. of New Mexico (United States); Eric Carnes, Carlee Ashley, Jeff Brinker, Sandia National Labs. (United States)

Mesoporous silica nanoparticle-supported lipid bilayers (protocells) can be loaded with a variety of drugs and/or imaging probes and modified using various surface chemistries. To enhance delivery of protocells to solid tumors, we investigated a novel delivery method, in which circulating mononuclear cells (MCs), which naturally infiltrate tumors, are used to actively deliver protocells to tumor tissue. MCs were extracted by density gradient separation from the spleens of immune-competent polyomavirus middle T (PyMT) transgenic mice, which spontaneously develop epithelial mammary tumors that mimic human breast cancer. MCs were loaded with DOPC (1,2-dioleoyl-sn-glycero-3-phosphocholine)-coated poly-disperse protocells (diameter <200 nm), further modified with PEG (polyethylene glycol), DOPS (1,2-dioleoyl-sn-glycero-3-phosphoserine), or DOTAP (1,2-dioleoyl-3-trimethylammonium-propane) and injected into tumor-bearing PyMT-FVB mice or FVB mice lacking the transgene, which have normal mammary glands. We observed the biodistribution of protocell-loaded MCs and directly-injected protocells in vivo by SPECT-CT imaging, and post-mortem via fluorescence microscopy and flow cytometry, demonstrating that MC-mediated delivery enhances localization of protocells to mammary tumors compared to direct injection. Further, both direct injection and MC-mediated delivery resulted in higher protocell concentrations in mammary tumors, relative to normal mammary tissue. In normal mice, we also demonstrated that fully-differentiated macrophages can be used to direct protocells to the lung. Additionally, we performed in vivo SPECT-CT to quantify the biodistribution of monosized mesoporous

silica particles as a function of diameter (25, 50, 90, 150 nm) in normal rats, demonstrating that smaller particle size correlates with increased circulation time and decreased uptake by the liver and spleen.

Effect of PKC? expression to cell death after photoactivation of Hypericin delivered to cell through different drug delivery systems

Matú? Mi?uth, Jaroslava Joniova, Pavol Jozef ?afárik Univ. in Kol?ice (Slovakia); Pavol Mi?kovsk?, Zuzana Nadova, Pavol Jozef ?afárik Univ. in Kol?ice (Slovakia) and Ctr. for Interdisciplinary Sciences (Slovakia)

Low-density lipoprotein (LDL), a natural in vivo carrier of cholesterol in the vascular system, plays a key role in the delivery of hydrophobic photosensitizer (pts) to tumor cells in PDT, including hypericin (Hyp), a potent natural pts. Hyp under light illumination causes antiproliferative and cytotoxic effects (necrosis as well as apoptosis) in many tumor cell lines.

These properties together with minimal dark toxicity, tumor selectivity and high clearance rate from the host body, make Hyp a promising agent for PDT of cancer as well as for tumor photo-diagnosis.

In the present study we aim to investigate the consequences on cell survival and cell death induced by photo-activated Hyp delivered to the cells through different drug delivery systems including LDL.

Hyp incorporation and redistribution, cell survival and type of the cell death were assessed by confocal fluorescence imaging and flow cytometry.

We have evaluated the influence of photo-activated Hyp delivered to the cells thhrough different drug delivery systems on cell death in non-transfected and transfected (PKCa-) human glioma cells (U-87 MG).

No significant differences were detected in cell survival between nontransfected and transfected PKCa- cells when Hyp was delivered without any carrier. However, the type of cell death was notably affected by silencing the pkca gene. Photo-activation of Hyp strongly induced apoptosis in non-transfected cells, but the level of necrotic cells in transfected PKCa- cells increased significantly. We suggest that PKCa, as Bcl-2 kinase, indirectly protects U-87 MG cells against oxidative stress and subsequent cell death.

9550-19, Session 4

Enhanced kinetics of quantum dot bound enzymatic nanosensors

Joyce Breger, Scott Walper, Mario G. Ancona, Michael Stewart, Kimihiro Susumu, Sebastian A. Diaz, Igor L. Medintz, U.S. Naval Research Lab. (United States)

Nanosensors employing quantum dots (QDs) and functional moieties such as enzymes offer tremendous promise for disease surveillance/diagnostics and chemical/biological threat activity. Advantages of QDs over other nanoscaffolds include their small size and inherent photochemical properties such as size tunable fluorescence, ease in attaching functional moieties, and resistance to photobleaching. Making QDs well-suited for rapid, optical measurement applications.

The mechanisms for increased catalytic activity of enzymes attached to nanoparticles was investigated by attaching various ratios of phosphotriesterase (PTE) enzymes to two distinctly sized QDs, with emission maxima centered at 525 or 625 nm. PTE catalyzes the detoxification of organophosphate pesticides to p-nitrophenol. To confirm assembly and characterize QD-PTE bioconjugates dynamic light scattering and gel electrophoresis were employed.

PTE activity was assayed using paraoxon, an analog of sarin, as a substrate. The conversion of paraoxon to p-nitrophenol was monitored over time by measuring the absorbance. Absorbance values were converted to concentration by employing a p-nitrophenol standard curve. Enzymatic activity and characteristic parameters were determined by fitting the initial rates of the progress curves to a Michaelis-Menten single substrate model.

We attempt to elucidate the mechanisms for enhanced catalytic activity when attached to nanoparticle surfaces as compared to free enzyme in solution. PTE hydrolytic activity was studied when attached to two differently sized QDs and significant enhancement in activity was observed when attached to QDs as compared to free enzyme with more dramatic increases when PTE was attached at lower ratios to the smaller sized QDs.

9550-20, Session 4

Nanoplasmonic lenses for bacteria sorting *(Invited Paper)*

Xiangchao Zhu, Ahmet A. Yanik, Univ. of California, Santa Cruz (United States)

We demonstrate that patches of two dimensional arrays of circular plasmonic nanoholes patterned on gold-titanium thin film enables subwavelength focusing of visible light in far field region. Efficient coupling of the light with the excited surface plasmon at metal dielectric interface results in strong light transmission. As a result, surface plasmon plays an important role in the far field focusing behavior of the nanohole-aperture patches device. Furthermore, the focal length of the focused beam was found to be predominantly dependent on the overall size of the patch, which is in good agreement with that calculated by Rayleigh-Sommerfield integral formula. The focused light beam can be utilized to separate bio-particles in the dynamic range from 0.1 ?m to 1 ?m through mainly overcoming the drag force induced by fluid flow. In our proposed model, focused light generated by our plasmonic lenses will push the larger bio-particles in size back to the source of fluid flow and allow the smaller particles to move towards the central aperture of the patch. Such a new kind of plasmonic lenses open up possibility of sorting bacterium-like particles with plasmonic nanolenses, and also represent a promising tool in the field of virology.

9550-21, Session 4

Nano scaffolds and stem cell therapy in liver tissue engineering

Laila M. Montaser, Menoufia Univ. (Egypt)

Tissue engineering and regenerative medicine have been constantly developing of late due to the major progress in cell and organ transplantation, as well as advances in materials science and engineering. Although stem cells hold great potential for the treatment of many injuries and degenerative diseases, several obstacles must be overcome before their therapeutic application can be realized. These include the development of advanced techniques to understand and control functions of micro environmental signals and novel methods to track and guide transplanted stem cells. A major complication encountered with stem cell therapies has been the failure of injected cells to engraft to target tissues. The application of nanotechnology to stem cell biology would be able to address those challenges. Combinations of stem cell therapy and nanotechnology in tissue engineering and regenerative medicine have achieved significant advances. These combinations allow nanotechnology to engineer scaffolds with various features to control stem cell fate decisions. Fabrication of Nano fiber cell scaffolds onto which stem cells can adhere and spread, forming a niche-like microenvironment which can guide stem cells to proceed to heal damaged tissues. In this paper, current and emergent approach based on human stem cells in the field of liver tissue engineering is presented for specific application in an animal model. The combination of stem cells and tissue engineering opens new perspectives in tissue regeneration for stem cell therapy because of the potential to control stem cell behavior with the physical and chemical characteristics of the engineered scaffold environment.

9550-22, Session 4

A creatinine biosensor based on admittance measurement

Congo Tak-Shing Ching, Tai-Ping Sun, Deng-Yun Jheng, Hou-Wei Tsai, Hsiu-Li Shieh, National Chi Nan Univ. (Taiwan)

Kidney disease is reportedly increasing in developed countries, including the US, Canada, Australia, and Europe. It imposes a substantial economic burden. Measurement of blood creatinine level is clinically important for the evaluation of renal dysfunction. Clinically, the normal physiological blood creatinine level is between 44 uM and 106 uM. Regular check of blood creatinine level can reduce the incidence rate for the people who are at the high risk of renal dysfunction. Biosensor provides point-of-care testing so as to achieve regular check of blood creatinine level at home. No paper has been found in the literatures on developing creatinine biosensor based on admittance measurement. Therefore, this study aims to develop a simple and reliable creatinine biosensor based on admittance measurement.

The creatinine biosensor was fabricated with the enzyme “creatinine deiminase” immobilized on screen-printed graphite electrodes by simple drop coating method.

Admittance measurement at specific frequency ranges (22.80 – 84.71 Hz) showed biosensor having an excellent linear (r2 > 0.95) response range (50 – 250 uM), with the maximum sensitivity of -3x10-6 Siemens/uM. Intraclass correlation coefficient (ICC) showed that the biosensor has excellent reliability and validity (ICC = 0.98). And the biosensor was reliable enough to determine the concentrations of creatinine (50 – 250 uM) with the coefficient of variation of about 5.5%.

In conclusion, a simple and reliable creatinine biosensor was developed and it is capable of precisely determining blood creatinine levels in both the normal physiological and pathological ranges.

9550-23, Session 4

Quantitative fluorescence nanoscopy for cancer biomedicine

Li-Jung Lin, Oregon Health & Science Univ. (United States); Tao Huang, Oregon Health and Science Univ (United States); Alec Peters, Xiaolin Nan, Oregon Health & Science Univ. (United States)

Cancer is a major health threat worldwide. Options for targeted cancer therapy, however, are often limited, in a large part due to our incomplete understanding of how key processes including oncogenesis and drug response are mediated at the molecular level. New imaging techniques for visualizing biomolecules and their interactions at the nanometer and single molecule scales, collectively named fluorescence nanoscopy, hold the promise to transform biomedical research by providing direct mechanistic insight into cellular processes. We discuss the principles of quantitative single-molecule localization microscopy (SMLM), a subset of fluorescence nanoscopy, and their applications to cancer biomedicine. In particular, we will examine oncogenesis and drug resistance mediated by mutant Ras, which is associated with ~1/3 of all human cancers but has remained an intractable drug target. At ~20 nm spatial and single-molecule stoichiometric resolutions, SMLM clearly showed that mutant Ras must form dimers to activate its effector pathways and drive oncogenesis. SMLM further showed that the Raf kinase, one of the most important effectors of Ras, also forms dimers upon activation by Ras. Moreover, treatment of cells expressing wild type Raf with Raf inhibitors induces Raf dimer formation in a manner dependent on Ras dimerization. Together, these data suggest that Ras dimers mediate oncogenesis and drug resistance in tumors with hyperactive Ras and can potentially be targeted for cancer therapy. We also discuss recent advances in SMLM that enable simultaneous imaging of multiple biomolecules and their interactions at the nanoscale. Our work demonstrates the power of quantitative SMLM in cancer biomedicine.

9550-24, Session 5

Resonant waveguide grating imagers for single cell analysis and high throughput screening *(Invited Paper)*

Ye Fang, Corning Incorporated (United States)

Resonant waveguide grating (RWG) biosensor systems use a microtiter plate array of diffractive nanograting waveguide structures to establish evanescent waves under illumination for measuring tiny changes in local refractive index arising from the dynamic mass redistribution (DMR) of living cells upon stimulation. Whole-plate RWG imager enables high-throughput profiling and screening of drugs in the context of distinct cellular phenotypes including cell adhesion, proliferation, signaling, and infection. RWG imager under microfluidics not only manifests distinct receptor signaling waves, but also differentiates long-acting agonism and antagonism. Spatially resolved RWG imager allows for single cell analysis including cell-to-cell variability of receptor signaling and the invasion of cancer cells in a spheroidal structure through 3-dimensional extracellular matrix. High frequency RWG imager permits real-time detection of drug-induced cardiotoxicity. The wide coverage in target, pathway, assay, and cell phenotype has made RWG biosensor systems widely accepted in both basic research and early drug discovery processes.

9550-25, Session 5

Motion behaviour of mammalian AT-SC under evanescent field illumination

Mukhzeer Mohamad Shahimin, Univ. Malaysia Perlis (Malaysia); Fhataheya Buang, Univ. Kebangsaan Malaysia (Malaysia); Nor Azura Malini B. Ahmad Hambali, Vithyacharan Retnasamy, Mohamad Halim Abdul Wahid, Univ. Malaysia Perlis (Malaysia); Ali Hussain Reshak, Univ. of West Bohemia (Czech Republic)

The motion behaviour of mammalian adipose tissue derived stem cells (AT-SC) on an integrated channel waveguide under the evanescent field illumination is demonstrated and analysed. An approximately 20μm diameter pseudospherical cells in aqueous medium are deposited in a reservoir over a copper ion-exchanged channel waveguide. Light from a tuneable laser operating at ~1064nm was coupled into the waveguide, causing the cells under the illumination of evanescent field and moved in a skewed stochastic motion in accordance to the laser power. The trajectory angle of the motion of the cells towards the illuminated channel waveguide was investigated and analysed to distinguish the factors that affect such behaviour. The cells reach a position relative to the illuminated channel that is dictated by the compounded effect of convectional current and evanescent field. The observations deduced that motion due to the optical field exists and were more pronounced when considering the trajectory angle towards the output facet. However, the optical forces are not significantly large enough to counter the motion due to the convection current. The results are discussed in light of the potential application of optical channel waveguides for bioanalytical applications, namely in the identification, sorting and analysis of differently sized mammalian cells without recourse to fluorescence or antibody staining.

9550-26, Session 5

Rational design of on-chip refractive index sensors based on lattice plasmon resonances

Linhan Lin, Yuebing Zheng, The Univ. of Texas at Austin (United States)

Lattice plasmon resonances (LPRs), which originate from the plasmonic-photonic coupling in gold or silver nanoparticle arrays, possess ultra-

narrow linewidth by suppressing the radiative damping and provide the possibility to develop the plasmonic sensors with high figure of merit (FOM). However, the plasmonic-photonic coupling is greatly suppressed when the nanoparticles are immobilized on substrates because the diffraction orders are cut off at the nanoparticle-substrate interfaces. Here, we develop the rational design of LPR structures for the high-performance, on-chip plasmonic sensors based on both orthogonal and parallel coupling. Our finite-difference time-domain simulations in the core/shell SiO2/Au nanocylinder arrays (NCAs) reveal that new modes of localized surface plasmon resonances (LSPRs) show up when the aspect ratio of the NCAs is increased. The height-induced LSPRs couple with the superstrate diffraction orders to generate the robust LPRs in asymmetric environment. The high wavelength sensitivity and narrow linewidth in these LPRs lead to the plasmonic sensors with high FOM and high signal-to-noise ratio (SNR). Wide working wavelengths from visible to near-infrared are also achieved by tuning the parameters of the NCAs. Moreover, the wide detection range of refractive index is obtained in the parallel LPR structure. The electromagnetic field distributions in the NCAs demonstrate the height-enabled tunability of the plasmonic “hot spots” at the sub-nanoparticles resolution and the coupling between these “hot spots” with the superstrate diffraction waves, which are responsible for the high performance LPRs-based on-chip refractive index sensors.

9550-28, Session 5

Ultra-broadband plasmonic super absorbers for universal surface enhanced Raman spectroscopy substrate

Nan Zhang, Kai Liu, Haomin Song, Xie Zeng, Dengxin Ji, Qiaoqiang Gan, Univ. at Buffalo (United States)

Although Raman spectroscopy has been commercialized, low-cost and large-area surface enhanced Raman spectroscopy (SERS) substrates with localized enhanced field are heavily required. However, currently dominant manufacturing techniques are expensive and complicated for large-area fabrication. Furthermore, most SERS substrates can only be used for individual excitation wavelengths. In this work, we will report an ultra-broadband super absorbing metasurface to enhance SERS signals in a broadband region (i.e. from 450 nm to 1000 nm). The design consisting of an Ag ground plate, a SiO2 spacer, and a layer of Ag nanoparticles was fabricated using simple film deposition and thermal annealing techniques. A broadband absorption over 80% from 414 nm to 956 nm was obtained, resulting in localized field enhancement between adjacent nanoparticles. We employed this metasurface to test its broadband SERS signal by adsorbing 1,2-Bis(4-pyridyl)-ethylene (BPE) molecules on top of it. We employed 5 laser lines (i.e., 514, 532, 633, 671 and 785 nm) to excite the sample and observed fingerprint signature of BPE molecules under all 5 excitation wavelengths with the average enhancement factor up to 5.3?107. Therefore, the designed SERS substrate can work for almost “all” available excitation wavelengths over a broadband, which is particularly useful for sensing a broad spectrum of chemicals on the same chip.

9550-29, Session 5

Plasmonic nanoparticles sensors utilizing hybrid modes, electrical excitation, and anisotropic particles

Wolfgang Fritzsche, Andre Dathe, Pavel Kliuiev, Jacqueline Jatschka, Uwe Hübner, Mario Ziegler, Matthias Thiele, Steffen Trautmann, Janina Wirth, Frank Garwe, Andrea Csaki, Ondrej Stranik, Leibniz-Institut für Photonische Technologien e.V. (Germany)

Surface Plasmon Resonance (SPR) in metallic nanostructures is an optical effect that can be exploited for the detection of small molecules. There is a broad range of metallic nanostructures supporting different SPR modes, and nanostructures can be even geometrically combined leading to the creation of new hybridised SPR modes.

In our study, we investigated the properties of a hybridised SPR mode (gap modes GM) created by the placement of metallic nanoparticles onto metallic layers and its use as a sensitive sensor.

A tunneling current passing through a metal-insulator-semiconductor structure can generate supported SPR modes, that can be scattered through GM, which was experimentally confirmed.

Moreover, we were able to experimentally follow the degradation of anisotropic (silver nanoprism) nanoparticles under ambient conditions in real time. Using atomic force microscopy and optical spectroscopy we observed an anisotropic corrosion that is starting from the tips of the nanoparticles.

9550-30, Session 5

Wafer-scale aluminum plasmonics for biosensing applications

Arash Farhang, Matthew C. George, Brent Williamson, Mike Black, Ted Wangensteen, James Fraser, Rumyana Petrova, MOXTEK, Inc. (United States)

Moxtek has leveraged existing capabilities in wafer-scale patterning of sub-wavelength wire grid polarizers into the fabrication of 1D and 2D periodic aluminum plasmonic structures. This work will discuss progress in 200 mm diameter wafer-scale fabrication of post and grating based aluminum nanostructures for SPR sensing as well as optical modeling results and device performance. More specifically, hybrid systems combining such periodic nanostructure arrays with a thin underlying metallic film on a glass substrate are investigated. These structures are of great interest as they combine the capabilities of both SPR and LSPR based sensors. The enhanced sensing advantage they offer is based on a nanofocusing mechanism. Specifically, the propagating surface plasmon launched on the metallic film couples to the nanostructure array and is thereby focused into a smaller volume than simply the evanescent plasmon field. This in turn results in a more enhanced surface sensitivity. This advantage, combined with the fact that the structures are operable in the same prism based configuration of standard SPR, i.e. existing commercial sensing platforms, makes them an obvious choice for future use. Potential markets include medical diagnostics, forensic testing, environmental monitoring, and food safety.

9550-31, Session 5

Real-time protein aggregation monitoring based on a simultaneous light scattering investigation and a bloch surface wave-based approach

Sara Santi, Elsie Barakat, Ecole Polytechnique Fédérale de Lausanne (Switzerland); Reinhard Neier, Univ. of Neuchâtel (Switzerland); Hans Peter Herzig, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

The misfolding and aggregation of amyloid proteins has been associated with incurable diseases such as Alzheimer’s or Parkinson’s disease. In the specific case of Alzheimer’s disease, recent studies have shown that cell toxicity is caused by soluble oligomeric forms of Amyloid-beta (A?) peptide aggregates appearing in the early stages of aggregation, rather than by insoluble fibrils. Research on new strategies of diagnosis is imperative to detect the disease prior to the onset of clinical symptoms.

Here, we propose the use of an optical method for protein aggregation dynamic studies using a Bloch surface wave (BSW) based approach. A one-dimension photonic crystal made of a periodic stack of silicon oxide and silicon nitride layers is used to excite a Bloch surface wave, which is sensitive to variation of the refractive index of an aqueous solution. The aim is to detect the early dynamic events of protein aggregation and fibrillogenesis of the amyloid-beta peptide A?42, which plays a central role in the onset

of the Alzheimer's disease. The detection principle relies on the refractive index changes caused by the depletion of the A?42 monomer concentration during oligomerization and fibrillization.

We demonstrate the efficacy of the BSW approach by monitoring in real-time the first crucial steps of A?42 oligomerization and in the presence of small molecular probes able to interfere with the dynamics of amyloid formation. Moreover, we improved the setup to perform a simultaneous light scattering measurement, with the purpose of real-time monitoring the size change of the A? aggregates, throughout fibrillization.

9550-32, Session PWed

Fluorescent cy5 silica nanoparticles for cancer cell imaging

Claire L. O'Connell, Robert I. Nooney, Macdara Glynn, Jens Ducrée, Colette McDonagh, Dublin City Univ. (Ireland)

Cancer is a leading cause of death worldwide, with metastasis responsible for the majority of cancer-related deaths. Circulating tumour cells (CTCs) play a central role in metastasis. Fluorescent silica particles (NPs), of diameter ~50 nm which contain a large concentration of Cy5 dye molecules and are extremely bright, have been developed to detect these rare CTCs. Due to this brightness, the particles have superior performance compared to single Cy5 dye molecule labels, for detecting cancer cells.

Fluorescence measurements show that the NPs are almost 100 times brighter than the free dye. They do not photobleach as readily and, due to the biocompatible silica surface, they can be chemically modified, layer by layer, in order to bind to cells.

The choice of these chemical layers, in particular the NP to antibody linker, along with the incubation period and type of media used in the incubation, has a strong influence on the specific binding abilities of the NPs.

In this work, NPs have been shown to selectively bind to the MCF-7 cell line by targeting epithelial cellular adhesion molecule (EpCAM) present on the MCF-7 cell membrane by conjugating anti-EpCAM antibody to the NP surface. Results have shown a high signal to noise ratio for this cell line in comparison to a HeLa control line.

NP attachment to cells was verified qualitatively with the use of fluorescence microscopy and quantitatively using image analysis methods. Once the system has been optimised, other dyes will be doped in the silica and their use in multiplexing will be investigated.

9550-33, Session PWed

Probing the interaction between Congo Red and ?-amyloid for diagnosis and inhibition of brain plaque formation in Alzheimer's disease

Kristine A. Zhang, Yat Li, Univ. of California, Santa Cruz (United States)

Alzheimer's disease (AD), the most common form of dementia, is an age-related neurodegenerative disorder and the seventh leading cause of death in the United States. One strong pathological indicator of AD is senile plaques, which are aggregates of fibrils formed from assemblies of 40- or 42- residue peptides, known as amyloid ?-peptides (A?). Thus, detection and inhibition of A? aggregation are actively investigated with the objective to prevent and treat AD. Congo red (CR) is one of the most widely used dye molecules for probing as well as inhibiting A? aggregation. However, the nature of interaction between CR and A? is not well understood at the molecular level, which hinders progress in this area. In this research, we have systematically studied the fundamental interaction between CR and A? using a combination of spectroscopic techniques. Compared to CR alone, interaction with A? results in a red-shifted or new absorption peak near 520 nm and significantly enhanced photoluminescence as well as surface-enhanced Raman scattering (SERS) signal. The results led us to propose a new model to explain the interaction between CR and A?, which suggests that CR exists primarily in a micellar or aggregated form in water down to about 0.5 ?M and, upon interacting with A? or similar proteins or peptides, dissociates into monomers. The results and new model have significant implications for developing new molecules and strategies to detect and inhibit brain plaque formation and thereby prevent and treat neurological diseases like AD in the long term.

9550-35, Session PWed

Evaluation of performance of portable respiratory monitoring system based on micro-electro-mechanical-system for respiratory gated radiotherapy

Jiwon Sung, Korea Univ. (Korea, Republic of) and Kyung Hee Univ. Hospital at Gangdong (Korea, Republic of); Dong Wook Kim, Weon Kuu Chung, Kyung Hee Univ. Hospital at Gangdong (Korea, Republic of)

Purpose:

This study evaluated the accuracy of the hand-made portable respiratory monitoring system (PRMS) based on Micro-electro-mechanical-system (MEMS) sensor.

Methods and materials:

The performance of the PRMS was estimated by comparing the actual and measured movements of linear motion by using a one-dimensional motion phantom which moved with periods of 3.50s ~ 7.50s and amplitude of 2.5cm. The PRMS was also tested for radiation hardness by irradiating accumulated radiation to MEMS sensor.

Results:

The difference between signal of the PRMS and real motion were measured up to 1% for periods and 3% for amplitude. The signal from PRMS was well matched with the motion of 1D motion phantom for direction, timing and amplitude. And maximum permissible exposure dose to PRMS was up to 900Gy approximately.

Conclusion:

In term of simplicity and convenience, we found the possibility of the PRMS as the patient training for respiratory gated radiotherapy. We have plan to apply the PRMS to the person or patients and evaluate it help them to make regular breathing by training. So we expect more detail of study for more realistic situation and it can be established in near future.

9550-36, Session PWed

Decoding the LasR quorum sensing communication system of Pseudomonas aeruginosa by SERS

Vanesa Lopez-Puente, Celina Costas, Cristina Fernandez-Lopez, Gustavo Bodelon-Gonzalez, Jorge Perez-Juste, Isabel Pastoriza-Santos, Univ. de Vigo (Spain); Luis M. Liz-Marzan, CIC biomaGUNE (Spain) and IKERBASQUE. Basque Foundation for Science (Spain)

Quorum sensing (QS) is a bacterial cell-to-cell communication system that relies in the activation of receptor proteins by small diffusible signals, which results in the regulation of important cellular processes including virulence, antibiotic resistance and biofilm formation. The study of such protein-ligand interactions provides a molecular framework for the development of QS modulators. Herein, we have applied Surface-enhanced Raman scattering (SERS) spectroscopy for investigating the conformational changes in the structure of LasR from Pseudomonas aeruginosa upon interaction with different QS modulators. With this aim, we generated plasmonic SERS substrates consisting in gold nanoparticles thin films. Then, we genetically modified the ligand-binding domain of LasR to incorporate a C-terminal cysteine that enabled precise control over the protein orientation onto

the gold surface. Based on SERS analyses we demonstrate structural rearrangements in the LasR polypeptide as a result of ligand binding. This study shows for first time SERS detection of conformational changes in a QS receptor, demonstrating its capacity as a powerful tool for the analysis of protein-ligand interactions. Therefore this spectroscopic technique could be successfully used as complementary tool for accelerating drug discovery.

9550-37, Session PWed

Low-temperature UV-resonance Raman spectroscopy: toward less damaging biomolecular imaging

Yuika Saito, Hikaru Yoshino, Yasuaki Kumamoto, Atsushi Taguchi, Satoshi Kawata, Osaka Univ. (Japan)

There has been a considerable interest on applying UV resonant Raman spectroscopy to biological materials, because of a high sensitivity and molecular selectivity caused by the resonant effect. The main drawback of UV resonance Raman spectroscopy is photodegradation during a laser exposure that cause a serious problem for observation of an actual biological processes especially in a microscopic imaging where the observation volume cannot be refreshed. Therefore, it is essential to figure out the origin of a photodegradation and choosing appropriate experimental parameter including environmental conditions .

In this work, the temperature-dependent photodegradation during UV-resonance Raman spectroscopy was investigated. Photodegradation was quantitatively probed by monitoring the temporal evolution of UV-resonance Raman spectra obtained from bacteriochlorophyll (BChl) showing resonance effect at a 355-nm excitation wavelength. At 80 K, the molecular photodecomposition rate was 5-times lower than at room temperature. The decomposition rates of BChl followed the Arrhenius formula, indicating that the mechanism of photodegradation can be explained by a thermal activation process.

9551-1, Session 1

Electrical control of the perpendicular magnetization in Pt/[Co/Ni]3/Al multilayers *(Invited Paper)*

Juan-Carlos Rojas-Sánchez, Unité Mixte de Physique CNRS/Thales (France) and Univ. Paris-Sud 11 (France); Joao Sampaio, Univ. Paris-Sud 11 (France); Piotr Laczkowski, Nicolas Reyren, Cyrile Deranlot, Sophie Collin, Henri Jaffrès, Unité Mixte de Physique CNRS/Thales (France) and Univ. Paris-Sud 11 (France); Alexandra Mougin, Univ. Paris-Sud 11 (France); Albert Fert, Jean-Marie George, Unité Mixte de Physique CNRS/Thales (France) and Univ. Paris-Sud 11 (France)

The spin to charge current conversion (SCCC) due to spin-orbit coupling (SOC) opens the way to manipulate the magnetization by electrical means. SCCC results either from bulk effects, in particular through Spin Hall Effect (SHE) [1-3], or from interfacial effects, for example in our recent experimental discovery of Rashba-Edelstein Effect (REE) [4]. We have investigated the SCCC by SHE in metals such as Pt [1,2], Au and AuW [3]. In the case of 2D systems, we recently demonstrated a large SCCC efficiency in Rashba type Ag/Bi interface [4]. An even larger effect can be even anticipated if topological insulators are used.

We will present a practical application of this SCCC to control the magnetization due to the spin-orbit torque induced by SHE [5-8], and focus on the case of Pt/(Co/Ni)3/Al multilayers with perpendicular magnetization. Using both the anomalous Hall Effect and Kerr experiments in patterned Hall bars, we are able to establish a scenario for the reversal mechanism involving domain wall motions and spin-orbit torques induced by SHE in Pt.

9551-2, Session 1

Ultra-fast three terminal perpendicular spin-orbit torque MRAM *(Invited Paper)*

Olivier Boulle, Murat Cubukcu, Claire Hamelin, SPINTEC (France); Nathalie Lamard, CEA-LETI (France); Liliana Buda-Prejbeanu, SPINTEC (France); Nikolai Mikuszeit, CEA-LETI (France); Kevin Garello, Pietro Gambardella, ETH Zürich (Switzerland); Juergen Langer, Berthold Ocker, SINGULUS TECHNOLOGIES AG (Germany); Mihai Miron, Gilles Gaudin, SPINTEC (France)

The discovery that a current flowing in a heavy metal can exert a torque on a neighboring ferromagnet has opened a new way to manipulate the magnetization at the nanoscale. This “spin orbit torque” (SOT) has been demonstrated in ultrathin magnetic multilayers with structural inversion asymmetry (SIA) and high spin orbit coupling, such as Pt/Co/AlOx multilayers. We have shown that this torque can lead to the magnetization switching of a perpendicularly magnetized nanomagnet by an in-plane current injection. The manipulation of magnetization by SOT has led to a novel concept of magnetic RAM memory, the SOT-MRAM, which combines non volatility, high speed, reliability and large endurance. These features make the SOT-MRAM a good candidate to replace SRAM for non-volatile cache memory application.

We will present the proof of concept of a perpendicular SOT-MRAM cell composed of a Ta/FeCoB/MgO/FeCoB magnetic tunnel junction and demonstrate ultra-fast (down to 300 ps) deterministic bipolar magnetization switching. Macrospin and micromagnetic simulations including SOT cannot reproduce the experimental results, which suggests that additional physical mechanisms are at stacks. Our results show that SOT-MRAM is fast, reliable and low power, which is promising for non-volatile cache memory application. We will also discuss recent experiments of magnetization reversal in ultrathin multilayers Pt/Co/AlOx by very short (<200 ps) current pulses. We will show that in this material, the Dzyaloshinskii-Moryia interaction plays a key role in the reversal process.

9551-3, Session 1

Spin-transfer torques from spin-orbit interactions in heavy metals and topological insulators *(Invited Paper)*

Daniel C. Ralph, Cornell Univ. (United States)

The manipulation of magnetic devices using spin transfer torque in conventional magnetic tunnel junctions faces a fundamental limit in efficiency. This conventional torque can be no stronger than the equivalent of one unit of hbar angular momentum transferred per unit charge in the applied current. I will discuss recent experiments which investigate the use of spin-orbit interactions in two different classes of materials to achieve magnetic manipulation with much better efficiency. First I will discuss the use of the spin Hall effect in certain heavy metals, which can provide spin-transfer torques that are more than a factor of 10 stronger per unit current than conventional spin torque in magnetic tunnel junctions. These torques can switch magnetic devices with either in-plane or perpendicular anisotropy, and can also drive very rapid domain wall motion in perpendicularly-magnetized samples. I will describe our efforts to identify the materials and device geometries that can provide the strongest spin Hall effects for applications, and to understand the physical mechanisms at work. Second, I will describe initial experiments on topological insulator/ferromagnet bilayers, which suggest that spin-momentum locking in the surface state of the topological insulator may generate spin-transfer torques at least another order of magnitude more efficient even than in the heavy metals.

9551-4, Session 1

Spin-transfer torque excited by spin-orbit effects in ferromagnetic bilayers *(Invited Paper)*

Tomohiro Taniguchi, National Institute of Advanced Industrial Science and Technology (Japan); Julie Grollier, Unité Mixte de Physique CNRS/Thales (France); Mark D. Stiles, National Institute of Standards and Technology (United States)

Spin-orbit effects in nonmagnetic heavy metals have attracted much attention because of their potential application to nanostructured magnetic devices. In a ferromagnetic/nonmagnetic bilayer system, an in-plane electric field applied to the nonmagnet produces spin current flowing in the direction perpendicular to the electric field by the spin-Hall effect. The spin current injected into the attached ferromagnet excites magnetization dynamics by the spin-transfer effect. Recent experiments have demonstrated switching of a perpendicular ferromagnet by this spin-transfer torque.

Spin-orbit effects are also observed in ferromagnets in the anomalous Hall effect and the anisotropic magnetoresistance. These effects also produce the spin-transfer torques in ferromagnetic bilayers. Based on spin transport theory and spin-dependent Landauer formula, we developed a theory of interlayer spin-transfer torque excited by the anomalous Hall effect and the anisotropic magnetoresistance in a ferromagnetic bilayer [1]. We derive an analytical formula of the spin-transfer torque, and show that

the spin-transfer torque can point to an arbitrary direction by changing the magnetization direction, in contrast to spin-Hall systems in which the direction of the spin-transfer torque is geometrically determined. It enables us to control the magnetization direction more efficiently than with spin-Hall systems. For example, by choosing an appropriate magnetization direction of one ferromagnet, the spin-transfer torque enables us to switch another perpendicular ferromagnet with low current and high accuracy. Coupled domain wall motion can also be excited.

9551-5, Session 2

Resonant optical control of the current-induced spin polarization in a two-dimensional electron system *(Invited Paper)*

Felix G. G. Hernandez, Gennady Gusev, Univ. de São Paulo (Brazil); Askhat Bakarov, A.V. Rzhanov Institute of Semiconductor Physics (Russian Federation)

Semiconductor quantum wells are largely explored systems for the future development of spintronic devices using optical or electrical techniques. For the successful implementation in practical technological platforms, the combination of such methods will be a desirable target for the steps of generation, control with amplification, and detection. Nowadays, the reported studies using optical detection, for example, Kerr rotation, are mainly divided in two branches depending on the spin polarization trigger used: light or electrical current. Among the optical techniques for the generation of spin polarization, those using periodical excitation are very attractive because they lead to remarkable phenomena such as the resonant spin amplification (RSA). On the other side, electrical generation of spin polarization (CISP) opens a possibility to develop spin current sources added to the tuning capability of the spin-orbit interaction. In a combination of optical and electrical techniques, the situation where a CISP signal is controlled by an optical pulse has not been reported. Here, we address the amplification and reorientation of the CISP by periodic optical excitation in resonance with a variable external magnetic field. We explored the manipulation of the spin polarization in a 2DEG by the applied electrical voltage, optical pulse power, and the signal amplitude dependence on the temperature and device geometry. The experimental data displays a RSA pattern with long-lived spin coherence oscillations where the polarization amplitude is enhanced by the electric field, the spin lifetime is independent of the current level but strongly damped by high optical power and temperature.

9551-6, Session 2

Dynamics of coupled carriers and Mn spins in a positively charged Mn-doped quantum dot *(Invited Paper)*

Lucien Besombes, Institut NÉEL (France)

Semiconductor quantum dots (QDs) allow for the manipulation of single charge and spins in a solid-state system. It has been shown that the optical properties of a QD can also be used to access the spin of individual or pairs of magnetic atoms. A magnetic atom spin can be prepared by the injection of spin polarized carriers and its spin state can be read through the energy and polarization of the photons emitted by the QD. Information processing using individual magnetic atom spins will require fast coherent control of a single spin and tuning the coherent coupling between two or more spins. The controlled exchange coupling of a carrier spin with the spin of individual magnetic atoms could be used to transfer information between localized spins.

Using the resonant photoluminescence (PL) of the positively charged exciton as a probe we analyze here the dynamics of coupled carriers and individual Mn spins in a p-doped CdTe/ZnTe QD. The electron-Mn spin relaxation channels are identified in the energy and polarization of the resonant PL. The auto-correlation of the resonant PL reveals a large photon bunching resulting from the spin fluctuations of the electron-Mn and hole-Mn complexes. The dynamics of the coupled hole-Mn spins is directly measured in time resolved resonant optical pumping experiments and the coherent dynamics of coupled electron and Mn spins is observed in the time resolved resonant PL. We show that a p-doped magnetic QD forms an ensemble of ten independent optical ? systems that could be used for a coherent manipulation of the coupled hole-Mn spins.

9551-7, Session 2

Semiconductor-based interface between photons and quantum registers using spins in self-assembled quantum dots *(Invited Paper)*

Danny Kim, Thaddeus D. Ladd, Matthew Rakher, Nathan C. Jones, Andrey A. Kiselev, Richard S. Ross, HRL Labs., LLC (United States)

Self-assembled semiconductor quantum dots are prime candidates as coherent spin-to-photon interfaces in proposed quantum repeaters or quantum networks. The spin of a trapped electron acts as the stationary or storage qubit while recombination from atom-like energy levels produces single photons. A strong optical transition dipole in the semiconductor medium provides salient advantages, such as quantum gates completed in picoseconds using ultrafast lasers, near unity photon extraction efficiency when embedded in engineered nanostructures, and the ability to provide a deterministic single photon turnstile operating at 100 MHz. These properties have enabled experiments demonstrating ultrafast one- and two-qubit gates, spin echo, and spin-photon entanglement.

This talk will present preliminary experiments and simulations towards realizing a semiconductor-based architecture for spin/photon interconversion based on self-assembled quantum dots. One key limitation of these dots for quantum memory is the short decoherence time due to nuclear field fluctuations. Although the demonstrated ratio of T2 to the single-qubit optical gate time (105) exceeds many systems, high-fidelity multi-qubit logic is still required for most quantum network architectures. A logic-enabled memory register larger than a few self-assembled dots is challenging to build with self-assembly, motivating architectures which transfer the spin information from these dots to microfabricated arrays of electrically gated dots. Critical performance parameters for this transfer are the coherence time and control fidelity of the self-assembled dots; we therefore investigate optical dynamical decoupling and composite pulse sequences and compare the performance to the requirements of future integrated devices.

9551-8, Session 3

Spin-orbit torques in magnetic bilayers *(Invited Paper)*

Paul M. Haney, Mark D. Stiles, National Institute of Standards and Technology (United States); Hyun-Woo Lee, Pohang Univ. of Science and Technology (Korea, Republic of); Aurélien Manchon, King Abdullah Univ. of Science and Technology (Saudi Arabia); Kyung-Jin Lee, Korea Univ. (Korea, Republic of)

Spintronics aims to utilize the coupling between charge transport and magnetic dynamics to develop improved and novel memory and logic devices. Future progress in spintronics may be enabled by exploiting the spin-orbit coupling present at the interface between thin film ferromagnets and heavy metals. In these systems, applying an in-plane electrical current can induce magnetic dynamics in single domain ferromagnets, or can induce rapid motion of domain wall magnetic textures. There are multiple effects responsible for these dynamics. They include spin-orbit torques and a chiral exchange interaction (the Dzyaloshinskii-Moriya interaction) in the

ferromagnet. Both effects arise from the combination of ferromagnetism and spin-orbit coupling present at the interface. There is additionally a torque from the spin current flux impinging on the ferromagnet, arising from the spin hall effect in the heavy metal. Using first principles calculations, we identify spin-orbit hybridization at the ferromagnet-heavy metal interface as central to the spin-orbit torques present in Co-Pt bilayers. We additionally propose that the transverse spin current (from the spin hall effect) is locally enhanced over its bulk value due to scattering at an interface which is oriented normal to the charge current direction.

9551-9, Session 3

Spin orbit torques and chiral spin textures in ultrathin magnetic films *(Invited Paper)*

Geoffrey S. Beach, Massachusetts Institute of Technology (United States)

Spin orbit coupling at interfaces can give rise to chiral magnetic textures such as homochiral domain walls and skyrmions, as well as current-induced torques that can effectively manipulate them [1-3]. This talk will describe interface-driven spin-orbit torques and Dzyaloshinskii-Moriya interactions (DMIs) in ultrathin metallic ferromagnets adjacent to nonmagnetic heavy metals. We show that the DMI depends strongly on the heavy metal, differing by a factor of ~20 between Pt and Ta [4], and describe the influence of strong DMI on domain wall dynamics and spin Hall effect switching [5]. We present high-resolution magnetic force microscopy imaging of static magnetic textures that directly reveal the role of DMI and allow its strength to be quantified. Finally, we will describe how SOTs can be enhanced through interface engineering [6] and tuned by a gate voltage [7] by directly controlling the interfacial oxygen coordination at a ferromagnet/oxide interface [8].

9551-10, Session 3

Anatomy of spin-orbit phenomena at ferromagnetic/nonmagnetic material interfaces *(Invited Paper)*

Hongxin Yang, Ali Hallal, Bernard Dieny, SPINTEC (France) and Univ. Grenoble Alps (France) and Ctr. National de la Recherche Scientifique (France); Andre Thiaville, Stanislas Rohart, Univ. Paris-Sud 11 (France) and Ctr. National de la Recherche Scientifique (France); Albert Fert, Unité Mixte de Physique CNRS/Thales (France) and Univ. Paris-Sud 11 (France); Mairbek Chshiev, SPINTEC (France) and Univ. Grenoble Alps (France) and CEA-INAC (France)

Spin-orbit coupling based phenomena such as perpendicular magnetic anisotropy (PMA) and Dzyaloshinskii-Moriya interaction (DMI) at interfaces between ferromagnetic (FM) metal and nonmagnetic (NM) insulator or metal have been an object of increased interest for spintronics including spin orbitronics in a view of ultra-dense information storage and spintronic devices such as MRAM. In this talk we elucidate mechanisms responsible for the PMA and DMI from first-principles for Co(Fe)|MgO and Co|Pt interfaces, respectively. First, we unveil the nature of PMA at Fe|MgO interfaces by evaluating the orbital and layer resolved contributions to magnetic anisotropy in Fe/MgO interfaces and MTJs with di?erent interfacial conditions [1,2]. It is demonstrated that the origin of the large PMA values is far beyond simply considering the hybridization between Fe-3d and O-2p orbitals at the interface between the metal and the insulator. Our on-site projected analysis show that the anisotropy energy is not localized at the interface but it rather propagates into the bulk showing an attenuating oscillatory behavior which depends on orbital character of contributing states and interfacial conditions [2]. Next, we calculate and clarify the main features and microscopic mechanisms of DMI in Co/Pt bilayers [3]. Here we found that DMI is predominantly located at the interfacial Co layer, originating from spin-orbit energy provided by the adjacent NM layer. Furthermore, no direct correlation is found between DMI and proximity induced magnetism in Pt. The thickness dependencies as well as the impact of interfacial mixing on DMI values in Co/Pt inetrfaces will be also discussed. These results clarify underlying mechanisms of DMI at FM/NM bilayers and should help optimizing material combinations for skyrmion- and DW-based storage and memory devices. [1] H.-X. Yang et al, Phys. Rev. B 84, 054401 (2011);

9551-11, Session 4

Long-range transfer of spin information using a single electron *(Invited Paper)*

Tristan Meunier, Ctr. National de la Recherche Scientifique (France)

The recently demonstrated on-demand transfer of a single electron using surface acoustic waves in AlGaAs heterostructures [1,2] opens the route towards electronics at the single electron level and is a promising strategy to scale up the system of electron spin qubits.

We will discuss the result of an experiment where the spin of an electron, initially prepared in a specific spin states in a first dot, is measured in a second dot four microns away after transfer. We demonstrate that spin information is preserved during the transfer with a fidelity close to 30%. We will discuss possible source of depolarization during the transfer and prior to the transfer.

9551-12, Session 4

Spin dynamics of isolated carrier spins in semiconductors *(Invited Paper)*

Michael Oestreich, Fabian Berski, Ramin Dahbashi, Julia Wiegand, Leibniz Univ. Hannover (Germany); Klaus Pierz, Physikalisch-Technische Bundesanstalt (Germany); Andreas D. Wieck, Ruhr-Univ. Bochum (Germany); Jens Hübner, Leibniz Univ. Hannover (Germany)

The spin of localized carriers is a prospective candidate for future quantum information systems like for example quantum repeaters or quantum information processing. In this talk we will present new results on the intriguing interaction of single and ensembles of localized spins with the surrounding nuclear spin bath and the subtle influence of electrically active defects in close vicinity of the corresponding spins. In the field of the central spin problem, we will discuss higher order spin correlations as an appropriate tool to shed more light on the complex type of spin interaction. We will furthermore elaborate on the coupling of light and spins in direct and indirect semiconductors at very low temperatures. We will experimentally verify the predicted multifaceted longitudinal and transverse spin relaxation times of localized carriers and explain the appearance of unexpected features in the spin noise spectrum which emerge as extremely sharp spin noise peaks indicating spin coherence times in the millisecond regime. Finally, we will show recent advances in the technique spin noise spectroscopy in view of an enhanced sensitivity and surprising observations concerning the magnetic field dependence of the longitudinal spin relaxation time of single electrons and holes in individually addressed

quantum dots and strong signatures of anisotropic spin interaction in nominally symmetric quantum systems.

9551-13, Session 4

Ultrafast phase-sensitive probes of the exchange interaction at ferromagnet/ semiconductor interfaces *(Invited Paper)*

Ezekiel Johnston-Halperin, The Ohio State Univ. (United States)

We investigate the ultrafast exchange mechanism between the magnetization of a metallic ferromagnet and the free carriers of an adjacent non-magnetic semiconductor using ultrafast optical pump probe techniques. Using Fe/MgO/GaAs heterostructures we explore the exchange-driven ferromagnetic proximity polarization (FPP) mechanism, which has previously been reported to lead to a non-equilibrium polarization of the free carriers in the GaAs layer that develops on timescales of less than 50 ps. This non-equilibrium electron polarization leads to a hyperpolarization of the nuclear spin system via the contact hyperfine interaction, which in turn dramatically modifies the ensemble spin dynamics of the free carriers. Here, we use the time and phase sensitivity of time-resolved Kerr rotation measurements to explore the role of inhomogeneity in both the exchange and hyperfine fields in determining the ensemble dephasing time, T2*, of spins in the GaAs. We find an unexpected and dramatic dependence of T2* on the effective nuclear field that suggests significant inhomogeneity in the local hyperfine interaction at low temperatures due to carrier freeze-out (i.e. localization at Si donor sites). These results provide a powerful new tool to explore the time dependent exchange interaction at ferromagnetic/ non-magnetic interfaces, with the potential to dramatically improve our understanding of dynamic spin phenomena ranging from spin-thermal interactions in heterostructures to ferromagnetic resonance driven spin pumping.

9551-14, Session 5

Spin-pumping-induced spin transport in semiconductors and related phenomena *(Invited Paper)*

Masashi Shiraishi, Yuichiro Ando, Kyoto Univ. (Japan)

Spin pumping is currently recognized as a quite potential tool for injecting spins and generating pure spin current into condensed matters, such as nonmagnetic metals [1], inorganic semiconductors [2], organic semiconductors [3], magnetic insulator [4], and so on. For detection of the generated spin current, the inverse spin Hall (ISHE) effect [5] is now widely used. We have been investigating spin transport properties and spin polarization in semiconductors and topological insulators by using spin pumping (Si [2], Graphene [6], GaAs [7] and Ge [8]) and electrical spin injection (Si [9], Graphene [10]) and BiSbTeSe [11]), and will present these recent results. In the course of these studies, we found that non-negligible electromotive forces can be generated from ferromagnetic metals, NiFe and Co [12], due to the self-induced ISHE. The detail of this interesting feature will be also presented.

Hot electrons transport in devices combining tunnel and Schottky barriers *(Invited Paper)*

Christopher Vautrin, Yuan Lu, Sylvain Le Gall, Guillaume Salla, Sylvie Robert, Olivier Lenoble, François Montaigne, Institut Jean Lamour (France); Ming-Wei Wu, Univ. of Science and Technology of China (China); Daniel Lacour, Michel Hehn, Institut Jean Lamour (France)

We have recently unveiled experimentally a new interfacial trapping phenomenon for hot electron injection in silicon [1]. The transport measurements indicate that an interfacial charge trapping and a backscattering-induced collector current limitation take place when the temperature is lower than 25?K. This results in a rapid decrease of the magneto-current ratio. In this presentation we will demonstrate an electrical control of this trapping effect thanks to a magnetic tunnel transistor made on wafer bonded substrate [2]. A model taking into account the effects of both electric field and temperature will be presented. It closely reproduces the experimental results and allows extraction of the trapping binding energy (1.6 meV). Finally we will also discussed the difficulties encountered during realization of equivalent devices having out of plane magnetizations. Links between Schottky barriers preparation techniques and the existence of perpendicular magnetic anisotropy in a CoNi multilayer are established made. A solution to join in the same devices a Schotkky barrier and perpendicular anisotropy will be revealed [3].

Electrical spin injection from ferromagnetic metals to silicon (Si) and germanium (Ge) is the first and basic requirement for the development of spintronic devices and their integration with mainstream semiconductor (SC) technology. The main obstacle to efficient spin injection is the conductivity mismatch between the ferromagnetic metal and Si, Ge and

requires tunneling spin injection through an oxide barrier (Ox). However, tunneling spin injection raises other important issues in the interpretation of electrical spin signals. In particular, the possible presence of localized states within the Ox or at the Ox/SC interface may lead to wrong conclusions. To study the exact origin of the spin signals measured in three and four-terminal geometries, we have grown Ta/CoFeB/MgO/SOI and GeOI samples with n and p type doping using variable MgO thicknesses. The use of SOI and GeOI substrates allows us to apply back gate voltages to the SC channel to vary its resistivity. Moreover we have used three different techniques to grow the MgO tunnel barrier: by sputtering of MgO or Mg followed by a plasma oxidation and e-beam evaporation of MgO. Using the Mg and plasma oxidation growth of the tunnel barrier, though less flexible than the other techniques, allowed us to show the temperature transition from the spin accumulation into interface states to the spin accumulation into the conduction band of n-Ge and n-Si. For this purpose, both electrical and dynamical spin injection measurements were carried out as a function of temperature and bias voltage for different MgO tunnel barriers.

9551-17, Session 6

Understanding bilayers of metals and magnetic insulators *(Invited Paper)*

Gerrit E. W. Bauer, Tohoku Univ. (Japan) and Delft Univ. of Technology (Netherlands)

The spintronics based on magnetic and non-magnetic elemental metals and their alloys has been very successful in the last decade. Discoveries such as the giant magnetoresistance, tunnel magnetoresistance, spin-transfer torque, (inverse) spin Hall effect, spin-orbit torques etc. not only lead to fundamental new physical insights, but also to functionalities that are employed in new nanoscale devices such as switches, memories, and sensors.

Magnetic insulators form another class of versatile materials with great technological importance. They have been central to the research in magnetism up to the 80's of the last century, but were later largely forgotten. The most important magnetic insulators are arguably the man-made yttrium iron garnets, ferrimagnets with Curie transitions far above room temperature and record magnetic quality [1-3]. In recent years, magnetic insulators have attracted much interest from the spintronics community, because K. Uchida, E. Saitoh c.s., demonstrated that they can be actuated thermally [4] and electrically [5] and thereby integrated into conventional electronics and thermoelectric devices. The discovery of entirely new phenomena, such as the spin Seebeck effect, raises the hope for a new and green spintronics [6].

This contribution reviews recent (published in 2014 [7-15] and yet unpublished) progress in the theoretical spin(calori)tronics of YIG and its heterostructures with normal metals,. After an elementary introduction into the basic physical concepts, a number of recent key theoretical insights and, where possible experimental evidence, will be reviewed. Topics such as spin Peltier effect, the figure or merit of spin Seebeck generators, exchange magnon-polaritons, acoustically induced spin pumping, current-induced spin torque resonance facilitated by the spin Hall magnetoresistance, and others will be presented.

I gratefully acknowledge collaboration with many researchers (see Refs. [5-16]). This work was supported by the FOM Foundation, Reimei program of the Japan Atomic Energy Agency, EU-FET "InSpin", the ICC-IMR, DFG Priority Program 1538 "Spin-Caloric Transport", and JSPS Grants-in-Aid for Scientific Research (Grant Nos. 25247056, 25220910, 26103006).

Spintronics in complex oxide hybrid and heterostructures *(Invited Paper)*

Georg Schmidt, Martin-Luther-Univ. Halle-Wittenberg (Germany)

Complex oxides are an interesting class of materials for spintronics research and applications. Among others they have been used in tunnelling magnetoresistance elements because of high spin polarization or in hybrid structures for spin pumping [1] where ferromagnetic insulators like yttrium iron garnet (YIG) greatly facilitate the interpretation of experimental results.

In this presentation further progress in the utilization of ferromagnetic oxides for spintronics will be shown. On the one hand spin pumping and inverse spin-Hall effect in all-oxide heterostructures are presented. In these structures complex oxides are not only the source of spin pumping but they also act as the detecting spin sink which exhibits the inverse spin-Hall effect.

In addition new experiments on tunnelling anisotropic magnetoresistance (TAMR) in oxides will be shown. While TAMR in inorganic systems was limited to a few % until recently [2], we demonstrate that in a fully epitaxial stack of a ferromagnetic oxide and a complex oxide tunnel barrier TAMR can be as large as 65 %.

Spin wave propagation in magnetic insulator thin film of nanometer thickness *(Invited Paper)*

Haiming Yu, BeiHang Univ. (China) and Technische Univ. München (Germany); Olivier d'Allivy Kelly, Unité Mixte de Physique CNRS/Thales (France) and Univ Paris-Sud 11 (France); Vincent Cros, Rozenn Bernard, Paolo Bortolotti, Abdelmadjid Anane, Unité Mixte de Physique CNRS/ Thales (France) and Univ. Paris-Sud 11 (France); Florian Brandl, Rupert Huber, Ioannis Stasinopoulos, Dirk Grundler, Technische Univ. München (Germany)

Wave control in the solid state has opened new avenues in modern information technology. Surface-acoustic-wave-based devices are found as mass market products in 100 millions of cellular phones. Spin waves (magnons) would offer a boost in today's data handling and security implementations, i.e., image processing and speech recognition. However, nanomagnonic devices realized so far suffer from the relatively short damping length in the metallic ferromagnets amounting to a few 10 micrometers typically. Here we demonstrate that nm-thick YIG films overcome the damping chasm. Using a conventional coplanar waveguide we excite a large series of short-wavelength spin waves (SWs). From the data we estimate a macroscopic of damping length of about 600 micrometers. The intrinsic damping parameter suggests even a record value about 1 mm allowing for magnonics-based nanotechnology with ultra-low damping. In addition, SWs at large wave vector are found to exhibit the non-reciprocal properties relevant for new concepts in nanoscale SW-based logics. We expect our results to provide the basis for coherent data processing with SWs at GHz rates and in large arrays of cellular magnetic arrays, thereby boosting the envisioned image processing and speech recognition.

Role of transparency of platinum-ferromagnet interface in determining intrinsic magnitude of spin Hall effect *(Invited Paper)*

Wei Han, Peking Univ. (China)

The spin Hall effect is a phenomenon in which electrical current generates pure spin currents in thin layers formed from materials with large spin orbit coupling. What determines the magnitude of the effect is of considerable debate. Whilst the spin Hall effect has been observed in a number of conducting materials one of the most interesting materials is platinum due, not only to the substantial large spin Hall effect that it exhibits, but also because Pt exhibits several other important properties related to its large spin orbit coupling including perpendicular magnetic anisotropy, a Dzyaloshinsky-Moriya exchange interaction, and a proximity induced magnetic moment when coupled to a magnetic layer.

The magnitude of the SHE is not easy to measure and most often is inferred from the effect of the spin current on neighboring magnetic moments. The spins diffuse from the non –magnetic layer in which they are formed across the interface into the magnetic material. What we show in our paper is that the "transparency" of this interface to the spin current strongly affects the magnitude of the spin Hall effect. The transparency has been ignored in all measurements of the SHE to date. In our manuscript we use a spin torque ferromagnetic resonance (ST-FMR) technique to measure the SHE. When the transparency is neglected we show that the magnitude of the SHE in platinum measured using ST-FMR can vary by more than a factor of 2 with different magnetic metals! The SHE should, however, not depend on the ferromagnet since it is an intrinsic property of the material itself. We show that we can readily account for our observations by taking account of the transparency of the platinum / magnet interface that we measure in independent measurements using the phenomenon of spin pumping. This is an enormous effect! For example, we find for the platinum/ permalloy interface only 1 in 4 spins cross the interface! This means that the spin current generated in the platinum layer from the SHE is 4 times larger than is inferred from the perturbation of the magnetic layer from the spin torque created by the spins that cross the interface. Correspondingly, this means that the magnitude of the SHE is also 4 times larger than was inferred from ST-FMR or related experiments which ignores the interface transparency.

Our work points to the importance of the interface transparency in understanding the origin of the SHE and how it can be used technologically. In hindsight the role of the interface transparency seems so important that it is surprising that it has been overlooked. Thus, we believe our paper will be of considerable interest and will play an important role in developing a detailed understanding of the physics underlying the spin Hall effect.

9551-21, Session 6

Quantum Well state oscillations of pure spin currents in Fe/Au/Pd(001) structures *(Invited Paper)*

Bret V. Heinrich, Eric Montoya, Simon Fraser Univ. (Canada)

Interlayer exchange coupling and spin pumping are caused by instantaneous and time delayed spin dependent potential at FM (ferromagnet) /NM (normal metal) interface, respectively. Therefore one can expect that in some structures the spin pumping contribution to the interface damping can result also in an oscillatory behavior with the NM layer thickness as it is observed readily for the interlayer coupling. Since no oscillatory behavior of spin pumping was found in FM/simple NM systems, we investigated spin pumping in Fe/Au/Pd(001); the Pd layer exhibits thermally excited spin fluctuations resulting in a large spin current decoherence in Pd on the length scale of 10 nm which is significantly smaller than the spin diffusion length in normal Au. Spin pumping contribution to the Gilbert damping in Fe/Au/Pd reached an asymptotic value corresponding to a thick Au layer on much shorter length scale than that expected for the spin diffusion length in Au. This behavior was possible to explain using a partial reflection of spin current at the Au/Pd interface which is caused by different Fermi velocities in Au and Pd. Surprisingly, for the Au layer thickness less than the momentum mean free path, the interface damping oscillated with a periodicities corresponding to long (belly of the Fermi surface) and short (necks) spanning k-vectors in Au(001) of the static interlayer exchange coupling. This means that even in the time irreversible process of spin pumping collective quantum well states play a significant role when the Au spacer is thinner that the electron momentum mean free path.

9551-22, Session 7

Origin of the spin-orbit interaction *(Invited Paper)*

Gianfranco Spavieri, Univ. de los Andes (Venezuela); Masud Mansuripur, College of Optical Sciences, The Univ. of Arizona (United States)

We consider a semi-classical model to describe the origin of the spin-orbit interaction in a simple system such as the hydrogen atom. The interaction energy U is calculated in the rest-frame of the nucleus, around which an electron, having linear velocity v and magnetic dipole-moment ?, travels in a circular orbit. The interaction energy U is due to the coupling of the induced electric dipole p=(v/c)?? with the electric field En of the nucleus. According to quantum mechanics, the radius of the electron's orbit remains constant during a spin-flip transition. Under such circumstances, our model predicts that the energy of the system changes by ΔE=?U, the factor ? emerging naturally as a consequence of equilibrium and the change of the kinetic energy of the electron. The correct ? factor for the spin-orbit coupling energy is thus derived without the need to introduce the well-known Thomas precession in the rest-frame of the electron.

Rashba spin-orbit effect and its electric field control at the surfaces and interfaces for spintronics applications *(Invited Paper)*

Sashi Satpathy, Univ. of Missouri (United States); Kavungal Veedu Shanavas, Oak Ridge National Lab. (United States)

The Rashba effect [1] describes the momentum-dependent spin splitting of the electron states at a surface or interface. It is the combined result of the relativistic spin-orbit interaction (SOI) and the inversion-symmetry breaking. The control of the Rashba effect by an applied electric field is at the heart of the proposed Rashba-effect-based spintronics devices for manipulating the electron spinfor manipulating the electron spin in the semiconductors. The effect is expected to be much stronger in the perovskite oxides owing to the presence of high-Z elements.

In this talk, I will introduce the Rashba effect and discuss how the Rashba SOI at the surfaces and interfaces can be tuned by manipulating the two dimensional electron gas (2DEG) by an applied electric field. The effect can be understood in terms of a tight-binding model Hamiltonian for the d orbitals incorporating the effect of electric field in terms of effective orbital overlap parameters [3]. From first principles calculations we see that the Rashba SOI originates from the first few layers near the surface and it therefore can be altered by drawing the 2DEG to the surface or by pushing the 2DEG deeper into the bulk with an applied electric field. These ideas will be illustrated by a comprehensive density-functional study of polar perovskite systems [4].

Microscopic theory of the inverse Edelstein effect *(Invited Paper)*

Roberto Raimondi, Univ. degli Studi di Roma Tre (Italy); Ka Shen, Giovanni Vignale, Univ. of Missouri (United States)

The spin Hall effect (SHE) and the inverse spin Hall effect (ISHE) are well established phenomena in current spintronics research. A third important effect is the current-induced spin polarization, which, within the Rashba model for a spin-orbit coupled two-dimensional disordered electron gas, has been predicted by Edelstein in 1990 and it is referred to as the Edelstein effect (EE). This effect is deeply connected to the above two effects thanks to a constraint dictated by the equation of motion. Less known is the inverse Edelstein effect (IEE), which is the Onsager reciprocal of the EE and according to which a charge current is generated by a non-equilibrium spin polarization. The IEE has been recently observed (Nature Commun. 4, 2944 (2013)) in a hybrid ferromagnetic-metal system. In this talk I provide a precise microscopic definition of the IEE and its description within the Rashba model. It turns out that the effect has a surprisingly simple interpretation when the spin-charge coupled drift-diffusion equations governing it are cast in the language of a SU(2) gauge theory, with the Rashba spin-orbit coupling playing the role of a generalized spin-dependent vector potential. After sketching briefly the derivation of the drift-diffusion equations, the latter are applied to the interpretation of the experiments. The role of spin-orbit coupling due to impurities is also considered, by showing that the strenght of the IEE can be controlled by the ratio of the spin relaxation rates associated to the two type of spin-orbit coupling.

9551-25, Session 7

Spin-orbit torques and the Dzyaloshinskii-Moriya interaction in Ta/CoFeB/MgO nanowires *(Invited Paper)*

Thomas A. Moore, Univ. of Leeds (United Kingdom)

The interaction between current and magnetization in Ta/CoFeB/MgO is of interest because this materials stack is already used for the fabrication of spintronic devices whose functionality is based on spin torque. With the advent of spin-orbit torques, the challenge is to understand what governs the torques and the strength and sign of the Dzyaloshinskii-Moriya interaction (DMI).

Firstly, we demonstrate spin-orbit torque switching of the magnetization in Ta/Co20Fe60B20/MgO nanowires by current pulse injection along the nanowires, both with and without a magnetic field collinear to the current. A component of magnetization along the current direction is required for the switching to occur, and we find that this may be present, even in zero field, due to thermally generated fluctuations. Our data are analysed using a generalized Neel-Brown model which enables the attempt frequency and effective energy barrier to be extracted.

Secondly, we observe current-induced domain wall motion in Ta/Co20Fe60B20/MgO nanowires against the electron flow when no magnetic field is applied. A field along the nanowires strongly affects the domain wall velocity, the magnitude and direction of which is in agreement with the spin-orbit torque model. A DMI effective field of 7.8+/-1.2 mT is measured, resulting in a DMI constant +0.06+/-0.01 mJ/m2, corresponding to right-handed domain walls. The positive DMI constant is attributed to the diffusion of B in the Ta layer and its segregation at the Ta/CoFeB interface. Using 1D model simulations that include pinning we reproduce the experimental data and extract a spin Hall angle of -0.11 for Ta.

9551-26, Session 7

Transport at spin-orbit and exchange-split interfaces and universal giant asymmetry

Huong Thi Dang, Ecole Polytechnique (France); Henri Jaffrès, Unité Mixte de Physique CNRS/Thales (France); T. L. Hoai Nguyen, Vietnam Academy of Science and Technology (Viet Nam); Henri-Jean Drouhin, Ecole Polytechnique (France)

We report on theoretical investigations and k.p calculations of carrier tunneling, both electrons and holes, in model systems and heterostructures composed of exchange-split III-V semiconductors, involving spin-orbit interactions. The two media are separated-or not-by a thin tunnel barrier made out of a (III-V) semiconductor. In a 2x2 exchange-split band model, we show that, when Dresselhaus interactions are included in the conduction band of two exchange-split semiconductors in contact in the antiparallel states of magnetization, the electrons are differently transmitted with respect to an axis orthogonal to both normal axis of the interface and of the magnetization. The transmission asymmetry (A) between +k// and -k// incidence is shown to be maximal (A=100%) at some points of the Brillouin zone corresponding to a totally quenched transmission at some given incidence angles. More generally, we derive a universal character of the transmission asymmetry A vs. the in-plane incidence wavevector, the reduced kinetic energy and exchange parameter, A being universally scaled by a unique function, independent of the spin-orbit strength and of material parameters. This particular asymmetry feature is reproduced by a more complete 14x14 band model involving coupling with the conduction band. On the other hand, calculations performed in the valence-band of equivalent model heterostructures and including tunnel barriers in both 6x6 (without inversion) and 14x14 k.p band model more astonishingly highlight, the same trends in the transmission asymmetry (A) which is related to the difference of orbital chirality and to the related branching (overlap) of the corresponding evanescent wavefunctions responsible for tunneling current. In both cases of electrons and holes, the asymmetry appears to be robust and persists only when a single electrode is magnetic.

9551-27, Session 8

Spin and phase relaxation dynamics in GaN and GaN/AlGaN quantum wells *(Invited Paper)*

Mathieu Gallart, Marc Ziegler, Bernd H. Hönerlage, Pierre Gilliot, Institut de Physique et Chimie des Matériaux de Strasbourg (France); Eric Feltin, Jean-François Carlin, Raphaël Butté, Nicolas Grandjean, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

By performing time-resolved optical non-degenerate pump-probe experiments, we study the relaxation dynamics of spin-polarized excitons in wurtzite epitaxial GaN and in nitride nanostructures. Those materials are indeed promising candidates for spintronic applications because of their weak spin-orbit coupling and large exciton binding energy (~ 17?meV and ~ 26meV in bulk GaN, respectively).

In epilayers, we show that the high density of dislocations increases dramatically the spin relaxation of electrons and holes through the defect assisted Elliott-Yafet mechanism. That makes the exciton dephasing time very short.

In high quality GaN/AlGaN quantum wells, both the exciton-spin lifetime ?S and the exciton dephasing-time T2 were determined via pump-probe spectroscopy using polarized laser pulses and time-resolved four wave-mixing experiments. The evolution of both quantities with temperature shows that spin relaxation occurs in the motional narrowing regime up to 80 K. Above this threshold, the thermal energy becomes large enough for excitons to escape from the QW. Such measurements demonstrate that GaN-based heterostructures can reach a very high degree of control that was previously mostly restricted to conventional III-V semiconductors and more specifically to the arsenide family.

9551-28, Session 8

Ultrafast magneto-optical spectroscopy of BiFeO3-BaTiO3 based structures *(Invited Paper)*

Giti A. Khodaparast, Brenden A. Magill, Michael A. Meeker, Anuj Chopra, Yuon Zhou, Hyun-Cheol Song, Virginia Polytechnic Institute and State Univ. (United States); Michael Bishop, Stephen A. McGill, National High Magnetic Field Lab. (United States); Christopher J. Stanton, Univ. of Florida (United States); Shashank Priya, Virginia Polytechnic Institute and State Univ. (United States)

Ultrafast optical spectroscopy can provide insight into fundamental microscopic interactions, dynamics and the coupling of several degrees of freedom. Pump/ probe studies can reveal the answer to questions like “What are the achievable switching speeds in multiferroics?”, “What is the influence of the crystallographic orientation and domain states on the available switching states?”, and “What is the effect of the hetrostructure on promoting the coupling between the varying field excitations?”. In this presentation, we report on two color (400/800nm) ultrafast pump-probe differential reflectance spectroscopy of BiFeO3-BaTiO3 structures to probe the coupling between optical and acoustic phonons to spin waves. The data presented here is a combination of different transient reflectivity measurements to probe both the carrier and spin dynamics. The (001)-BiFeO3-BaTiO3 thin films were prepared using pulsed laser deposition on vicinal SrTiO3 substrates using La0.70 Sr0.30MnO3 bottom electrodes. Crystal orientation and topography were analyzed by x-ray diffraction and atomic force microscopy. . Our results are important to developing devices on the basis of this material system.

This work was supported by the AFOSR through grant FA9550-14-1-0376,NSF-Career Award DMR-0846834, and the Virginia Tech Institute for Critical Technology and Applied Science.

9551-29, Session 8

Ultrafast spectroscopy in high magnetic fields using the 25 Tesla Split Florida Helix *(Invited Paper)*

David J. Hilton, The Univ. of Alabama at Birmingham (United States)

Two-dimensional systems offer a rich array of physical phenomena that include the integer and fractional quantum Hall effects, both of which have been observed in multiple materials systems to date. The mitigation and control of coherence in quantum states in 2D systems is an area of great current interest that is critical for the development of the next generation of solid state electronics based on quantum phenomena. In the first experiments that I will discuss, we investigate the terahertz frequency properties of a high mobility (? ≥ 106 cm2 V-1 s-1) gallium arsenide two-dimensional electron gas (2DEG) at cyclotron resonance in a perpendicular magnetic field, which results in the formation of a spectrum of Landau levels. Our experiments reveal a strong increase in the decoherence at low temperatures and a power law dependence to the decoherence time from T = 0.4 - 100 K. In the second part of the talk, I will discuss our high fluence, nondegenerate pump-probe spectroscopic experiments of GaAs in the Florida Split Helix magnet at 15 K and 25 T. We model the electronic component of our data with an approximate four level system, from which we have extracted scattering and recombination rates in high magnetic field. We also observe coherent phonons, which were isolated and fitted to a sinusoid with an oscillation frequency of 43.5 GHz at 25 T, which is 3.0% larger than the previously measured zero field frequency.

9551-30, Session 9

Time-resolved spectroscopy of coupled spin-valley-dynamics in monolayer transition metal dichalcogenides at low temperatures *(Invited Paper)*

Gerd Plechinger, Philipp Nagler, Christian Schüller, Tobias Korn, Univ. Regensburg (Germany)

The recent interest in semiconducting transition metal dichalcogenides (TMDs) such as MoS2, and WS2 has been kindled by their fascinating optical properties and peculiar band structure, which suggest potential applications for spintronics. In contrast to the bulk crystals, single-layer TMDs have a direct bandgap located at the K points in the Brillouin zone. They show strong excitonic effects due to the two-dimensional carrier confinement, and a coupling of valley and spin degrees of freedom. In these materials, optical selection rules allow valley-selective excitation of spin-polarized electron-hole pairs using resonant, circularly-polarized excitation, and the valley polarization can directly be determined by helicity-resolved photoluminescence.

Here, we demonstrate the exfoliation of large-area monolayer flakes prepared from bulk TMD crystals. The flakes are first characterized using Raman and photoluminescence measurements. We then utilize time-resolved Kerr rotation (TRKR) measurements to probe the valley dynamics in the monolayer flakes at low temperatures. This technique allows resonant excitation of the excitonic transitions and yields sub-picosecond resolution.

We find valley lifetimes of about 60 ps at a temperature of 4 K in monolayer MoS2 for resonant excitation. With increasing temperatures, we observe a dramatic decrease of the valley lifetimes, indicating that valley dephasing is mediated by phonon-related scattering processes. The MoS2 valley lifetime can be significantly enhanced by mildly annealing the samples in vacuum to remove surface adsorbates, indicating that these adsorbates, acting as scattering centers, also play an important role in valley depolarization.

Financial support by the DFG via SFB 689, GRK1570 and KO3612-1/1 is gratefully acknowledged.

9551-31, Session 9

Disentangling intra and intervalley dynamics in monolayer MoS2 by ultrafast optical techniques *(Invited Paper)*

Stefano Dal Conte, CNR-Istituto di Fotonica e Nanotecnologie (Italy) and Politecnico di Milano (Italy)

The field of spintronics has recently experienced a strong boost after the advent of atomically thin Transition Metal Dichalcogenides (TMDs). In this work we measure separately the spin and valley relaxation dynamics of both electrons and holes in the prototypical TMD monolayer MoS2. We combine together two ultrafast optical spectroscopy techniques i.e. Time Resolved Circular Dichroism (TRCD) and Time Resolved Faraday Rotation (TRFR) in order to disentangle intra and intervalley relaxation processes. TRCD experiments are performed by exciting the sample with an ultrashort circularly polarized pulse, resonant with the optical gap, and measuring the difference between the transient absorption response probed by co- and counter- circularly polarized pulses. These measurements reveal an extremely fast intravalley relaxation of the spin of the photoexcited electrons and demonstrate that the valley polarization is strongly quenched after few ps. TRFR experiments are performed in a two-color configuration, i.e. the energy of the probe pulse is tuned well below the absorption gap. In these conditions, the Faraday rotation transient signal is related to an unbalanced distribution of the photoexcited carrier orbital degrees of freedom. Since the orbital momentum in MoS2 single layer is locked with the valley index, TRFR measurements probe exclusively the intervalley dynamics of electrons and holes. The combination of TRFR and TRCD allows us to disentangle intervalley and intravalley dynamics. Both TRCD and TRFR experiments are quantitatively explained by a set of rate equations which take into account intervalley and intravalley relaxation channels.

9551-32, Session 9

Exciton fine structure and spin/valley dynamics in nanosystems *(Invited Paper)*

Mikhail M. Glazov, Ioffe Physical-Technical Institute (Russian Federation)

In my invited talk the fine structure of neutral and charged excitons for GaAs/AlGaAs quantum dots (QDs) grown on (111) plane as well for transition metal dichalcogenides (TMDCs) monolayers will be discussed. These, at first glance, different systems posses similar trigonal symmetry, which makes exciton fine structure and spin dynamics unusual compared with standard low-dimensional semiconductors. The effects of long-range exchange interaction induced mixing of excitons in two valleys of TMDCs and of magneto-induced mixing of bright and dark excitonic states in trigonal QDs are predicted and confirmed experimentally. Manifestations of excitonic spin/valley dynamics in photoluminescence, pump-probe Kerr rotation and spin noise are discussed.

The presentation will be based on the following references:

Generation of valley-spin currents in 2D transition metal dichalcogenides *(Invited Paper)*

Wang Yao, The Univ. of Hong Kong (Hong Kong, China)

The recent emergence of two-dimensional transition metal dichalcogenides (TMDs) provides a new laboratory for exploring the internal quantum degrees of freedom of electrons for new electronics [1]. These include the real electron spin and the valley pseudospin that labels the degenerate band extrema in momentum space. The generation and control of spin and valley pseudospin currents are at the heart of spin and valley based electronics. We will discuss two mechanisms for generating spin and valley currents of electrons in 2D transition metal dichalcogenides: (I) the valley and spin Hall current arising from the Berry curvatures [2,3]; and (II) the nonlinear valley and spin currents arising from Fermi pocket anisotropy [4]. We discuss the possibility to observe and distinguish the two effects as distinct patterns of polarized electroluminescence at pn junction in monolayer TMDs. We show that the nonlinear current response allow two unprecedented possibilities to generate pure spin and valley flows without net charge current, either by an AC bias or by an inhomogeneous temperature distribution. We will also discuss the valley Hall effect of charged excitons in monolayer TMDs, which arises from the exchange interaction between the electron and hole constituents [5].

Spin relaxation and intervalley scattering in 2D semiconductors *(Invited Paper)*

Aubrey Hanbicki, Marc Currie, U.S. Naval Research Lab. (United States); George Kioseoglou, Univ. of Crete (Greece); C. Stephen Hellberg, Kathleen M. McCreary, Adam L. Friedman, Berend T. Jonker, U.S. Naval Research Lab. (United States)

Monolayer transition metal dichalcogenides, MX2 (M = Mo, W and X = S, Se), are direct-gap semiconductors with some interesting properties. First, the low-dimensional hexagonal structure leads to two inequivalent K-points, K and K', in the brillioun zone. Second, this valley index and spin are intrinsically coupled, and spin-dependent selection rules enable one to independently populate and interrogate a unique K valley with circularly polarized light. Here we probe the degree of circular polarization of the emitted photoluminescence as function of the photo-excitation energy and temperature to elucidate spin-dependent inter- and intra-valley relaxation mechanisms. Monolayer flakes of MoS2 and MoSe2 show a strong depolarization as the excitation energy is increased. However, WS2 maintains significant polarization for high excitation energies, even at room temperature when properly prepared. We discuss the behavior of the polarization in terms of various phonon assisted intervalley scattering processes. This work was supported by NRL and the NRL Nanoscience Institute

9551-35, Session 10

Valley dynamics and excitonic effects in transition metal dichalcogenide monolayers *(Invited Paper)*

Gang Wang, Xavier Marie, Iann Gerber, Thierry Amand, Delphine Lagarde, Louis Bouet, Maël Vidal, Andréa Balocchi, Bernhard Urbaszek, Lab. de Physique et Chimie des Nano-objets (France) and Ctr. National de la Recherche Scientifique (France) and Univ. de Toulouse (France)

The closely related transition metal dichalcogenides (TMDC) MoS2, MoSe2, WSe2 and WS2 have a direct optical bandgap in the visible region around 1.8 eV when thinned down to one monolayer (ML) and show strong optical absorption (>10% / ML). ML TMDCs provide unique and convenient access to controlling the electron valley degree of freedom in k-space in the emerging field of 'valleytronics'. We show how the electron valley index can be initialized and read out optically in time and polarization resolved photoluminescence measurements [1]. The polarization properties of bilayers will be discussed for comparison [2].

When electrons and holes are simultaneously present in a ML, they will form excitons as the Coulomb interaction is enhanced by the strong quantum confinement, the large effective masses and the reduced dielectric screening in these ideal 2D systems. We determine large exciton binding energies of typically 0.5eV. We will demonstrate a variation over several orders of magnitude of the non-linear and linear optical response of ML WSe2 and MoSe2. This is achieved by tuning the optical excitation 'ON' and 'OFF' resonance with respect to the ground (1s) and excited (2s, 2p, ...) exciton states. We show that at these particular energies, identified in 1 and 2-photon excitation spectroscopy, the light-matter interaction is strongly enhanced [3].

Homoepitaxial graphene tunnel barriers for spin transport *(Invited Paper)*

Adam L. Friedman, U.S. Naval Research Lab. (United States)

Tunnel barriers are key elements for both charge-and spin-based electronics, offering devices with reduced power consumption and new paradigms for information processing. Such devices require mating dissimilar materials, raising issues of heteroepitaxy, interface stability, and electronic states that severely complicate fabrication and compromise performance. Graphene is the perfect tunnel barrier. It is an insulator out-of-plane, possesses a defect-free, linear habit, and is impervious to interdiffusion. Nonetheless, true tunneling between two stacked graphene layers is not possible in environmental conditions (magnetic field, temperature, etc.) usable for electronics applications. However, two stacked graphene layers can be decoupled using chemical functionalization. Here, we demonstrate homoepitaxial tunnel barrier devices in which graphene serves as both the tunnel barrier and the high mobility transport channel. Beginning with multilayer graphene, we fluorinate or hydrogenate the top layer to decouple it from the bottom layer, so that it serves as a single monolayer tunnel barrier for both charge and spin injection into the lower graphene transport channel. We demonstrate successful tunneling by measuring non-linear IV curves, and a weakly temperature dependent zero bias resistance. We perform lateral transport of spin currents in non-local spin-valve structures and determine spin lifetimes with the non-local Hanle effect to be commensurate with previous studies (~200 ps). However, we also demonstrate the highest spin polarization efficiencies (~45%) yet measured in graphene-based spin devices [1].

9551-37, Session 10

Long distance spin transport in CVD graphene and spin filtering with h-BN barrier *(Invited Paper)*

Saroj P. Dash, Chalmers Univ. of Technology (Sweden)

Spintronics research in two dimensional (2D) atomic crystals is considered to be very promising. It provides a large class of materials proposed to be important for long distance spin transport and insulators for spin polarized tunneling. Here we will present two important advancements in graphene spintronics: (i) Long distance spin communication in CVD graphene on SiO2/Si substrate at room temperature, and (ii) Spin filtering in ferromagnet/hBN-graphene van der Waals heterostructures. Graphene is proposed to be an ideal material for spin transport channels due to the high mobility and long spin lifetime of the carriers. We demonstrated the effect of ferromagnetic tunnel contacts [1] and channel length dependence on the spin signal, achieving spin transports over distances of 16 μm and spin lifetimes up to 1.2 ns in CVD graphene [2]. These spin parameters are up to five times higher than previous reports on CVD graphene and highest at room temperature for any form of pristine graphene on industrial standard SiO2¬¬¬/Si substrates. Our detailed investigations reinforce the observed performance over a wafer scale demonstrating CVD graphene as an excellent material for long distance spin transport in lateral spin based devices. Furthermore, using the h-BN as a tunnel barrier on graphene, we observe an enhancement in spin polarization [3], and negative spin polarization for thicker h-BN layers [4]. The large magnitude of spin polarization together with its negative sign provides experimental evidence of the spin filtering across the ferromagnet/hBN-graphene van der Waals heterostructures. These results highlight the potential role of 2D atomic crystals in future spintronic devices.

Spintronic and optical properties of 2D materials *(Invited Paper)*

Roland K. Kawakami, Univ. of California, Riverside (United States)

As atomically-thin conductors, two dimensional (2D) materials enable new behaviors for spintronics and optoelectronics. The ability to stack 2D materials with differing properties allows one to combine and manipulate their electronic, spintronic, and optical properties at the atomic scale. The majority of our work has focused on graphene, which has been demonstrated to be an excellent spin channel material with extremely long spin diffusion lengths at room temperature (several microns). We have demonstrated efficient spin injection and spin transport in graphene, investigated the effects of adatom doping. Most strikingly, spin transport has been utilized as a very sensitive magnetometer to detect the formation of magnetic moments due to point defects including hydrogen adatoms and lattice vacancies. Beyond graphene, we have investigated new 2D semiconductors including transition metal dichalcogenides and germanane.

Both have direct bandgap transitions with optical selection rules that permit the optical excitation of spin polarization and/or valley polarization. Our efforts include the combined optical and electrical study of 2D semiconductors and their junctions with graphene and metals via transport, photoluminescence, photoconductivity, and ultrafast optics.

Graphene: new venues for spintronics *(Invited Paper)*

Pierre Seneor, Unité Mixte de Physique CNRS/Thales (France)

The recent discovery of graphene has opened novel exciting opportunities in terms of functionalities and performances for spintronics devices. We will present experimental results on the impact and potential of graphene for spintronics. We will show that unprecedented highly e?cient spin information transport can occur in graphene [1] leading to large spin signals and macroscopic spin di?usion lengths (?100 microns), potentially a key enabler for the advent of envisioned beyond-CMOS spinbased logic architectures. Furthermore, we will show that a thin graphene passivation layer can prevent the oxidation of a ferromagnet [2], enabling its use in novel humide/ambient low-cost processes for spintronics devices (such as Atomic Layer Deposition (ALD) already used intensively in micro-electronics industry but absent from spintronics), while keeping its highly surface sensitive spin current polarizer/analyzer behavior and adding new enhanced spin filtering property with almost full spin polarization reversal [3]. This could be of strong interests for MTJs or molecular spintronics [4]. These different experiments unveil promising uses of graphene for spintronics.

Properties of light emission from multilayer InGaAs/GaAsP solid-state spin-lasers and VECSELs

Tibor Fördös, Ecole Polytechnique (France) and V?B-Technical Univ. of Ostrava (Czech Republic); Henri Jaffrès, Unité Mixte de Physique CNRS/Thales (France); Kamil Postava, V?B-Technical Univ. of Ostrava (Czech Republic); Jean-Marie George, Unité Mixte de Physique CNRS/Thales (France); Jaromír Pi?tora, V?B-Technical Univ. of Ostrava (Czech Republic); Henri-Jean Drouhin, Ecole Polytechnique (France)

Spin-polarized light sources such as spin-polarized light-emitting diodes (spin-LEDs) and spin-polarized lasers (spin-lasers and VECSELS) are prospective devices in which the spin information carried-out by the injected electrons is encoded into the circular polarization of emitted photons [1]. We will first report on a new approach for modeling of polarized light emission from spin-polarized vertical-cavity surface-emitting lasers and diodes with multiple quantum well dipole sources. The proposed method [2] is based on a 4x4 matrix formalism describing propagation of electromagnetic field in multilayer system and including boundary conditions of Maxwell equations on interfaces as well as dipolar sources in active regions or quantum wells to describe spontaneous (spin-LEDs) and stimulated (spin-VECSELs) emission. Impact of the particular linear birefrigence of the overall heterostructure [3] caused by in-plane symmetry breaking due to lattice strain, residual stress, on the emitted polarization state is demonstrated on InGaAs/GaAsP MQW laser structure characterized by a series of experiments using Mueller matrix spectroscopic ellipsometry. In particular, we will give, by numerical methods, the properties of the output laser modes under spin-polarized carrier pump (optical and electrical) vs. the degree of linear birefringence within the heterostructure competing with the circular gain imposed by optical recombination.

Electron spin injection and transport in (110) quantum wells for room temperature operation of spin-controlled vertical-cavity surface-emitting lasers *(Invited Paper)*

Nobuhide Yokota, Kazuhiro Ikeda, Nara Institute of Science and Technology (Japan); Nozomi Nishizawa, Hiro Munekata, Tokyo Institute of Technology (Japan); Hitoshi Kawaguchi, Nara Institute of Science and Technology (Japan)

Spin-controlled vertical-cavity surface-emitting lasers (sc-VCSELs) have been attracting researchers' interest because they can achieve oscillation with a single circular polarization mode controlled by electron spin polarization in the active region. A long electron spin relaxation time ts is crucial for sc-VCSELs to exhibit a high degree of circular polarization Pc. (110)-oriented quantum wells (QWs) are thus attractive owing to their ts much longer than (100)-oriented QWs even at room temperature (RT). In this presentation, we report our recent studies toward realization of sc-VCSEL operating at RT.

We investigated electrical spin injection into (110) GaAs QWs in light-emitting diodes having Fe/crystalline-AlOx (Fe/x-AlOx) tunnel barrier contacts. A Pc of 2.6% was obtained at RT even with a current density of 1.5 kA/cm2 required for VCSELs to oscillate. The degree of initial electron spin polarization in the QWs estimated from the measured value of Pc was 9.3% at RT, which suggests that lasing with a high Pc value can be achieved under electrical spin injection in VCSELs with the Fe/x-AlOx contacts.

Observation of a 37-um electron spin transport at RT in (110) GaAs QWs with an in-plane electric field of 1.75?kV/cm suggests that (110) QWs are useful as a spin transport layer for sc-VCSELs.

The electron spin relaxation originating from the D'yakonov-Perel' and Bir-Aronov-Pikus mechanisms was found to be small in both (110) and (100) InGaAs/InAlAs QWs. This result implies that the sc-VCSEL operating at RT and a telecom wavelength of 1.55 um will be obtained by using conventional (100) InGaAs/InAlAs QWs.

9551-42, Session 11

Growth condition dependence of carrier and spin lifetimes in GaAs-based quantum wells *(Invited Paper)*

Satoshi Iba, Hidekazu Saito, National Institute of Advanced Industrial Science and Technology (Japan); Ken Watanabe, Yuzo Ohno, Univ. of Tsukuba (Japan); Shinji Yuasa, National Institute of Advanced Industrial Science and Technology (Japan)

Spin-polarized light-emitting diode (spin-LED), which consists of a ferromagnetic (FM) contact and semiconductor quantum well (QW), is an essential element for future spin-optical devices such as spin laser [1,2]. So far, the FM contact has attracted much attention to achieve a highly circularly polarized electroluminescence (EL). However, it is also important

to study carrier and spin dynamics in the QW part because the polarizability strongly depends on those properties [1]. In this study, we systematically investigated the effect of growth conditions on the carrier and spin lifetimes in the (001) GaAs/AlGaAs QWs at room temperature.

All the undoped samples were grown using MBE under the different As4/Ga flux ratios and growth temperature conditions. The carrier lifetimes (t_c) strongly depend on both the As4/Ga ratio and the growth temperature (0.4-9 ns), whereas the spin relaxation times (t_s) are almost constant at about 0.2 ns. These results suggest that the circular polarization of the PL (P_PL) is largely affected by the growth conditions because the P_PL is given by t_s/(t_c+t_s)P_s, where the P_s is the electron spin polarization (constant in our measurements). Actually, we confirmed that the P_PL values depend considerably on growth conditions as expected from the t_c and t_s values. Hence, choosing the appropriate growth condition of the QW is indispensable for obtaining a high EL polarization from the spin-LED.

Continuous visible-light emission at room temperature in Mn-doped GaAs and Si light-emitting diodes *(Invited Paper)*

Masaaki Tanaka, Pham Nam Hai, Le Duc Anh, The Univ. of Tokyo (Japan)

We demonstrate visible-light electroluminescence due to d-d transitions in GaAs:Mn based light emitting diodes (LEDs) [1][2]. We prepared p+n junctions with a p+GaAs:Mn layer. At a reverse bias voltage (-3 to -6V), holes are injected from the n-type layer to the depletion layer and accelerated by the intense electric field, and excite the d electrons of Mn in the p+GaAs:Mn layer by impact excitations. We observe visible-light emission E1 = 1.89eV and E2 = 2.16eV, which are exactly the same as the 4T1 -> 6A1 and 4A2 -> 4 T1 transition energy of Mn.

Furthermore, by utilizing optical transitions between the p-d hybridized orbitals of Mn atoms doped in Si, we demonstrate Si-based LEDs that continuously emit reddish-yellow visible light at room temperature. The Mn p-d hybrid states are excited by hot holes that are accelerated in the depletion layers of reverse biased Si pn junctions. Above a threshold reverse bias voltage of about -4V, our LEDs show strong visible light emission with two peaks at E1 = 1.75eV and E2 = 2.30eV, corresponding to optical transitions from the t-a (spin-down anti-bonding) states to the e- (spin-down non-bonding) states, and from the e- to the t+a (spin-up anti-bonding) states. The internal quantum efficiency of the E1 and E2 transitions is 3-4 orders of magnitude higher than that of the indirect band-gap transition [3].

Time-evolution of wave-packets in topological insulators *(Invited Paper)*

Gerson J. Ferreira, Univ. Federal de Uberlândia (Brazil); Poliana H. Penteado, José Carlos Egues, Univ. de São Paulo (Brazil)

The electronic structure of topological insulators (TIs) are well described Dirac-like equations, e.g. the BHZ model, with a mass term that changes sign at some interface. This simplistic description includes a pseudo-spin-orbit coupling that is intrinsic to the Dirac Hamiltonian. Consequently, the TIs share common properties with the Dirac equation. Among them, the interference between positive and negative energy bands leads to the relativistic oscillatory motion known as the Zitterbewegung. Here we discuss the ballistic time-evolution (pico and nanoseconds) of wave-packets in TIs in the presence of an external electric field. We show that the guiding center of large wave-packets have a finite motion transversal to the electric field equivalent to side-jump in Rashba GaAs. However, for narrow wave-packets the dynamics change and the guiding center description is not complete. We also discuss the reflection of a wave-packet colliding with the edge of the system and the effects of the edge states.

Skyrmions in quasi-2D chiral magnets with broken bulk and surface inversion symmetry *(Invited Paper)*

Mohit Randeria, The Ohio State Univ. (United States); Sumilan Banerjee, Weizmann Institute of Science (Israel); James Rowland, The Ohio State Univ. (United States)

Most theoretical studies of chiral magnetism, and the resulting spin textures, have focused on 3D systems with broken bulk inversion symmetry, where skyrmions are stabilized by easy-axis anisotropy. In this talk I will describe our results on 2D and quasi-2D systems with broken surface inversion, where we find [1] that skyrmion crystals are much more stable than in 3D, especially for the case of easy-plane anisotropy. These results are of particular interest for thin films, surfaces, and oxide interfaces [2], where broken surface-inversion symmetry and Rashba spin-orbit coupling naturally lead to both the chiral Dzyaloshinskii-Moriya (DM) interaction and to easy-plane compass anisotropy. I will then turn to systems that break both bulk and surface inversion, resulting in two distinct DM terms arising from Dresselhaus and Rashba spin-orbit coupling. I will describe [3] the evolution of the skyrmion structure and of the phase diagram as a function of the ratio of Dresselhaus and Rashba terms, which can be tuned by varying film thickness and strain.

Spirals and skyrmions in two dimensional oxide heterostructures *(Invited Paper)*

Xiaopeng Li, Univ. of Maryland, College Park (United States); W. Vincent Liu, Univ. of Pittsburgh (United States); Leon Balents, Univ. of California, Santa Barbara (United States)

Metallic interfaces between insulating oxides such as STO-LAO or STO-GTO provide a versatile platform to study two dimensional electron liquids. Numerous experiments have observed magnetism and significant spin-orbit effects in such structures. We construct the general free energy governing long-wavelength magnetism in two-dimensional oxide heterostructures, which applies irrespective of the microscopic mechanism for magnetism. This leads, in the relevant regime of weak but non-negligible spin-orbit coupling, to a rich phase diagram containing in-plane ferromagnetic, spiral, cone, and skyrmion lattice phases, as well as a nematic state stabilized by thermal fluctuations.

9551-47, Session 12

Electrical injection and detection of spin-polarized currents in 3D topological insulators *(Invited Paper)*

Jifa Tian, Purdue Univ. (United States)

Topological insulators (TIs) are an unusual phase of quantum matter with nontrivial spin-momentum locked topological surface states (TSS). The electrical detection of spin-momentum locking of the TSS in 3D TIs has been lacking till very recently. In this talk, we will present the spin potentiometric measurements in thin flakes exfoliated from 3D TI Bi2Te2Se (BTS221) and Bi2Se3 bulk crystals, using two outside nonmagnetic (Au) contacts for driving a DC spin helical current and a middle ferromagnetic (FM)-Al2O3 tunneling contact for detecting spin polarization. The voltage measured by the FM electrode exhibits a hysteretic step-like change when sweeping an in-plane magnetic field between opposite directions along the easy axis of the FM contact to switch its magnetization. Importantly, the direction of the voltage change can be reversed by reversing the direction of the DC current, and the amplitude of the change as measured by the difference in the detector voltage between opposite magnetization increases linearly with increasing bias current, consistent with the current-induced spin polarization of spin-momentum-locked TSS. Our work directly demonstrates the electrical injection and detection of spin polarization in TI and may enable utilization of spin-helical TSS for future applications in nanoelectronics and spintronics.

Magnon Hall effect *(Invited Paper)*

Yoshinori Onose, The Univ. of Tokyo (Japan)

In itinerant ferromagnets, the Hall effect proportional to the magnetization, which is termed anomalous Hall effect, is driven by the relativistic spin-orbit interaction, and does not require the Lorentz force. Therefore, an important question is whether charge neutral magnons can show the anomalous Hall effect.

Recently, we have succeeded in observing the magnon Hall effect for the first time in terms of thermal transport. We also observe the distinct effect of lattice geometry on the magnon Hall effect, which can be well explained by the picture of the Dzyaloshinskii-Moriya interaction-induced magnon Hall effect.

9551-49, Session 13

Magnonic Hall effect and topological magnonic crystals *(Invited Paper)*

Shuichi Murakami, Tokyo Institute of Technology (Japan)

In electronic systems it is well established that when there is a magnetic field or spontaneous magnetization, the Hall effect, and in some cases the quantum Hall effect appears. We theoretically pursue analogs of these phenomena in magnons (spin waves) and plasmons. In the case of magnons in ferromagnets, the Hall effect or quantum Hall effect requires some kind of a spin-orbit coupling (similar to electronic systems), and we show that the dipolar interaction, as well as the Dyaloshinskii-Moriya interaction, plays the role. By calculating the Berry curvature from the wavefunction, we can calculate thermal Hall effect for magnons in ferromagnets with dipolar interaction. We found that only the magnetostatic forward volume-wave mode exhibits the thermal Hall effect while the backward mode and the surface mode do not. In addition, by introducing some artificial spatial periodicity into the magnet, for example by fabricating nanostructures with two different magnets in a periodic structure or by making a periodic array of nanomagnets, we theoretically find appearance of quantum Hall effect in a certain range of the magnetic field. There appear chiral edge states which propagate along the edge of the magnet in one way. We call this a topological magnonic crystal. In the plasmon case, we should begin with constructing a fundamental band theory, and we theoretically show that on a metal surface with corrugations forming a triangular lattice under the magnetic field, the quantum Hall effect appears. It can be called a topological plasmonic crystal.

Magnon Hall effect and planar Righi-Leduc effect measured in NiFe and YIG ferromagnets

Benjamin Madon, Do Chung Pham, Ecole Polytechnique (France); Daniel Lacour, Institut Jean Lamour (France); Abdelmadjid Anane, Unité Mixte de Physique CNRS/Thales (France) and Univ. Paris-Sud 11 (France); Rozenn Bernard, Vincent Cros, Unité Mixte de Physique CNRS/Thales (France) and Univ. Paris Sud 11 (France); Michel Hehn, Institut Jean Lamour (France); Jean-Eric Wegrowe, Ecole Polytechnique (France)

A pure magneto-thermal signal (described by the anisotropic Fourier law) was measured in ferromagnets that possess a chiral structure (Lu2V2O7): this is the magnon hall effect (or equivalently “anomalous Righi-Leduc effect”) [1], that is the thermal analogue of the electric anomalous Hall effect. It has then been proposed [2] that the effect could be universal, in the sense that it can also be measured in ferromagnetic materials without specific crystalline structures, like NiFe (metallic) or Yttrium Iron Garnets (YIG, electric insulator). Furthermore, it has been predicted that the Magnon-Hall effect should be associated with the “Planar Righi-Leduc effect” (which is the thermal analogue of the electric planar-Hall effect).

We report here about a comparative study of the Magnon-Hall and planar Righi-Leduc effect performed on both NiFe and YIG ferromagnets. For the first time, the magneto-thermal effect is measured with a thin electrode deposited on the top of a ferromagnetic layer. This electrode plays the role of the thermocouple. The corresponding magneto-thermo-voltage is measured as a function of the quasi-static magnetization states. It is shown that, for a heat current confined in the plane of the ferromagnetic layer and oriented perpendicular to the electrode, the Magnon-Hall signal follows a 360° periodicity as a function of the out-of-plane angle of the magnetization, while the Planar Righi-Leduc signal follows a 180° periodicity as a function of the in-plane angle.

The relation between these observations and the occurrence of the inverse spin-Hall effect (which is responsible for the spin-Seebecl effect[3]) is discussed.

Helimagnetism in nanometer small bilayer iron islands *(Invited Paper)*

Dirk Sander, Max-Planck-Institut für Mikrostrukturphysik (Germany)

We report a novel noncollinear magnetic order in individual nanostructures of a prototypical magnetic material, bilayer iron islands on Cu (111) [1]. Spin-polarized scanning tunnelling microscopy reveals a magnetic stripe phase with a period of 1.28 nm, which is identified as a one-dimensional helical spin order. Ab initio calculations reveal reduced-dimensionality-enhanced long-range antiferromagnetic interactions as the driving force of this spin order. Our findings point at the potential of nanostructured magnets to establish noncollinear magnetic order in a nanostructure, which is magnetically decoupled from the substrate.

9551-52, Session 14

Toward the realization of a single atom magnet *(Invited Paper)*

Fabio Donati, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Single atoms adsorbed on a solid surface represent a paradigm for investigating the ultimate size limit of a magnet. The main request for their use in information storage and computation is the magnetic bistability, which requires protecting the magnetization of an atom against thermal fluctuations and quantum tunneling. Different strategies have been attempted in this direction, aiming to increase the magnetic anisotropy energy of the adsorbed atom, decouple its spin from the conduction electron of the substrate, and tailor the angular symmetry of the crystal field of the surface. However, the complexity of the interactions between magnetic atoms and surface electrons makes the experimental realization of a single atom magnet a challenging task.

In this talk, I will present the recent advancements in the field, discussing the results achieved in the engineering of the magnetic properties of transition metal and rare earth atoms. First, I will describe how graphene can be successfully used to induce a large magnetic anisotropy in adsorbed Co atoms [Phys. Rev. Lett. 111, 236801 (2013); 113, 177201 (2014)]. For the same atoms, I will show how the magnetic anisotropy can be enhanced to the maximum limit of 58 meV imposed by the spin-orbit coupling by exploiting the almost cylindrical crystal field environment offered by the MgO/Ag(100) surface [Science 344, 988 (2014)]. Finally, I will illustrate how the magnetism of Ho and Er atoms can be tailored via the interaction with closed packed metal surfaces [Phys. Rev. Lett. 113, 237201 (2014)].

9551-53, Session 14

Geometrical phase and inertial regime of the magnetization: Hannay angle and magnetic monopole *(Invited Paper)*

Jean-Eric Wegrowe, Ecole Polytechnique (France)

It is well known that the Landau-Lifshitz-Gilbert (LLG) equation for a macroscopic magnetic moment find its theoretical limit of validity at very short time scales or equivalently at very high frequencies. The reason for this limit of validity is well understood in terms of separation of the characteristic times between slow (the magnetization) and fast (the environment) degrees of freedom, as pointed-out in the stochastic derivation of the LLG equation first proposed by W. F. Brown in 1963 [1]. Indeed, the ferromagnetic moment is a slow collective variable, but fast degrees of freedom are also playing a role in the dynamics, and especially the angular momentum responsible for inertia. In the last couple of years, the generalization of the LLG equation with inertia (ILLG) has been derived by different means [2,3,4]. The signature of the inertial regime of the magnetization is the nutation oscillation - added to the usual precession - that can be measured by resonance experiments (but it has not been observed up to know). However, we show that even for the pure precession movement, the fast degrees of freedom can also play an important role.

We developed an approach in terms of geometrical phase (defining the corresponding Hannay angle [5], which is the classical analog to the quantum Berry phase), that has recently been used with success to analogous problems [6]. We calculated the Hannay angle for the precession of the magnetization in the case of the inertial effect. This analysis allows the slow vs. fast variable expansion to be calculated in the specific case of pure precession. The result is interpreted in terms of classical magnetic monopole.

Laser-induced spin precession for magnetic alloy films in THz wave range *(Invited Paper)*

Shigemi Mizukami, Tohoku Univ. (Japan)

No Abstract Available

9551-55, Session 14

Magnetism in thin films: a spin-resolved investigation of single and multi-layer systems *(Invited Paper)*

Alberto Calloni, Politecnico di Milano (Italy)

An overview of our past and present activity in the study of the magnetic properties of ultrathin films of transition metal elements is presented, with emphasis on spin resolved electron spectroscopy results. The development of perpendicular anisotropies, the observation of oscillatory magnetic coupling and giant magnetoresistence in such multilayer systems are widely exploited by the microelectronic industry for data manipulation and storage. The practical realization and characterization of selected model systems is devised to investigate some of these peculiar magnetic phenomena. In this respect, specific topics will be discussed, such as: (i) the epitaxial growth of monolayer range thin films of Fe and Ni on non-magnetic substrates [such as W(110)], focusing on the occurrence of a spontaneous magnetization as a function of the film thickness and the crystal structure evolution. (ii) The characterization of the magnetic phenomena occurring at the interface/surface of magnetic films. In particular, recent results on the coupling of a thin Cr layer to a Fe(100) substrate, where a layered antiferromagnetic order is induced, will be illustrated, together with some strategies devised to tune the anisotropy energy in thin films made of stacked Fe/Ni(111) and Co/Ni(111) layers, eventually leading to perpendicular magnetization. The role of structural (i.e. the effect of film strain) chemical (i.e. the stability of the interface against atomic diffusion) and procedural issues (i.e. the different strategies devised to promote the layer-by-layer growth of atomically flat interfaces), often the key ingredients for the determination of the magnetic behavior of such systems, will be highlighted.

9551-56, Session 15

Voltage control of nanoscale magnetoelastic elements: theory and experiments *(Invited Paper)*

Gregory P. Carman, Univ. of California, Los Angeles (United States)

Electromagnetic devices rely on electrical currents to generate magnetic fields. While extremely useful this approach has limitations in the small-scale. To overcome the scaling problem, researchers have tried to use electric fields to manipulate a magnetic material’s intrinsic magnetization (i.e. multiferroic). The strain mediated class of multiferroics offers up to 70% of energy transduction using available piezoelectric and magnetoelastic materials. While strain mediated multiferroic is promising, few studies exist on modeling/testing of nanoscale magnetic structures.

This talk presents motivation, analytical models, and experimental data on electrical control of nanoscale single magnetic domain structures. This research is conducted in a NSF Engineering Research Center entitled Translational Applications for Nanoscale Multiferroics TANMS. The models combine micromagnetics (Landau-Lifshitz-Gilbert) with elastodynamics using the electrostatic approximation producing eight fully coupled nonlinear partial differential equations. Qualitative and quantitative verification is achieved with direct comparison to experimental data. The modeling effort guides fabrication and testing on three elements, i.e. nanoscale rings (onion states), ellipses (single domain reorientation), and superparamagnetic elements. Experimental results demonstrate electrical and deterministic control of the magnetic states in the 5-500 nm structures as measured with Photoemission Electron Microscopy PEEM, Magnetic Force Microscopy MFM, or Lorentz Transmission Electron Microscopy TEM. These data strongly suggests efficient control of nanoscale magnetic spin states is possible with voltage.

9551-57, Session 15

Reversible electric field driven magnetic domain wall motion *(Invited Paper)*

Kevin J. A. Franke, Aalto Univ. School of Science and Technology (Finland); Ben Van de Wiele, Univ. Gent (Belgium); Yasuhiro Shirahata, Tokyo Institute of Technology (Japan); Sampo J. Hämäläinen, Aalto Univ. School of Science and Technology (Finland); Tomoyasu Taniyama, Tokyo Institute of Technology (Japan); Sebastiaan van Dijken, Aalto Univ. School of Science and Technology (Finland)

Control of magnetic domain wall motion by electric fields has recently attracted scientific attention because of its potential for magnetic logic and memory devices. Here, we report on a new mechanism for reversible and deterministic motion of magnetic domain walls using an electric field only. Full electric-field control over the magnetic domain-wall velocity in the absence of a magnetic field or spin-polarized electric current is demonstrated using epitaxial Fe films on single-crystal BaTiO3 substrates with alternating in-plane (a domains) and out-of-plane (c domains) ferroelectric polarization [1]. The magnetic domain walls of the Fe film are strongly pinned onto the a-c boundaries of the BaTiO3 substrate by abrupt changes in the symmetry and strength of magnetic anisotropy as a result of strain transfer and inverse magnetostriction [2]. Repeatable back-and-forth motion of a ferroelectric a-c boundary and a pinned magnetic domain wall is realized by the application of positive and negative out-of-plane voltage pulses. The domain-wall velocity is varied over 5 orders of magnitude by adjusting the electric-field strength. Patterning of the magnetic film reveals that near-180° transverse magnetic domain walls can be stabilized in magnetic nanowires on top of BaTiO3 due to competing shape anisotropy. Moreover, the driving mechanism is not affected by pinning centers such as grain boundaries or notches that usually influence the motion of magnetic-field or electric-current driven magnetic domain walls.

Magnetoelectric imaging of multiferroic heterostructures *(Invited Paper)*

Massimo Ghidini, Arnaud Lesaine, Bonan Zhu, Xavier Moya, Wenjing Yan, Sam Crossley, Bhasi Nair, Rhodri Mansell, Russell P. Cowburn, Crispin H. W. Barnes, Univ. of Cambridge (United Kingdom); Florian Kronast, Sergio Valencia, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany); Francesco Maccherozzi, Sarnjeet S. Dhesi, Diamond Light Source Ltd. (United Kingdom); Neil Mathur, Univ. of Cambridge (United Kingdom)

Electrical control of magnetism has been demonstrated in multiferroic compounds and ferromagnetic semiconductors, but electrical switching of a substantial net magnetization at room temperature has not been demonstrated in these materials. This goal has instead been achieved in heterostructures comprising ferromagnetic films in which electrically driven magnetic changes arise due to strain or exchange bias from ferroic substrates, or due to charge effects induced by a gate. However, previous work focused on electrical switching of an in-plane magnetization or involved the assistance of applied magnetic fields.

In heterostructures made of juxtaposed ferroelectric and ferromagnetic layers, we have shown electrical control with no applied magnetic field of the perpendicular magnetization of small features [1] and of magnetic stripe domains patterns [2].

Here we investigate Ni81Fe19 films on ferroelectric substrates with and without buffer layers of Cu, whose presence precludes charge-mediated coupling. Ni81Fe19 has virtually zero magnetostriction, but sufficiently thin films show large magnetostriction, and thus, on increasing film thickness through the threshold for zero magnetostriction, we have seeked the crossover from charge- to strain-mediated coupling.

We will then show that strain associated with the motion of 90°-ferroelectric domain walls in a BaTiO3 substrate, can switch the magnetization of an array of overlying single-domain Ni dots.

Non-collinear magnetic structure in La2/3Sr1/3MnO3/LaNiO3 superlattices *(Invited Paper)*

Anand Bhattacharya, Argonne National Lab. (United States)

Non-collinear magnetic textures give rise to interesting charge and spin transport properties, and allow for control of of magnetism using small electric currents. While these textures have been observed in a number of bulk materials and in thin films, realizing non-collinear magnetism in heterostructures may lead to new avenues to control their properties using tailored interfaces and gate electric fields. We have discovered a non-collinear magnetic coupling in superlattices comprised of two metallic perovskites,

La2/3Sr1/3MnO3 (LSMO) and LaNiO3 (LNO). The angle between the magnetization of the LSMO layers varies in an oscillatory manner with the thickness of the intervening LNO. The magnetic field and temperature dependence of this angle cannot be explained using models that incoporate bilinear and biquadratic coupling, commonly used to describe non-collinear magnetism in conventional metallic heterostructures. Furthermore, we observe substantial electron transfer from the LSMO into the LNO layer, causing the Ni sites in the vicinity of interfaces to be in approximately a 2+ oxidation state. We propose a model where these localized Ni2+ spins in the LNO couple to a momentum dependent spin susceptibility, giving rise to a spiral magnetic structure within the LNO. All our superlattices are synthesized using oxide-MBE, and characterized with a variety of means, including neutron scattering.

Efficient spin-to-charge conversion at LaAlO3/SrTiO3 interfaces *(Invited Paper)*

Edouard Lesne, Juan-Carlos Rojas-Sánchez, Unité Mixte de Physique CNRS/Thales (France); Simon Oyarzun, Yu Fu, CEA-INAC (France); Nicolas Reyren, Eric Jacquet, Vincent Cros, Unité Mixte de Physique CNRS/Thales (France); Gérard Desfonds, Serge Gambarelli, Matthieu Jamet, Jean-Philippe Attané, CEA-INAC (France); Jean-Marie George, Albert Fert, Agnès Barthélémy, Unité Mixte de Physique CNRS/Thales (France); Laurent Vila, CEA-INAC (France); Henri Jaffrès, Unité Mixte de Physique CNRS/Thales (France) and Peter Grünberg Institute (Germany) and Institute for Advanced Simulation (Germany); Manuel Bibes, Unité Mixte de Physique CNRS/Thales (France)

The Rashba effect is a manifestation of spin-orbit interaction (SOI) in solids, where the spin degeneracy associated with the spatial inversion symmetry is lifted due to a symmetry-breaking electric field normal to the heterointerface [1] and giving rise to an electric field modulation effect at e.g. the canonical LaAlO3/SrTiO3 interface, as demonstrated very recently [2]. On the other hand, Eldelstein was the first to realize that in a Rashba two-dimensional electron system, the flow of a charge current is accompanied by a non-zero spin accumulation coming from uncompensated spin-textured Fermi surfaces [3]. Recently, the converse effect, corresponding to a spin-to-charge conversion through SOI (inverse Edelstein effect or IEE), was demonstrated at Ag/Bi(111) interfaces [3].

Here we report on spin-pumping experiments performed on a series of NiFe/LaAlO3/SrTiO3 heterostructures, with possible evidence of efficient spin-to-charge conversion from perpendicular spin injection by spin-pumping method to lateral current measured in voltage detection method. We tentatively interpret these results in terms of the large SOI at the LaAlO3/SrTiO3 interface [5], discuss the corresponding electrostatic modulation of the IEE by a back-gate voltage and give perspectives for oxide-based spintronics free of ferromagnetism.

Periodic and quasiperiodic artificial spin ices: magnetic structure and dynamics *(Invited Paper)*

Christopher H. Marrows, Univ. of Leeds (United Kingdom)

Artificial spin ices are frustrated systems constructed using nanotechnology, where single-domain magnetic nanoislands are arranged in such a manner that their magnetostatic interactions cannot all be simultaneously satisfied. They are often described as designer metamaterials, since all the system parameters can be tuned during the design of the lithography pattern. They are often touted to be model statistical mechanical systems, yet most instances to date are athermal systems described by an effective thermodynamics. Here we report on square ice systems where the island size has been shrunk to the point where the energy barrier to reversal is of the order of kT, and the moment of the islands therefore fluctuates as time passes. These islands are too small to be imaged by conventional magnetic microscopy techniques. Real space X-ray transmission microscopy and reciprocal space X-ray photon correlation spectroscopy studies, both using soft X-rays with XMCD contrast, show the thermally activated dynamics of the system as it explores its phase space.

We have also prepared systems based on Penrose tilings. These have a multiplicity of different structural vertex types, each with its own energy spectrum. MFM shows that high-magnetic charge configurations are avoided, but long-range magnetic order is difficult to observe. Analysis of the vertex energies suggests that the structure can be divided into two parts: a percolating 'skeleton' that possesses a rigid twofold ground state, containing spins that are 'flippable' and do not affect the overall system energy, a signature of true frustration.

Unconventional spin textures in magnetically frustrated topologies *(Invited Paper)*

Nicolas Rougemaille, Ioan Chioar, Institut NÉEL (France); Michel Hehn, Daniel Lacour, François Montaigne, Institut Jean Lamour (France); Benjamin Canals, Institut NÉEL (France)

Frustration is a general concept in physics and can be found in many condensed matter systems. Frustration arises when all pairwise interactions can not be satisfied simultaneously, for example due to the system geometry. In some cases, frustration effects lead to an extensively degenerate ground state, i.e a low-temperature manifold built with a infinite number of configurations with identical energy. Frustrated systems may then have a finite entropy, even at zero temperature.

Progress in fabrication and characterization techniques allowed researchers to produce, artificially, two-dimensional frustrated arrays of nanostructures and to investigate their collective magnetic behavior. These studies have stimulated new research activities motivated by the quest for exotic magnetic phases in condensed matter physics, bringing together the communities of magnetic frustration, statistical physics, and nanomagnetism.

In this contribution, we'll show, experimentally (magnetic imaging techniques) and theoretically (mainly Monte Carlo simulations), that simple magnetic topologies can lead to unconventional, non-collinear spin textures. For example, kagome arrays of ferromagnetic nano-islands with ferromagnetic nearest neighbor interactions do not show magnetic order. Instead, these systems are characterized by spin textures with intriguing properties, such as chirality, coexistence of magnetic order and disorder, and charge crystallization. However, in kagome arrays of ferromagnetic nano-disks with antiferromagnetic interactions between neighboring elements, the system is also characterized by a new magnetic phase, but with a still unknown spin texture.

Direct visualization of the thermodynamics of artificial spin ice systems *(Invited Paper)*

Alan Farhan, Paul Scherrer Institut (Switzerland)

Recent years have shown a significant amount of research being directed towards investigations on artificial spin ice systems [1, 2], which mimic the behavior of geometrically frustrated pyrochlore spin ice [3]. Here, we present first direct observations of thermally induced magnetic relaxation in extended arrays of artificial square ice [4] and building block structures of artificial kagome spin ice [5, 6]. While thermal relaxation leads to a clear route towards the ground state in artificial square ice [4], we observe an increasing difficulty in accessing the predicted ground state configuration in artificial kagome spin ice with increasing system size [5, 6]. This makes artificial kagome spin ice an ideal system to visualize an optimization of applied annealing procedures. From a general point of view, our methods offer the possibility to observe and investigate the thermodynamics of two-dimensional frustrated systems in real space and time, and provide a way to directly investigate the nature of complex stochastic processes.

Artificial spin ice: from scientific toy to material by design *(Invited Paper)*

Cristiano Nisoli, Los Alamos National Lab. (United States); Peter Schiffer, Ian Gilbert, Univ. of Illinois at Urbana-Champaign (United States)

Frustration, the presence of constraints/interactions that cannot be completely satisfied, is ubiquitous in the physical sciences as well as in life and a source of degeneracy and disorder which gives rise to new and interesting physical phenomena. In the past years a new perspective has opened in the study of frustration through the creation of artificial frustrated magnetic systems, consisting of arrays of lithographically fabricated single-domain ferromagnetic nanostructures that behave like giant Ising spins. The interactions can be controlled through their geometric properties and arrangement: The degrees of freedom of the material can be directly tuned, but also individually observed. Experimental studies have unearthed intriguing connections to the out-of-equilibrium physics of disordered systems and non-thermal "granular" materials, while revealing strong analogies to spin ice materials and their fractionalized magnetic monopole excitations, lending the enterprise a distinctly interdisciplinary flavor.

In this talk we outline the more recent developments and future vistas for progress in this rapidly expanding field. We show how recent results have opened paths to new territories. Higher control, inclusive of genuine thermal ensembles have replaced the earlier and coarser methods based on magnetic agitation. Dynamical versions are now being realized, characterized in real time via PEEM, revealing statistical mechanics in action. This has lead us to afford implementation of new geometries, not found in nature, for dedicated bottom up design of desired emergent properties. Born as a scientific toy to investigate frustration-by-design, artificial spin ice might now be used to open "a path into an uncharted territory, a landscape of advanced functional materials in which topological effects on physical properties can be explored and harnessed."

Controlling electric and magnetic currents in artificial spin ice *(Invited Paper)*

Will R. Branford, Imperial College London (United Kingdom)

I will discuss the collective properties of arrays of single domain nanomagnets called Artificial Spin Ice.1 The shape of each nanomagnet controls the magnetic anisotropy and the elements are closely spaced so dipolar interactions are important. The honeycomb lattice geometry prevents the satisfaction of all dipole interactions. Here I will show direct magnetic imaging studies of magnetic charge flow.2 The magnetic charge is carried by transverse domain walls and the chirality of the domain wall is found to control the direction of propagation.3,4 Injection of domain walls within the arrays with local fields is also explored.5

Ordering and thermal excitations in dipolar coupled single domain magnet arrays *(Invited Paper)*

Erik Östman, Uppsala Univ. (Sweden); Unnar Arnalds, Univ. of Iceland (Iceland); Vassilios Kapaklis, Björgvin Hjörvarsson, Uppsala Univ. (Sweden)

For a small island of a magnetic material the magnetic state of the island is mainly determined by the exchange interaction and the shape anisotropy. Two or more islands placed in close proximity will interact through dipolar interactions. The state of a large system will thus be dictated by interactions at both these length scales. Enabling internal thermal fluctuations, e.g. by the choice of material, of the individual islands allows for the study of thermal ordering in extended nano-patterned magnetic arrays [1,2]. As a result nano-magnetic arrays represent an ideal playground for the study of physical model systems.

Here we present three different studies all having used magneto-optical imaging techniques to observe, in real space, the order of the systems. The first study is done on a square lattice of circular islands. The remanent magnetic state of each island is a magnetic vortex structure and we can study the temperature dependence of the vortex nucleation and annihilation fields [3]. The second are long chains of dipolar coupled elongated islands where the magnetization direction in each island only can point in one of two possible directions. This creates a system which in many ways mimics the Ising model [4] and we can relate the correlation length to the temperature. The third one is a spin ice system where elongated islands are placed in a square lattice. Thermal excitations in such systems resemble magnetic monopoles [2] and we can investigate their properties as a function of temperature and lattice parameters.

Majorana modes and Kondo effect in a quantum dot attached to a topological superconducting wire *(Invited Paper)*

Edson Vernek, Univ. Federal de Uberlândia (Brazil); David Ruiz-Tijerina, Luis G. Dias da Silva, José Carlos Egues, Univ. de São Paulo (Brazil)

Quantum dot attached to topological wires has become an interesting setup to study Majorana bound state in condensed matter[1]. One of the major advantage of using a quantum dot for this purpose is that it provides a suitable manner to study the interplay between Majorana bound states and the Kondo effect.

Recently we have shown that a non-interacting quantum dot side-connected to a 1D topological superconductor and to metallic normal leads can sustain a Majorana mode even when the dot is empty. This is due to the Majorana bound state of the wire leaking into the quantum dot. Now we investigate the system for the case in which the quantum dot is interacting[3]. We explore the signatures of a Majorana zero--mode leaking into the quantum dot, using a recursive Green's function approach. We then study the Kondo

regime using numerical renormalization group calculations. In this regime, we show that a "0.5" contribution to the conductance appears in system due to the presence of the Majorana mode, and that it persists for a wide range of the dot parameters. In the particle-hole symmetric point, in which the Kondo effect is more robust, the total conductance reaches $3e^2/2h$, clearly indicating the coexistence of a Majorana mode and the Kondo resonance in the dot.

However, the Kondo effect is suppressed by a gate voltage that detunes the dot from its particle-hole symmetric point as well as by a Zeeman field. The Majorana mode, on the other hand, is almost insensitive to both of them. We show that the zero--bias conductance as a function of the magnetic field follows a well--known universal curve. This can be observed experimentally, and we propose that this universality followed by a persistent conductance of $0.5,e^2/h$ are evidence for the presence of Majorana--Kondo physics.

Universal parity-crossing statistics in spin-polarized hybrid normal-superconductor nanostructures *(Invited Paper)*

Inanc Adagideli, Sabanci Univ. (Turkey)

We focus on topologically protected crossings of Andreev bound states in spin-polarized normal-superconductor hybrid structures [1]. Such crossings, signaling a change in the ground state fermion parity, became the focus of recent attention as they are regarded to be precursors to Majorana fermions that appear in the long-wire limit. In recent work, we showed how a topological state can be induced from regular or irregular scattering in (i) p-wave superconducting wires and (ii) Rashba wires in proximity to an s-wave superconductor. We also related the topological properties of such nanowires to their normal state properties such as conductance [2]. In the present work, we build on these results and study the correlation between parity-crossings in the superconducting state and the normal state properties of a hybrid nanostructure. Surprisingly, we find that the crossing points as well as their statistics are universal and are described solely by their normal-state properties. We obtain formulae for mean spacing between parity crossings as well as crossing statistics in disordered wires/cavities. We finally discuss under what conditions these crossings signal Majorana fermions. [1] I. Adagideli et al . [2] I. Adagideli, M. Wimmer, A. Teker, Phys Rev B 89, 144506 (2014)

Magnetic noise from Kondo charge traps *(Invited Paper)*

Luis G. Dias da Silva, Univ. de São Paulo (Brazil); Rogério de Sousa, Univ. of Victoria (Canada)

Magnetic noise impacts a wide variety of solid-state devices, from quantum bits in superconductor and semiconductor-based quantum computer architectures to spintronic devices made of metals and semiconductors. Developing a theory of magnetic noise will have great impact in minimizing fluctuations in these devices. Magnetic noise is commonly detected as flux noise in superconducting quantum interference devices (SQUIDs). At low frequencies, SQUID flux noise spectral density decreases with frequency as $1/f^{alpha}$ with $alpha=0.5-0.8$ in a wide variety of devices. However, at higher frequencies (above ~1~GHZ) flux noise was found to be Ohmic, i.e. increasing linearly with frequency. This puzzling behavior is not explained by any model of magnetic fluctuations.

Here we present a theory for the magnetic noise produced by local charge traps, elucidating the kind of noise that the majority of defects produce in a typical solid-state device. Our numerical renormalization group calculations reveal a deviation from 1/f behavior in the magnetic noise of charge traps in the Kondo regime over a wide range of frequencies. Remarkably, such behavior is not present in the charge noise, which is dominated by single-particle processes, consistent with a mean-field picture. The results show that, when Kondo correlations are present, magnetic noise originating from charge traps has a many-particle character, while charge noise does not. Since Kondo temperatures can be relatively high in charge traps, these findings indicate that electron-electron interactions can lead to a strong contribution to the magnetic noise that has not been captured by current models.

Intrinsic spin Hall effect of vector beam with rotational symmetry-breaking

Xiaohui Ling, Shenzhen Univ. (China); Zhiping Dai, Hengyang Normal Univ. (China); Xunong Yi, Shenzhen Univ. (China); Liezun Chen, Youwen Wang, Hengyang Normal Univ. (China); Shuangchun Wen, Shenzhen Univ. (China)

We report the observation of intrinsic photonic spin Hall effect (SHE) of cylindrical vector beam by breaking its rotational symmetry using a fan-shaped aperture to block part of the vector beam. The spin accumulation occurs at the edge of the beam, and the spin-dependent splitting increases with the topological charge of the vector beam and restricts by the aperture angle. The underlying mechanism is attributed to the discontinuous local energy flow that results from the broken, opposite vortex phases. It is large enough to be directly observed without using a weak measurement technology. Because of the inherent nature of the phase and independency of light-matter interaction, the observed photonic SHE is intrinsic. This enables us to observe a direct and giant photonic SHE. Our findings reveal that the photonic SHE may be manipulated (enhanced or inverted) by directly tailoring the polarization geometry of light, which may provide a possible route for generation and manipulation of spin-polarized photons, and enables spin-controlled photonics applications.

Fabrication of Fe/MgO/Fe low-resistance nano-contact on pn-GaAs photodetector as a memory element for a high-speed non-volatile optical memory

Vadym Zayets, Hidekazu Saito, Koji Ando, Shinji Yuasa, National Institute of Advanced Industrial Science and Technology (Japan)

The high-speed non-volatile optical memory has been proposed [1], which is utilized a high-speed spin injection of a spin-polarized photo current from a semiconductor-made pn-junction into a metal nanomagnet. The demultiplexing of a train of optical pulses at the speed of 2200 GBit/s was experimentally demonstrated for this memory [1].

For the successful operation of the memory it is essential to inject photo-excited electrons form the semiconductor detector into the nanomagnet within a time interval shorter than the spin life time in the semiconductor. The spin life time in the GaAs is short and it does not exceed 100 picoseconds at room temperature. In the case of the injection time longer than the spin life time, the spin information is lost inside the semiconductor before it is injected into the nanomagnet.

The injection time significantly depends on the nanocontact resistance. The lowest contact resistance is important to shorten photocurrent injection time from the pn-photodetector to the nanomagnet. The photocurrent was excited by 170-fs 10-pJ optical pulses at wavelength of 860 nm. The area

of the MTJ nanocontact was 0.01 um2. The tunnel magneto resistance was 100%. The injection time was measured to be 3 ns, 350 ps and 75 ps for the MTJ nanocontacts with contact resistance of 7000, 250 and 30 Ohm um2. The injection time shorter than the spin life time in the GaAs is achieved. The dependence of the tunnel magneto-resistance on the light intensity was observed.

Band structure of thin films materials

Amine Elhaimeur, Zouhair Sofiani, Univ. Ibn Tofail (Morocco)

Calculations of ferromagnetic properties using local density approximation (LDA) based on the parameterization given by Moruzzi, Janak, and Williams (MJW), were investigated in datail. We found that Nickel concentration in ZnO could induce magnetism effects. These effects from Ni impurties incorporation in ZnO matrice are explored using the Korringa-Rostocker potential approximation (KKR-CPA). The magnetic effect is due to the hybredization between 3d and 2p oxygen of Zn, O, and nickel atoms.

The titanium-antisite (TiO) magnetism effect on Ti0.98Cr0.02O2(0.98)(TiO)0.02 system within ab-initio calculation

Zakaryaa Zarhri, Univ. Mohammed V (Morocco)

The ab-initio calculations, based on the Korringa Kohn Rostoker approximation approach combined with Coherent Potential Approximation (KKR-CPA) were used to study the magnetic properties of the Titanium antisite (TiO) and Chromium (Cr) doped TiO2. In the considered systems, we used different concentrations for TiO defect and Cr doping. In TiO2(0.98)(TiO)0.02, the obtained results indicate that TiO is an acceptor having the half-metal behavior. TiO[3d] band is located at the Fermi level, although isn't 100% polarized, the ferromagnetic (FM) state is verified as being more stable than Disordred Local Moment (DLM) one. For Ti0.98Cr0.02O2 the Cr introduced new states which give the material half-metallic feature. The majority spin of Cr impurity are located at the Fermi level and the conduction electrons around the Fermi level are 100% spin polarized. This indicates the stability of (FM) state. Moreover, in Ti0.98Cr0.02O2(0.98)(TiO)0.02, the top of the conduction band (TCB) related to TiO2 shifted to lower energy and the n-type of TiO2 is verified. the majority spin of Cr[3d] are located at 0.025 Ry close Fermi level. The predicted Curie temperatures (Tc) were calculated using the Mean Field Approximation (MFA) and we predicted that TiO defect in Cr doped TiO2 makes Tc higher. This kind of defect makes the material useful for spinotronics's applications and devices.

Description of the spin proximity effect from a solution of the modified Boltzmann transport equations

Vadym Zayets, National Institute of Advanced Industrial Science and Technology (Japan)

The spin proximity effect was measured experimentally [1,2]. The Spin Proximity effect describes the fact that at a contact between two conductors, the spin accumulation diffuses from the conductor of a higher spin polarization to the conductor of a smaller spin polarization. For example, in the vicinity of a contact between a ferromagnetic and non-magnetic metals, in the ferromagnetic metal the equilibrium spin accumulation becomes smaller than in the bulk and the electron gas in the non-magnetic metal becomes spin-polarized.

When a drift current flows through the contact, the spin accumulation is drifted from one metal to the other metal, because of the spin injection. The spin injection only modifies the distribution of the spin accumulation across the contact, which was initially established due to the Spin Proximity effect.

From a solution of the modified Boltzmann transport equations [3,4] it was found that the contributions of the electrons and holes to the spin injection are of opposite signs. In contrast, the contributions of the electrons and holes to the Spin Proximity effect are of the same sign. For this reason, in a metal a significant drift current is required in order to modify the distribution of the spin accumulation across a contact enough so that the modification can be detected.

The features of the spin Proximity effect will be discussed.

Ultrafast affection of electron spin dynamics in GaAs by a ferromagnetic film

Dagmar Butkovi?ová, Petr N?mec, Charles Univ. in Prague (Czech Republic); Kamil Olejník, Vít Novák, Institute of Physics of the ASCR, v.v.i. (Czech Republic); Tomá? Janda, Franti?ek Trojánek, Charles Univ. in Prague (Czech Republic); Tomá? Jungwirth, Institute of Physics of the ASCR, v.v.i. (Czech Republic)

Spin-polarized electrons can be optically injected in semiconductor by absorption of circularly-polarized light. If an external magnetic field Hext perpendicular to the light propagation direction is applied, the electron spins presses around this field. Consequently, an oscillatory signal reflecting the electron spin dynamics in the material can be measured using the time-resolved pump-probe magneto-optical technique.

We studied the electron spin dynamics in GaAs substrate overgrown by a thin (~ 20 nm) epilayer of ferromagnetic semiconductor (Ga,Mn)As with different Mn doping [1] at temperature of 15 K using the light tuned to ~ 25 meV above the band gap of GaAs. Since the light penetration depth is much bigger than the thickness of the (Ga,Mn)As epilayer, the spin-polarized electrons are injected in both (Ga,Mn)As and GaAs. We observed that the presence of a thin ferromagnetic layer induced a very pronounced initial phase shift of the measured oscillations relative to the initial phase present in a bare GaAs. This phase shift of the electron spin precession arises within ~ 50 ps after the impact of a laser pulse on the sample, is dependent on the sample temperature and it disappears if an insulating barrier is inserted between GaAs and (Ga,Mn)As. Overall, our experimental data suggest that there is an ultrafast mechanism by which the ferromagnetic layer can modify the electron spin dynamics in the adjacent paramagnetic semiconductor.

Giant stress field in a single Ni nanowire generated by an external mechanical strain

Giuseppe Melilli, CEA-Ctr. de SACLAY (France); Marie-Claude Clochard, Commissariat à l'Énergie Atomique (France); Mohamed tabellout, Univ. du Maine (France); Daniel Lacour, Laurent Bouvot, Univ. de Lorraine (France); Nicolas Biziere, Ctr. d'Elaboration de Matériaux et d'Etudes Structurales (France); Jean-Eric Wegrowe, Ecole Polytechnique (France)

The effects of thermoelastic and piezoelectric strain of an active track-

etched ?-PVDF polymer matrix on an electrodeposited single-contacted Ni nanowire (NW) are investigated at the nanoscale by measuring the change of magnetization (i.e. using the inverse magnetostriction effect). The magnetization state is measured locally by anisotropic magnetoresitance (AMR). The ferromagnetic NW plays thus the role of a mechanical probe that allows the effects of mechanical strain to be characterized and described qualitatively and quantitatively.

The inverse magnetostriction was found to be responsible for a quasi-disappearance of the AMR signal for a variation of the order of ?T ≈ 10 K. In other terms, the variation of the magnetization due to the stress compensates the effect of external magnetic field applied on the NW resistance.

The induced stress field in a single Ni NW was found 1000 time higher than the bulk stress field (due to thermal expansion measured on the PVDF). This amplification could be attributed to three nanoscopic effects: (1) a stress mismatch between the Ni NW and the membrane, (2) a non-negligible role of the surface tension on Ni NW Young modulus, and (3) the possibility of non-linear stress-strain law.

We investigate here the role of these different contributions using various types of track-etched polymer membranes leading, after electrodeposition, to embedded Ni NWs of different diameters and orientations.

Controlled switching and frequency tuning of polarization oscillations in vertical-cavity surface-emitting lasers

Markus Lindemann, Henning Höpfner, Nils C. Gerhardt, Martin R. Hofmann, Ruhr-Univ. Bochum (Germany); Tobias Pusch, Rainer Michalzik, Univ. Ulm (Germany)

Spintronic lasers offer promising perspectives for novel concepts and characteristics superior to conventional purely charge-based devices. This applies in particular to spin-polarized vertical-cavity surface-emitting lasers (spin- VCSELs), which exhibit ultrafast spin and polarization dynamics. Using pulsed spin-injection, oscillations in the circular polarization degree can be generated, which have the potential to be much faster than conventional relaxation oscillations and may exceed frequencies of 100 GHz. The oscillations originate from the coupled carrier-spin-photon system in birefringent VCSEL cavities. The polarization oscillations are independent from conventional relaxation oscillations and thus can be the cornerstone for ultrafast directly modulated spin-VCSELs in the near future. It is possible to switch the oscillations on and off, depending on phase and amplitude conditions of two consecutive excitation pulses. Even half-cycles can be generated, which is the basis for short polarization pulses, only limited by the polarization oscillation resonance frequency. Experimental results of oscillation switching are given using an 850 nm oxide-confined single-mode VCSEL. In order to increase the polarization oscillation frequency, birefringence has to be tuned to higher values. We demonstrate a method to manipulate the birefringence by adding mechanical strain to the substrate in vicinity of the VCSEL. With this method the polarization oscillation frequency can be tuned over a wide range of several tens of GHz. The results are compared to the theory with simulations using the spin-flip-model.

Spin relaxation dynamics of an individual Co2+ ion in a CdTe/ZnTe quantum dot

Aleksander M. Bogucki, Mateusz Goryca, Kacper Oreszczuk, Tomasz Smolenski, Jakub Kobak, Wojciech Pacuski, Piotr Kossacki, Univ. of Warsaw (Poland)

Studies of single dopants in semiconductors constitute one of the research areas of the dynamically developing field of solotronics.

In this work we present studies of spin dynamics of a single Co2+ ion embedded in a CdTe/ZnTe quantum dot (QD) – a new system of single magnetic ion in semiconductor QD. In order to determine spin-relaxation time of the single Co2+ ion we performed time-resolved measurements of the QD photoluminescence under quasi-resonant, modulated excitation for various magnetic fields. It is experimentally simpler than the method previously used for the Mn2+ ion. The obtained relaxation times stay in an agreement with the values determined previously under non-resonant excitation and are much shorter than those reported for the Mn2+ ion.

We discuss the impact of the local strain on the spin relaxation. The Co2+ ion has non-zero orbital momentum, thus it is more sensitive to the local anisotropy of surrounding lattice than the Mn2+ ion. Analyzing different dots, we show that local distortion has minor influence on the cobalt relaxation time. This new observation can help to determine the spin-lattice relaxation mechanism of a single magnetic ion in a QD.

We also show that similarly to the case of the QDs with Mn2+ ions, quasi-resonant injection of spin polarized excitons leads to the orientation of the Co2+ spin. The time resolved measurements of this effect reveals that the spin orientation efficiency per one exciton for a Co2+ ion in a CdTe dot is much larger than for Mn2+ ion in a similar dot.

Spin-lasers: from threshold reduction to large-signal analysis

Sean Bearden, Evan Wasner, Univ. at Buffalo (United States); Jeongsu Lee, Univ. at Buffalo (United States) and Univ. of Regensburg (Germany); Igor Zutic, Univ. at Buffalo (United States)

Lasers in which spin-polarized carriers are injected provide paths to different practical room temperature spintronic devices, not limited to magnetoresistive effects. Considering spin-lasers, it is necessary to revisit simple concepts in spintronics. Is longer spin relaxation always better? How does a simultaneous spin relaxation of electrons and holes affect the device operation? Unfortunately, the proper framework to investigate such questions is usually overlooked. Theoretical studies mostly focus only on spin-polarized electrons, the holes are merely spectators with vanishingly short spin relaxation time, losing their spin polarization instantaneously. Unlike the conventional understanding of spintronic devices, an optimal performance of such spin-lasers can arise for finite, not infinite, spin relaxation time. By considering spin-relaxation times of both electrons and holes, we elucidate advantages of spin-lasers over their conventional (spin-unpolarized) counterparts. In addition to the steady-state threshold reduction, spin-lasers can improve transient operation leading to shorter turn-on delay times, reduced ringing of emitted light, and an enhanced bandwidth [1,2].

Spin photonics and spin-photonic devices with dielectric metasurfaces *(Invited Paper)*

Hailu Luo, Yachao Liu, Shizhen Chen, Yougang Ke, Xinxing Zhou, Hunan Univ. (China)

Dielectric metasurfaces with spatially varying birefringence fabricated by transparent materials can exhibit exceptional abilities for controlling the photonic spin states. We present here some of our works on spin photonics and spin-photonic devices with dielectric metasurfaces. We develop a hybrid-order Poincare sphere to describe the evolution of spin states of wave propagation in the metasurface. We extend the orbital Poincare sphere and high-order Poincare sphere to a more general form. The spin evolutionin the metasurface with special geometry can be conveniently described by state evolution along the longitude and the latitude lines on

the hybrid-order Poincare sphere. Similar to that in previously proposed Poincare spheres, the Berry curvature can be regarded as an effective magnetic field with monopole centered at the origin of sphere and Berry connection can be interpreted as the vector potential. Both the Berry curvature and the Pancharatnam-Berry phase on the hybrid-order Poincare sphere are demonstrated to be proportional to the variation of total angular momentum. Moreover, we show that the dielectric metasurfaces can provide great flexibility in the design of novel spin-photonic devices such as spin filter and spin-dependent beam splitter. The high transmission efficiency of dielectric metasurfaces makes it possible to utilizing the spin-dependent effect based on Pancharatnam-Berry phase in optical far field, which would substantially facilitate the development of spin-dependent devices in photonics.

Spin-photonic devices based on crystalline-AlOx / GaAs for emission and detection of circular polarized light *(Invited Paper)*

Hiro Munekata, Masaki Aoyama, Ronel Roca, Nozomi Nishizawa, Tokyo Institute of Technology (Japan)

In the papers published in APL 2014 [1] and JMSJ 2014 [2], we reported electrical helicity switching of circularly polarized light (CPL) at 1 KHz with spin-LEDs having dual spin injection electrodes [3] of Fe and detection of CPL up to RT by operating reversely the spin-LEDs. Those LEDs consisted of a n-AlGaAs/InGaAs/p-AlGaAs double heterojunction and a newly developed crystalline x-AlOx tunnel barrier [4]. Presented here are helicity switching of CPL at 1 MHz and a phenomenological model of spin photodiode (PD), the recent progresses towards the realization of spin-photonics based devices. The same type of a dual-electrodes spin-LED is used for experiments. Only a quarter waveplate and a linear polarizer are used to distinguish helicity of electroluminescence (EL). The degree of EL-CPL is 10 to 15 % at around peak wavelength of 840 nm. Alternating a current between the two electrodes with the frequency of 1 MHz has yielded dynamic change in the intensity output, indicating helicity switching at same frequency. A model of spin-PD is based on a picture that a spin polarized photo-current yielded in a pn junction is split into two independent spin channels R(up) and R(down) including those due to spin-dependent tunneling. The advantage of our model is the direct estimation of relaxation of carrier spin polarization gmma from experimental data; e.g., gamma = 0.4 % at low temperatures referring the data shown in ref. 2.

Development of plasmonic isolator for integration into photonic integrated circuits *(Invited Paper)*

Vadym Zayets, Hidekazu Saito, Koji Ando, Shinji Yuasa, National Institute of Advanced Industrial Science and Technology (Japan)

An optical isolator is an important component of an optical network. At present, there is a significant commercial demand for an optical isolator, which can be integrated into the Photonic Integrated Circuits (PIC). A new design of an integrated optical isolator, which utilizes unique non-reciprocal properties of surface plasmons, has been proposed [1]. The main obstacle for a practical realization of the proposed design is a substantial propagation loss of the surface plasmons in structures containing a ferromagnetic metal. The reduction of the propagation loss of a surface plasmon is the key to make the plasmonic isolator competitive with other designs of the integrated isolator.

We studied experimentally optical and magneto-optical properties of a Fe plasmonic waveguide integrated with an AlGaAs rib waveguides and a Co plasmonic waveguide integrated with Si nanowire waveguides. It was demonstrated experimentally that by utilizing a double-dielectric plasmonic waveguide it is possible to reduce significantly the optical loss in a plasmonic waveguide. For Fe/SiO2/AlGaAs double-dielectric plasmonic waveguide the low optical loss of 0.03 dB/um is obtained. As far as we know at present it is a lowest optical loss demonstrated for a plasmon propagating at a surface of a ferromagnetic metal. For Co/Ti2O3/SiO2 double-dielectric plasmonic waveguide integrated with a Si nanowire waveguide on a Si substrate the optical loss of 0.7 dB/um was demonstrated. The designs of the plasmonic isolator utilizing a ring resonator or a non-reciprocal coupler were studied.

9551-74, Session 19

Integrated optical isolators using magnetic surface plasmon *(Invited Paper)*

Hiromasa Shimizu, Terunori Kaihara, Saori Umetsu, Masashi Hosoda, Tokyo Univ. of Agriculture and Technology (Japan)

Optical isolators are one of the essential components to protect semiconductor laser diodes (LDs) from backward reflected light in integrated optics. In order to realize optical isolators, nonreciprocal propagation of light is necessary, which can be realized by magnetic materials. Semiconductor optical isolators have been strongly desired on Si and III/V waveguides. We have developed semiconductor optical isolators based on nonreciprocal loss owing to transverse magneto-optic Kerr effect, where the ferromagnetic metals are deposited on semiconductor optical waveguides1). Use of surface plasmon polariton at the interface of ferromagnetic metal and insulator leads to stronger optical confinement and magneto-optic effect. It is possible to modulate the optical confinement by changing the magnetic field direction, thus optical isolator operation is proposed2, 3). We have investigated surface plasmons at the interfaces between ferrimagnetic garnet/gold film, and applications to waveguide optical isolators. We assumed waveguides composed of Au/Si(38.63nm)/Ce:YIG(1700nm)/Si(220nm)/Si , and calculated the coupling lengths between Au/Si(38.63nm)/Ce:YIG plasmonic waveguide and Ce:YIG/Si(220nm)/Si waveguide for transversely magnetized Ce:YIG with forward and backward directions. The coupling length was calculated to 232.1um for backward propagating light. On the other hand, the coupling was not complete, and the length was calculated to 175.5um. The optical isolation by using the nonreciprocal coupling and propagation loss was calculated to be 43.7dB when the length of plasmonic waveguide is 700um.

Electrical generation and manipulation of spin polarization in semiconductors *(Invited Paper)*

Vanessa Sih, Univ. of Michigan (United States)

Utilizing spins for information processing requires developing methods to generate and manipulate spin polarization. Current-induced spin polarization is a phenomenon in which carrier spins in a semiconductor are oriented when subjected to current flow. However, the mechanism that produces this spin polarization remains an open question. Existing theory predicts that the spin polarization should be proportional to the spin-orbit splitting, yet no clear trend has been observed experimentally. We perform experiments on semiconductor samples designed so that the magnitude and direction of the in-plane current and applied magnetic field can be varied and measure the electrical spin generation efficiency and spin-orbit splitting using optical techniques. These techniques can sensitively measure the electron g-factor and effective magnetic fields produced by spin-

orbit splitting and nuclear spin polarization. Contrary to expectation, the magnitude of the current-induced spin polarization is shown to be larger for momentum directions corresponding to smaller spin-orbit splitting [1]. In addition, angle-dependent measurements demonstrate that the steady-state spin polarization is not along the direction of the spin-orbit field, which we attribute to anisotropic spin relaxation. Furthermore, we show that this electrically-generated electron spin polarization can produce a nuclear spin hyperpolarization through dynamic nuclear polarization [2].

Semiconductor microcavities form an important class of semiconductor systems in which light is strongly coupled to excitons. The resulting polaritons have advantageous dispersion relations that, in the past, have allowed for the observations of many prominent effects, ranging from Bose condensation to the optical spin Hall effect. Our group has recently predicted and observed formation of patterns in the spatial polariton density and far-field emission signals. These patterns are created by a coherent optical pump field that enters the microcavity in normal incidence and that is tuned above the minimum of the lowest polariton branch. Four-wave mixing instabilities involving pump photons and polaritons on the elastic circle (off-axis polaritons) are the main process for pattern formation. An important aspect of patterns involving linearly polarized pump fields is the TE/TM splitting, which in the past has been associated with important characteristics of semiconductor microcavities, including the optical spin Hall effect.

In our previous research, we have investigated spin-dependent exciton-exciton interaction in semiconductor quantum wells and microcavities, and recently we found that the TE/TM splitting, together with the spin-dependent exciton-exciton interaction, leads to specific characteristics in the polariton pattern formation. For example, the spin-dependent exciton-exciton interaction favors a linearly x-polarized pump beam to produce y-polarized off-axis polaritons. Depending on the pump conditions, this can create patterns involving TE or TM polarized polaritons. The patterns offer the possibility of external control as they can be rotated simply through rotation of the pump polarization. We review the theoretical framework as well as experimental results.

9551-77, Session 20

Effect of the Pauli principle on photoelectron spin transport in p+ GaAs *(Invited Paper)*

Daniel Paget, Ecole Polytechnique (France)

In p+ GaAs thin films, the effect of photoelectron degeneracy on spin transport is investigated theoretically and experimentally by imaging the spin polarization profile as a function of distance to the light excitation spot. Under degeneracy of the electron gas (high concentration, low temperature), a dip at the center of the polarization profile appears, with a polarization maximum at a distance of about 2μm from the center. This counterintuitive result reveals that photoelectron diffusion depends on spin, as a direct consequence of the Pauli principle which causes a concentration dependence of the spin stiffness while the spin dependence of the mobility is found weak in doped material.

The various effects which can modify spin transport in a degenerate electron gas under local, circularly-polarized, laser excitation are considered. A comparison of the data with a numerical solution of the coupled diffusion equations reveals that ambipolar coupling with holes increases the steady-state photo-electron density at the place of excitation and therefore the amplitude of the degeneracy-induced dip. Thermoelectric currrents are predicted to depend on spin under degeneracy (spin Soret currents), but these currents are negligible except at very high excitation power where they play a relatively small role. Coulomb spin drag and bandgap renormalization are negligible due to electrostatic screening by the hole gas.

9551-78, Session 20

Efficient conversion of light to charge and spin in Hall-bar microdevices

Lukas Nadvornik, Institute of Physics of the ASCR, v.v.i. (Czech Republic); James A. Haigh, Hitachi Cambridge Lab. (United Kingdom); Kamil Olejnik, Institute of Physics of the ASCR, v.v.i. (Czech Republic); Andrew C. Irvine, Univ. of Cambridge (United Kingdom); Vit Novak, Tomá? Jungwirth, Institute of Physics of the ASCR, v.v.i. (Czech Republic); Joerg Wunderlich, Hitachi Cambridge Lab. (United Kingdom)

During the last decade, the spin related Hall effects have developed from subtle academic phenomena to practical tools for exploring a variety of fields in the fundamental and applied spintronics research. One of the recently proposed concepts, where these effects can find utility, is the spin Hall based polarimeter.

In this contribution, we report an experimental study of the direct conversion of light into electrical signals in GaAs/AlGaAs Hallbar microdevices. Our approach based on different modulation frequencies of the intensity and polarization of the laser beam allows us to disentangle the charge and spin dependent parts of the induced electrical signal, and to link them to the incident light intensity and polarization, respectively.

In our electrical polarimeter, the degree of circular polarization of incident light is directly converted into transverse electrical voltage via spin-orbit interaction acting on optically generated spin-polarized photocarriers. We demonstrate that the efficiency of the light to spin conversion is strongly enhanced by adding a drift component to the transport of the spin-polarized photocarriers, as compared to a purely diffusive transport regime of the device. We show that this is in agreement with the theory of spin-related Hall effects.

For a micron-size focused laser beam, the experiments also demonstrate that the light to charge and spin conversion efficiency depends on the precise position of the light spot, reflecting the spatially dependent response function of the Hall cross.

All these observations may find utility in designing spin Hall based convertors, modulators, polarimeters or other related opto-spintronic microdevices.

9551-79, Session 21

Current-induced magnetization dynamics and thermal stability of perpendicular STT-MRAM devices *(Invited Paper)*

Huanlong Liu, Luc Thomas, Guenole Jan, Son Le, Yuan-Jen Lee, Jian Zhu, Ru-Ying Tong, Keyu Pi, Yu-Jen Wang, Tom X. Zhong, Terry Torng, Po-Kang Wang, Headway Technologies, Inc. (United States)

Spin-transfer torque–magnetic random access memory (STT-MRAM) devices, combining non-volatility and fast read/write operations, have the potential of becoming next generation “universal memory”. In this presentation, we will discuss some of the interesting challenges we face in developing the STT-MRAM technology. Firstly, we will show that millions of devices can be switched reliably by electrical pulses as short as sub-nanoseconds. However, complex magnetization dynamics is occasionally observed, especially for large devices in the deep statistics regime. We will discuss the origin of these phenomena and how they can be avoided by improving the design of the MTJ stacks. Secondly, we will address the thermal stability of the devices. In particular, we will discuss methods of evaluating the energy barrier Eb at different temperatures in order to assess data retention of different MTJ designs.

9551-80, Session 21

Spintronic devices for space applications *(Invited Paper)*

Malik Mansour, Lab. de Physique des Plasmas (France)

In this presentation we aim to review some implementations of spintronic devices in the frame of space applications. Because they are compact and can easily be adapted to a space environment, we will show that magnetoresistive effects based sensors (MR) (as AMR, GMR or TMR sensors) can not only be used as positioning sensing devices but are also new assets to develop highly integrated space magnetometers dedicated to space science. Their sensitivity as well as their ability to cover a large frequency range allows using them for magnetometry applications ranging from the Martian soil mapping up to the measurement of interplanetary magnetic waves fluctuations. Whether used alone or as part of new instrumental concepts we will endeavor to show that MR sensors have the potential to be a must in the field of magnetic measurement in a space environment.

9551-81, Session 21

Monolithic integration of focused 2D GMR spin valve magnetic field sensor for high-sensitivity (compass) applications *(Invited Paper)*

Olaf Ueberschär, Fraunhofer-Institut für Elektronische Nanosysteme (Germany); Maria J. Almeida, Fraunhofer-Institut für Elektronische Nanosysteme (Germany) and Technische Univ. Chemnitz (Germany); Patrick Matthes, Technische Univ. Chemnitz (Germany); Mathias Müller, Hochschule Mittweida (Germany); Ramona Ecke, Fraunhofer-Institut für Elektronische Nanosysteme (Germany); Horst Exner, Hochschule Mittweida (Germany); Stefan E. Schulz, Fraunhofer-Institut für Elektronische Nanosysteme (Germany) and Technische Univ. Chemnitz (Germany)

We have designed and fabricated 2D GMR spin valve sensors on the basis of IrMn/CoFe/Cu/CoFe/NiFe nanolayers in monolithic integration for high sensitivity applications. For a maximum signal-to-noise ratio, we realize a focused double full bridge layout featuring an antiparallel exchange bias pinning for neighbouring meanders and an orthogonal pinning for different bridges. This precise alignment is achieved with microscopic precision by laser heating and subsequent in-field cooling.

Striving for maximum signal sensitivity and minimum hysteresis, we study in detail the impact of single meander geometry on the total magnetic structure and electronic transport properties. The investigated geometrical parameters include stripe width, stripe length, cross bar material and total meander length. In addition, the influence of the relative alignment between reference magnetization (pinned layer) and shape anisotropy (free layer) is studied. The experimentally obtained data are moreover compared to the predictions of tailored micromagnetic simulations.

Using a set of optimum parameters, we demonstrate that our sensor may readily be employed to measure small magnetic fields, such as the ambient (geomagnetic) field, in terms of a 2D vector with high spatial (~200 µm) and temporal (~1 ms) resolution.

9551-82, Session 21

State of the art of the equivalent magnetic sensor noise: from intrinsic sensor performances to application, the challenges *(Invited Paper)*

Christophe Dolabdjian, Univ. de Caen Basse-Normandie (France)

This talk deals with on the problematic of the development on highly sensitive magnetic sensors to applications. The sensor performances were described and analysed, mainly, in term of intrinsic or equivalent input magnetic noise in the Tesla per square root Hertz. Based on our laboratory researches, three sensor technologies were outlined: Giant MagnetoResistance, Magneto(Elasto)Electric and Magneto-Impedance devices. These sensors are based on different physical principles. In each case, a soft magnetic material is used and can be seen as an intrinsic or as an extrinsic sensing element, which is coupled to the active part of the sensor. The material properties and conditioning electronic parameters were detailed versus sensor working principles. Both have to be well considered in highly sensitive magnetic magnetometer development. To improve this analysis, the relation between the sensitivity and the equivalent input magnetic noise of the sensors and the sensor material properties have to be study, carefully! We notice that sensor noise improvements can be done, only, by considering a system theory or systems engineering approach, which includes the material properties, the working principle, the conditioning electronics and often, the fluctuation dissipation theorem! The general trends, predicted by the (and our) theoretical models, which are associated to these different sensor technologies, are very well supported by experiments. These analyses provide a view of the technological limits and insights for material, design, working principle, optimization and used. To conclude this presentation, some applications (NDT, magnetic detection, magnetorelaxometry, imagery of NMPs, biomagnetism...) as example, will be given. The link between the intrinsic sensor noise and performances and measurement problematics will be pointed out.

9551-83, Session 22

Tailoring and manipulating spin in semiconductor nanostructures *(Invited Paper)*

Christopher J. Stanton, Gary D. Sanders, Univ. of Florida (United States)

There has been much interest in III-V and II-VI dilute magnetic semiconductors in which incorporation of magnetic impurities, such as manganese, is used to tailor the electronic, magnetic, and magneto-optical properties. In particular, carrier-induced ferromagnetism in dilute magnetic semiconductors has opened up opportunities for device applications. We present a theory for the electronic and magneto-optical properties of

magnetically doped semiconductor nanostructures and investigate how the effects of i) quantum confinement, ii) interfacial strain and iii) precise control of the magnetic impurity position can be used to change and tune these properties. We study two systems: 1) quantum wells and 2) core shell quantum dots. Calculations in the quantum wells are based on an 8 band calculation and allows for valence/conduction band mixing in narrow gap materials. The spherical quantum dots consist of an inner core surrounded by an outer shell. This core-shell quantum dot is doped by magnetic Mn impurities all of which are implanted at a preselected and controllable radius on a spherical surface within the dot. The electronic states in the presence of a magnetic field are treated in an effective mass model which includes the s-d and p-d exchange interaction with the Mn electrons. Strain in both systems due to the lattice is assumed to be pseudomorphic and the effect of this strain field on the electronic and spin states is included. The optical properties are computed using electronic states from our calculations using Fermi's golden rule.

This work was supported by the NSF through grant DMR-1105437.

9551-84, Session 22

100% spin polarized surface resonance in the half metallic Heusler compound Co2MnSi *(Invited Paper)*

Martin Jourdan, Johannes Gutenberg Univ. Mainz (Germany); Jan Minar, Juergen Braun, Ludwig-Maximilians-Univ. München (Germany); Alexander Kronenberg, Johannes Gutenberg Univ. Mainz (Germany); Stanislav Chadov, Max-Planck-Institut für Chemische Physik Fester Stoffe (Germany); Benjamin Balke, Johannes Gutenberg Univ. Mainz (Germany); Andrey Gloskovskii, Deutsches Elektronen-Synchrotron (Germany); Michaela Kolbe, Hans-Joachim Elmers, Gerd Schoenhense, Johannes Gutenberg Univ. Mainz (Germany); Hubert Ebert, Ludwig-Maximilians-Univ. München (Germany); Claudia Felser, Max-Planck-Institut für Chemische Physik Fester Stoffe (Germany); Mathias Klaeui, Johannes Gutenberg Univ. Mainz (Germany)

The magnitude of the room temperature spin polarization of ferromagnetic materials is a key property for their application in spin transport-based electronics. Thus Heusler compounds, due to their predicted bulk half-metallic properties, i.e. 100% spin polarization at the Fermi energy, are in the focus of interest. However, for most applications it is not the bulk but the surface or interface of the material, which is relevant.

Investigating optimized thin films of the compound Co2MnSi by in situ spin-resolved UPS, we were able to demonstrate for the first time half-metallicity in combination with directly measured 93(+7/-11) % spin polarization at room temperature in the surface region of a Heusler thin film [Jou14]. Our novel band structure and photoemission calculations including all surface-related effects [Bra14] show that the observation of a high spin polarization in a wide energy range below the Fermi energy is related to a stable surface resonance in the majority band of Co2MnSi extending deep into the bulk of the material. Spin-integrated ex situ HAXPES with a photon energy of 6 keV on Co2MnSi thin films and spin-integrated in situ UPS was carried out. The UPS and the HAXPES results fundamentally agree although the information depth of both experiments varies from less than 1 nm to 20 nm. Nearly quantitative agreement of the calculations with the experiments for both, UV and hard X-ray photon energies, was obtained.

Valence control of Eu ions in Eu-doped GaN grown by organometallic vapor phase epitaxy *(Invited Paper)*

Yasufumi Fujiwara, Masaaki Matsuda, Wanxin Zhu, Takanori Koijma, Atsushi Koizumi, Osaka Univ. (Japan)

We have intensively investigated rare-earth (RE)-doped III-V semiconductors grown by atomically controlled organometallic vapor phase epitaxy and fabricated new types of functional devices using the materials. Eu-doped GaN has been identified as a promising red emitter because it has excellent luminescence properties in the red spectral region, resulting from the specific optical properties of RE materials, such as a sharp, intense, and temperature-independent emission peak due to the intra-4f shell transitions. We have succeeded in growing Eu-doped GaN layers with high crystalline quality, and have demonstrated for the first time a low-voltage current-injected red emission from p-type GaN /Eu-doped GaN/n-type GaN LEDs with an applied voltage of as low as 3 V [1]. A main emission line with a half width of less than 1 nm was observed at 621 nm, which can be assigned to the 5D0–7F2 transition of Eu3+ ions. By optimizing growth conditions and device structures, the light output power has been increasing steadily to sub-mW at an injected current of 20 mA [2]. The valence of Eu ions can be controlled by codoping with other elements. In AlxGa1-xN with high Al contents, Eu2+ state with a magnetic moment was obviously revealed by XANES, while the volume increased with the Al content [3]. These results suggest strongly a possibility to create novel devices for combined applications of optronics and spintronics.

Novel 2D electron gases at the surface of transition-metal oxides: fundamentals and perspectives for spintronics *(Invited Paper)*

Andrés F. Santander-Syro, Univ Paris-Sud 11 (France)

Transition-metal oxides (TMOs) show remarkable properties, such as high-temperature superconductivity or large magnetoresistance. The realization of two-dimensional electron gases (2DEGs) at surfaces or interfaces of TMOs, a field of current intense research, is crucial for harnessing the functionalities of these materials for future applications. Additionally, these 2DEGs offer the possibility to explore new physics emerging from the combined effects of electron correlations and low-dimensional confinement.

Recently, we discovered that 2DEGs can be simply realized at the surface of various insulating transparent TMOs, such as the quantum paraelectric SrTiO3 [1] or the strong spin-orbit coupled KTaO3 [2]. In this talk, I will show that by choosing various surface terminations one can additionally tailor the electronic structure and symmetries of these 2DEGs [3-4], paving the way for the quest of topological states in correlated oxides. Furthermore, I will discuss our latest observation of a giant spin splitting, of 100 meV, of bands with opposite spin chiralities in the 2DEG at the surface of SrTiO3 [5]. These results show that confined electronic states at oxide surfaces can be endowed with novel properties, not present in the bulk, which are promising for technological applications.

Spin electronic magnetic sensor based on functional oxides for medical imaging *(Invited Paper)*

Aurelie Solignac, Commissariat à l'Énergie Atomique (France); Georg Kurij, Ruben Guerrero, Guillaume Agnus, Thomas Maroutian, Institut d'Électronique Fondamentale (France); Claude Fermon, Myriam Pannetier-Lecoeur, Commissariat à l'Énergie Atomique (France); PHILIPPE LECOEUR, Institut d'Électronique Fondamentale (France)

There is a strong interest in developing ultrasensitive sensors able to detect magnetic signals coming from the body, in particular those produced by the electrical activity of the heart or of the brain. Magnetoresistive sensors, stemming from spin electronics, are very promising devices. For example, tunnel magnetoresistance (TMR) junctions based on MgO tunnel barrier have a high sensitivity. Nevertheless, TMR also often have high level of noise. Full spin polarized materials like manganite La0.67Sr0.33MnO3 (LSMO) are attractive alternative candidates to develop such sensors because LSMO exhibits a very low 1/f noise when grown on single crystals [1], and a TMR response has been observed with values up to 2000% [2]. This kind of tunnel junctions, when combined with a high Tc superconductor loop, opens up possibilities to develop full oxide structures working at liquid nitrogen temperature and suitable for medical imaging. In this work, we investigated on LSMO based tunnel junctions the parameters controlling the overall system performances, including not only the TMR ratio, but also the pinning of the reference layer and the noise floor [3]. We especially focused on studying the effect of the quality of the barrier, the interface and the electrode, by playing with materials and growth conditions.

Development of micronic GMR-magnetoresistive sensors for non-destructive sensing applications *(Invited Paper)*

Henri Jaffrès, Yves LeMaitre, Sophie Collin, Frédéric Nguyen Vandau, Unité Mixte de Physique CNRS/Thales (France); Natalia Sergeeva-Chollet, CEA-Ctr. de SACLAY (France); Jean-Marc Decitre, CEA-Ctr. de SACLAY (France)

We will present our last development of GMR-based magnetic sensors devoted to sensing application for non-destructive control application. In these first realizations, we have chosen a so-called shape anisotropy – exchange biased strategy to fulfill the field-sensing criteria in the μT range in devices made of micronic single elements. Our devices realized by optical lithography, and whose typical sizes range from 150 μm x 150 μm to 500 μm x 500 μm elements, are made of trilayers GMR-based technology and consist of several circuitries of GMR elements of different lengths, widths and gaps. To obtain a full sensing linearity and reversibility requiring a perpendicular magnetic arrangement between both sensitive and hard layer, the magnetization of the latter have been hardened by pinning it with an antiferromagnetic material. The specific geometry of the design have been engineered in order to optimize the magnetic response of the soft layer via the different magnetic torques exerted on it essentially played by the dipolar fields or shape anisotropy, and the external magnetic field to detect. The smaller dimensions in width and in gap are then respectively of 2 μm and 3 μm to benefit of the full shape anisotropy formatting the magnetic response.

3D magnetic surfaces *(Invited Paper)*

Denys Makarov, Leibniz-Institut für Festkörper- und Werkstoffforschung Dresden (Germany)

Conventionally magnetic films and structures are fabricated on flat surfaces. The topology of curved surfaces has only recently started to be explored and leads to new fundamental physics and applied device ideas. Advancing in this field calls for the understanding of the magnetic responses of thin films on curved surfaces. Here, two basic geometries, i.e. hemi-spherical [1,2] and tubular [3,4], will be addressed. To enable the microscopic characterization of 3D architectures, we put forth the concept of magnetic soft x-ray tomography. I will introduce this concept and present the angle- and layer-resolved imaging of rolled-up tubes [4,5].

Based on this knowledge, we fabricated flexible [6,7], printable [8] and stretchable [9] magnetic sensorics. The unique mechanical properties open up new application potential of magnetic field sensors for printable electronics and smart skins, allowing to sense and manipulate objects of the surrounding us physical as well as digital world.

Organic analogues of diluted magnetic semiconductors: bridging quantum chemistry to condensed matter physics *(Invited Paper)*

Madalina I. Furis, Naveen Rawat, Kim Ngan Hua, The Univ. of Vermont (United States); Stephen A. McGill, National High Magnetic Field Lab. (United States)

The selective coupling between polarized photons and electronic states in materials enables polarization-resolved spectroscopy studies of exchange interactions, spin dynamics, and collective magnetic behavior of conduction electrons in semiconductors. At the University of Vermont we employ Magnetic Circular Dichroism (MCD) and polarization-resolved photoluminescence (PL) spectroscopy techniques to investigate the excitonic and magnetic properties of electrons in crystalline thin films of small molecule organic semiconductors.

We focus on the collective magnetic properties of d-shell ions (Cu2+, Co2+ and Mn2+) metal phthalocyanine (Pc) thin films that one may think of as organic analogues of diluted magnetic semiconductors (DMS). These films were deposited in-house using a recently developed pen-writing method that results in crystalline films with macroscopic long range ordering and improved electronic properties, ideally suited for spectroscopy techniques.

Our experiments reveal that, in analogy to DMS, the extended ϖ-orbitals of the Pc molecule mediate the spin exchange between highly localized d-like unpaired spins. We established that exchange mechanisms involve different electronic states in each species and/or hybridization between d-like orbitals and certain delocalized ϖ-orbitals. More recently, we focused our studies on "alloys" made of a mixture of Mn2+, Co2+ and metal-free (H2) soluble derivatives of the Pc molecule that offer insight into the possibility of tuning the magnetic interactions in these organic systems. Unprecedented 25T MCD and PL experiments conducted in the unique Florida State Split HELIX

magnet at the National High Magnetic Field Laboratory (NHMFL) reveal that we may be able to induce an exchange mechanism that involve different band edge states by varying the mixing ratio.

9551-91, Session 24

Photocontrol of magnetism above 77 K in nanoscaled heterostructures of cyanometallate coordination networks *(Invited Paper)*

Mark W. Meisel, Daniel R. Talham, Univ. of Florida (United States)

Using nanometer-sized heterostructures of cyanometallate coordination networks, specifially core@shell nanoparticles of CoFe@CrCr-PBA (PBA = Prussian blue analogues), irradiation by white light at 80 K modifies the magnetic response, and these changes remain intact and persist without continued irradiation to nominally 125 K [1]. Preliminary pressure studies indicate the photoinduced changes can be maintained up to 200 K, the transition temperature of the ferromagnetic CrCr-PBA component. The effect, which we first reported up to 70 K [2,3], arises from thermally induced interface strain, which is relaxed by irradiation of the photactive consituent, CoFe-PBA. The ferromagnetic domains in the strained interface region are affected and generate the persistent changes of the magnetism. Our understanding of this photo-magnetostructural mechanism enabled us to extend the phenomenon to include photoactive spin-crossover systems [4] and other ferromagnetic PBAs [5]. The potential path to higher temperatures will be sketched. This presentation is coauthored with Daniel R. Talham, UF Chemistry, and supported by the NSF via DMR-1405439 (DRT), DMR-1202033 (MWM), and DMR-1157490 (NHMFL), and by the UF Division of Sponsored Research.

Tailoring spintronics interfaces with organic molecules *(Invited Paper)*

Mirko Cinchetti, Technische Univ. Kaiserslautern (Germany)

Control of spin on the shortest and fastest scale is the holy grail of modern research in magnetism, as it holds the key to the ultimate miniaturization of energy-efficient and non-volatile spintronics devices. A very promising approach to this end is the deposition of isolated organic molecules, as small atomic-scale units, on a magnetic surface. The hybridization between the electronic bands at the surface of the magnet and the orbitals of the molecule can lead to a drastic change of the magnetic properties of the atoms coupled to the molecule. As hybridization can be controlled through the electronic properties of the organic components, the intrinsic multifunctionality of organic molecules could make hybrid interfaces the long-sought ultrafast handle for spin down to the atomic scale. Recent progress in organic spintronics and molecular spintronics has thus focused on the remarkably promising functionality of hybrid interfaces formed between magnetic surfaces and organic molecules — 'spinterfaces'.

In this talk I will show that the versatility of organic molecules for spin applications is not only limited to interfaces formed with magnetic materials, but extends to the much broader class of non-magnetic spin-textured materials, like Rashba systems and topological insulators. In this context, the unique combination of chemical synthesis and state-of-the-art theoretical and experimental methods allows one to define the fundamental and general design rules of spinterfaces with stable and tunable spintronics properties, opening new and still unexplored avenues where the spin functionality of spin-textured surfaces is tailored both locally (on the molecular scale) and temporally (on the femtosecond time-scale).

9551-93, Session 25

Fundamental electric circuit elements based on the linear and nonlinear magnetoelectric effects *(Invited Paper)*

Young Sun, Dashan Shang, Yisheng Chai, Zexian Cao, Jun Lu, Institute of Physics (China)

From the viewpoint of electric circuit theory, the three fundamental two-terminal passive circuit elements, resistor R , capacitor C, and inductor L, are defined in terms of a relationship between two of the four basic circuit variables, charge q, current i, voltage v, and magnetic flux ?. From a symmetry concern, there should be a fourth fundamental element defined from the relationship between charge q and magnetic flux ?. Here we present both theoretical analysis and experimental evidences to demonstrate that a two-terminal passive device employing the magnetoelectric (ME) effects can exhibit a direct relationship between charge q and magnetic flux ?, and thus is able to act as the fourth fundamental circuit element. The ME effects refer to the induction of electric polarization by a magnetic field or magnetization by an electric field, and have attracted enormous interests due to their promise in many applications. However, no one has linked the ME effects with fundamental circuit theory. Both the linear and nonlinear-memory devices, termed transtor and memtranstor, respectively, have been experimentally realized using multiferroic materials showing strong ME effects. Based on our work, a full map of fundamental two-terminal circuit elements is constructed, which consists of four linear and four nonlinear-memory elements. This full map provides an invaluable guide to developing novel circuit functionalities in the future.

Emerging functionalities in devices with complex oxides *(Invited Paper)*

Tamalika Banerjee, Univ. of Groningen (Netherlands)

Interfaces of complex oxides host new physical phenomena and novel functionalities due to the interplay between strain, charge-transfer, orbital-reconstruction etc. Electronic devices on oxide semiconductors such as Nb doped SrTiO_3, bring in additional functionalities derived from temperature and electric field dependence of their dielectric permittivity, allowing manipulation by electric and magnetic field and tuning by spin-orbit relativistic effects. In this talk, I will discuss emerging functionalities that have been observed at oxide interfaces a) between Nb doped SrTiO_3 and SrRuO_3- a pervoskite metal, where ferromagnetism and metallicity evolve with decreasing temperature and increasing thickness, influencing electronic transport at the interface b) between carefully tuned spin injection contacts and Nb doped SrTiO_3, exhibiting an unusal bias dependence of the spin lifetime and features that demonstrate a strong influence of the interface electric field on spin accumulation and charge transport, unlike that found in conventional semiconductors and c) influence of dielectric screening on charge and spin transport when complex oxides are integrated with graphene. Our findings open up new directions in the field of oxide electronics and spintronics.

9551-95, Session 25

Tuning magnetic nanostructures and flux concentrators for magnetoresistive sensors *(Invited Paper)*

Xiaolu Yin, Univ. of Nebraska-Lincoln (United States); Yen-Fu Liu, Sy-Hwang Liou, Univ. of Nebraska-Lincoln (United States)

The methods for the optimization of the magnetoresistive (MR) sensors are to reduce sources of noises, to increase the signal, and to understand the involved fundamental limitations. The high-performance MR sensors are resulting from the important MTJ properties, such as tunneling magnetoresistance ratio (TMR), coercivity (Hc), exchange coupling field (He), domain structures, and noise property as well as the external magnetic flux concentrators. All these parameters are sensitively controlled by the magnetic nanostructures, which can be tuned by varying junction geometry, magnetic annealing process and so on. With all the efforts, we had achieved optimized magnetic sensor with a sensitivity as high as 5,146 %/mT. This sensitivity is currently the highest among all MR-type sensors that has been reported. The estimated noise of our magnetoresistive sensor is 47 pT/Hz1/2 at 1 Hz and 1.4 pT/Hz1/2 at 1 kHz, respectively. This magnetoresistance sensor dissipates only 100 μW of power while operating under an applied voltage of 1 V at room temperature.

9551-106, Session 25

Towards high-frequency operation of polarization oscillations in spin vertical-cavity surface-emitting lasers *(Invited Paper)*

Markus Lindemann, Nils C. Gerhardt, Martin R. Hofmann, Ruhr-Univ. Bochum (Germany); Tobias Pusch, Rainer Michalzik, Univ. Ulm (Germany)

Compared to purely charge based devices, spintronic lasers offer promising perspectives for new superior device concepts. Especially vertical-cavity surface-emitting lasers with spin-polarization (spin- VCSELs) feature ultrafast spin and polarization dynamics. Oscillations in the circular polarization degree can be generated using pulsed spin-injection. The oscillations evolve due to the carrier-spin-photon system, which is coupled for the linear modes in the VCSEL's cavity via birefringence. The polarization oscillations are independent of the conventional relaxation oscillations and have the potential to exceed frequencies of 100 GHz. The oscillations are switchable and can be the basis for ultrafast directly modulated spin-VCSELs for e.g. communication purposes. The polarization oscillation frequency is mainly determined by the birefringence. We show a method to tune the birefringence and thus the polarization oscillation frequency by adding mechanical strain to the substrate in vicinity of the laser. We demonstrate first experimental results for high frequency operation using 850 nm oxide-confined single-mode VCSELs. The results are compared with simulations using the spin-flip-model for high birefringence values. By means of this model, theoretical limitations of high frequency operation beyond 100 GHz are discussed.

9551-96, Session 26

An efficient biological source for light induced spin injection: photosystem I *(Invited Paper)*

Chanoch Carmeli, Tel Aviv Univ. (Israel); Ron Naaman, Weizmann Institute of Science (Israel); Itai Carmeli, Omri Heifler, Tel Aviv Univ. (Israel); Karuppannan S. Kumar, National Univ. of Singapore (Singapore)

Recent research in spintronics is aimed at introducing spin-based devices in medical and biological applications. An essential component in these devices is the spin injector. We observed very high spin selectivity in electron transfer the chlorophyll protein complex photosystem I (PSI). Light-induced spin injection was observed by adsorbing the PSI complex on a silver substrate, exciting it with red light and using a spin analyzer device developed recently for detecting spin polarization. It was found that the photoexcitation-induced charge separation across PSI is spin selective and that the system has an efficiency of almost 100% in spin-specific injection. Temperature dependence studies revealed that the injection is especially efficient at room temperature. The observation that the nano-size protein operates at room temperature and in a dry environment renders PSI as a possible spintronic component for applications in nano optoelectronic devices. At physiological relevant temperatures the spin selectivity is extremely high and is superior to the spin polarization obtained by most inorganic spin injectors at room temperature. This finding opens the possibility of combining spintronics with bio-applications having a bio-system-based spin injector. Since the system properties are not related to the exchange interaction, that controls magnetism, this system can be miniaturized to a scale of a few nm. This size is difficult to obtain with ferromagnetic-based devices which become superparamagnetic and their spin orientation is not stable at temperatures relevant to many applications.

9551-97, Session 26

Spin injection and relaxation in a highly doped organic polymer film *(Invited Paper)*

Motoi Kimata, Daisuke Nozaki, Yasuhiro Niimi, The Univ. of Tokyo (Japan); Hiroyuki Tajima, Univ. of Hyogo (Japan); YoshiChika Otani, The Univ. of Tokyo (Japan)

The organic semiconductors (OSCs) are promising candidates for long-distance spin current transport. However, most of the OSCs have a strongly disordered structure, so that the transport and relaxation properties of spin currents in OSCs have not been fully understood unlike the usual metallic materials. To resolve this problem, we have performed the systematic studies on the spin current transport and relaxation mechanism in a highly doped OSC, PEDOT: PSS. In this study, we have respectively carried out spin pumping, electron paramagnetic resonance, and charge transport experiments to determine the spin diffusion length (SDL), the spin lifetime and spin diffusion constant. The obtained SDL of the order of one hundred nanometers is comparable to the calculated SDL using the experimentally obtained spin lifetime and the spin diffusion constant. However, the spin lifetime is much shorter than the reported value, meaning that the spin relaxation mechanism in doped OSCs is quite different from the previous discussions. In the present work, we propose the overall spin transport and relaxation mechanism in the hopping conduction regime of doped OSCs: the spin angular momentum is almost preserved in the hopping event, on the other hand, the spin relaxation mainly occurs within the nano-scale OSC crystal grains.

9551-98, Session 26

Tuning exchange interactions in organometallic semiconductors

Naveen Rawat, Madalina I. Furis, The Univ. of Vermont (United States)

Development of organic semiconductors has emerged as a leading area of research as they are expected to overcome limitations of inorganic semiconductor devices for certain applications where low cost manufacturing, device transparency in the visible range of white light spectrum or mechanical flexibility are more important than fast switching times. Solution processing methods produce thin films with millimeter -sized crystalline grains at very low cost manufacturing prices, ideally suited for optical spectroscopy investigations of long range many-body effects in organic systems. Our research is focused on a quest for magnetic organic semiconductor systems where magnetic ordering is achieved through a

tunable carrier-mediated spin exchange interaction, an organic analogue of an RKKY mechanism.

To this end we synthesized an entire family of organo-soluble 3-d transition metal Pc's and we successfully employed a novel solution-based pen-writing deposition technique to fabricate long range ordered thin films of mixtures of metal-free (H2Pc) molecule and Organo-metallic Phthalocyanines (MPc's) without any loss of long range order.

Our previous studies on the parent MPc crystalline thin films identified different electronic states mediating exchange interactions in these materials. This understanding of spin-dependent exchange interaction between delocalized ϖ-electrons with unpaired d-spins has driven us to further tune these interactions by mixing Co or MnPc and H2Pc in different ratios ranging from 1:1 to 1000:1 H2Pc:MPc. Variable temperature Magnetic Circular Dichroism (VTVH-MCD) reveal that magnetic exchange switches sign from AFM to FM as a function of ratio in the 1:1 through 10:1 range. The magnitude of the exchange is also tunable as a function of the average distance between unpaired spins in these materials. Furthermore, high magnetic field (B < 25T) MCD and Magneto-PL show evidence of spin-polarized band-edge excitons in the same materials.

Conference 9552: Carbon Nanotubes, Graphene, and Emerging 2D Materials for Electronic and Photonic Devices VIII

SPIE. OPTICS+ PHOTONICS NANOSCIENCE+ ENGINEERING

9552-1, Session 1

Using wafer-scale epitaxial graphene for producing twisted bilayers with controlled twist angle for electronics applications *(Invited Paper)*

Christos D. Dimitrakopoulos, Univ. of Massachusetts Amherst (United States)

Graphene's exceptional properties make it attractive for technological applications in many areas, including high-speed electronics. The establishment of processes for producing high quality, large-scale graphene is necessary for such applications. Large area growth of epitaxial graphene on the Si-face of hexagonal SiC (0001) wafers exhibits manageable growth kinetics, and most importantly, its azimuthal orientation is fixed, as it is determined by the structure of the single crystal substrate. Therefore, this is a viable method for producing graphene with uniform coverage and structural coherence at wafer-scale.[1],[2]

Semi-insulating SiC is a good substrate for graphene RF transistors, however, its cost is so high that potentially only niche applications of graphene on SiC (e.g. defense or space related) can be viable.

Furthermore, to enable hybrid electronics, where standard circuits built on Si perform digital logic functions while graphene that does not exhibit a band gap is used for ultrafast analog devices, we would need to transfer epitaxial graphene onto Si wafers. To address these issues, we have developed a method in which a graphene film grown on a 4" SiC wafer is exfoliated via the stress induced by an overgrown Ni film and transferred to other substrates, resulting in a wafer-scale monolayer of graphene that is continuous and has a single azimuthal orientation.[3] This growth and transfer process can be repeated on the same SiC wafer hundreds to thousands of times, dramatically reducing the cost per wafer-sized graphene layer. The characterization of the transferred films shows that they are of quality similar to the pristine films on SiC.

Capitalizing on this new method for single crystal epitaxial graphene transfer, we have initiated a project to produce bilayers of graphene with deterministically controlled twist angles. The inspiration for this experimental work is recent theoretical work by Maroudas and coworkers4 that predicts the opening of substantial band gaps at specific twist angles in bilayer graphene. We will report our methods for producing twisted bilayers with controlled twist angle, their characterization and device results.

Lithographically defined 3-dimensional graphene scaffolds *(Invited Paper)*

D. Bruce Burckel, Sandia National Labs. (United States)

Graphene, single atomic layer 2-dimensional sheets of sp2-bonded carbon atoms, has attracted significant attention since the "Scotch tape" exfoliation method was demonstrated as a method to prepare useable areas of material. The excitement over potential applications for graphene has placed renewed interest in development of alternative, scalable methods to prepare graphene. Transition metals (e.g. nickel and copper) are known to catalyze the formation of sp2 bonds when carbon is deposited on them, forming a route to production of graphene. Recently we have demonstrated fabrication of 3D graphene following a variation of this process. Starting from lithographically defined photoresist structures which are converted to sp3 bonded carbon by heating to ~1000 degrees C in a reducing atmosphere, nickel is deposited conformally on the exterior of the carbon scaffold and subsequently annealed. During the anneal process, the carbon diffuses through the nickel and emerges on the exterior of the nickel as sp2 bonded carbon. The 3D topology of the scaffold results in buckling of the graphene to accommodate the non-2D nature of the structure, but otherwise, high quality graphene is formed, suitable for a variety of electrochemical applications. This paper will detail the fabrication, characterization and electrochemical application of these 3D graphene scaffolds.

Supported by the Laboratory Directed Research and Development program at Sandia National Laboratories. Sandia National Laboratories is a multi-program laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000.

Engineering catalytic activity via ion beam bombardment of catalyst supports for vertically aligned carbon nanotube growth *(Invited Paper)*

Ahmad E. Islam, Air Force Research Lab. (United States) and National Research Council (United States) and National Academy of Sciences (United States); Pasha Nikolaev, Air Force Research Lab. (United States); Placidus B. Amama, Kansas State Univ. (United States); Sammy Saber, Air Force Research Lab. (United States); Dmitri Zakharov, Brookhaven National Lab. (United States); Daniel Huffman, Gordon Sargent, Michelle Erford, Sheldon Semiatin, Air Force Research Lab. (United States); Eric A. Stach, Brookhaven National Lab. (United States); Benji Maruyama, Air Force Research Lab. (United States)

We have developed a method to control catalyst activity for super-growth of vertically aligned carbon nanotubes (VA-CNT) by defect engineering the catalyst support. In earlier work, we showed the importance of the structure and surface state of different alumina catalyst supports as a

distinguishing characteristic driving catalyst lifetime and carbon nanotube yield. Our comparison of different types of alumina deposited using e-beam evaporation, magnetron sputtering, and atomic layer deposition gave insight into the mechanisms of catalyst deactivation, but did not give us direct control over the catalyst activity. Here we used ion beam bombardment to control activity transforming sapphire, a substrate that normally does not support VA-CNT growth, into a substrate that supports super-growth of VA-CNT as good as the best deposited alumina's. A wide range of surface characterization techniques were used to characterize the material transformation induced by ion beam bombardment and hence to study the catalyst activity during VA-CNT growth. By tuning the degree of ion beam bombardment, we purposely control the structure and chemistry of the support, the resultant catalyst diameter and areal density, and ultimately the activity of the catalyst. This ability to control the catalyst activity enables us to grow VA-CNTs with tunable height and also offers a versatile way to pattern VA-CNT growth by masked ion bombardment. The capability to grow carbon nanotubes on substrates that otherwise do not support growth offers promising applications in many electronic, thermal, energy storage uses of carbon nanotubes.

9552-5, Session 1

Noncontact carrier dynamic characterization of hybrid graphene-based thin films by terahertz pulsed and CW techniques

Ehsan Dadrasnia, Sujitha Puthukodan, Univ. Carlos III de Madrid (Spain); Guillaume Ducournau, Jean-François Lampin', Univ. des Sciences et Technologies de Lille (France); Frédéric Garet, Jean-Louis Coutaz, IMEP-LAHC (France); Horacio R. Lamela Rivera, Univ. Carlos III de Madrid (Spain)

The graphene-based thin films are usually stacked on substrate for different optoelectronic devices. A profoundly study of the graphenes' electrical and optical characterization is necessary in order to be applied them in novel optic and electronic applications. Four-point probe (Klarskov et al.,Nanotechnol., 2011) or van der Pauw (Li et al.,Nano Letters, 2009) method, and Hall effect measurements (Zhang et al.,Nature, 2005) applied to measure the characteristics of the graphene-like materials as contact techniques. Four-point probe and van der Pauw measure only the conductivity or resistivity, while Hall effect method measures the carrier density and the carrier mobility. The contacting issue may damage such fragile device and thus may prevent a multiple measurement procedure and/or a subsequent use of the tested devices.

We have recently reported the noncontact and nondestructive pulsed terahertz time-domain spectroscopy (THz-TDS) (Dadrasnia et al.,Appl. Phys. Lett., 2014, Dadrasnia et al.,Adv. Condens. Matter Phys,2014) and continuous wave (CW) techniques (Puthukodan et al.,Electron. Lett., 2014, Dadrasnia et al.,J. SPECTROSC.,2014) to measure the electrical conductivity of such high conductance graphene and carbon-based materials at AC and DC levels.

The novelty of this new work is to apply non-Drude responses to demonstrate the potential features of both THz CW and TDS transmission/reflection measurements not only to derive the electrical conductivity, but also to study the optical and ultrafast mobility carrier transport parameters without the need for application of gating potentials. In this study, we test this approach for nanometric hybrid silver nanowires-graphene films grown using common chemical vapor deposition on the top of a quartz substrate.

9552-40, Session 1

Design of nanomaterials for energy storage *(Invited Paper)*

Cengiz Sinan Ozkan, Univ. of California, Riverside (United States)

I will describe innovative approaches for the design and synthesis of hierarchical three dimensional graphene hybrid materials which possess characteristics including ultra large surface area, tunability, and high conductivity which are appealing to diverse energy storage systems. Next, I will talk about three-dimensional cone-shape carbon nanotube clusters decorated with amorphous silicon for lithium ion battery anodes. An innovative silicon decorated cone-shape CNT clusters (SCCC) is prepared by depositing amorphous silicon onto CCC. The seamless connection between silicon decorated CNT cones and graphene facilitates the charge transfer in the system and provides a binder-free technique for fabricating lithium ion batteries.

9552-7, Session 2

Genomics with graphene nanotechnology *(Invited Paper)*

Jean-Pierre Leburton, Univ. of Illinois at Urbana-Champaign (United States)

The single-atom thickness of monolayer graphene makes it an ideal candidate for DNA sequencing as it can scan molecules passing through a nanopore at high resolution. Additionally, unlike most insulating membranes, graphene is electrically active, and this property can be exploited to control and electronically sense biomolecules. We show that the shape of the edge as well as the shape and position of the nanopore can strongly affect the electronic conductance through a lateral constriction in a graphene nanoribbon as well as its sensitivity to external charges. In this context the geometry of the graphene membrane can be tuned to detect the rotational and positional conformation of a charge distribution inside the nanopore. We show that a quantum point contact (QPC) geometry is suitable for the electrically-active graphene layer and propose a viable design for a graphene-based DNA sequencing device.

9552-8, Session 2

Optoelectronic properties of CZTS(e) as revealed by low-temperature photoluminescence studies *(Invited Paper)*

Talia Gershon, IBM Thomas J. Watson Research Ctr. (United States); Byungha Shin, KAIST (Korea, Republic of); Tayfun Gokmen, Yun S. Lee, Supratik Guha, IBM Thomas J. Watson Research Ctr. (United States)

CZTSSe photovoltaic devices have long held promise as earth-abundant substitutes for the commercial thin film absorber material CIGS. Efficiencies up to 12.6% have been demonstrated with the mixed sulfo-selenide CZTSSe, however this performance is well below the levels achieved with CIGS (>20%). A leading explanation of the lower performance relates to the highly defective nature of the CZTSSe bulk, which causes electrical distortions of the valence and conduction bands and hence a reduction in quasi Fermi level splitting in the material under illumination, and ultimately a low Voc. This talk will describe a method for examining the bulk defects in CZTS and CZTSe materials using low-temperature photoluminescence measurements (4K). It will be shown that a larger concentration of defects as measured using this technique is correlated with a reduction in device Voc. The talk will also discuss some of the optoelectronic consequences of sodium incorporation into CZTS(e), including a change in the energetic depth of the optically-active defects with respect to the band gap and a change in the radiative luminescence efficiency. The results presented will help explain the empirical observation that the presence of sodium in the absorber is correlated with high performance CZTSSe photovoltaic devices.

9552-9, Session 2

Bromination of graphene: a new route to making high performance transparent conducting electrodes with low optical losses

Ahmed E. Mansour, Aram Amassian, King Abdullah Univ. of Science and Technology (Saudi Arabia); Minas H. Tanielian, Boeing Research and Technology (United States)

The high optical transmittance, electrical conductivity, flexibility and chemical stability of graphene have triggered great interest in its application as a transparent conducting electrode material and as a potential replacement for indium doped tin oxide. However, currently available large scale production methods such as chemical vapor deposition produce polycrystalline graphene, and require additional transfer process which further introduces defects and impurities resulting in a significant increase in its sheet resistance. Doping of graphene with foreign atoms has been a popular route for reducing its sheet resistance which typically comes at a significant loss in optical transmission.

Herein, we report the successful bromine doping of graphene resulting in air-stable transparent conducting electrodes with up to 80% reduction of sheet resistance reaching ~180 ?/? at the cost of 2-3% loss of optical transmission in case of few layer graphene and 0.8% in case of single layer graphene. The remarkably low tradeoff in optical transparency leads to the highest enhancements in figure of merit reported thus far. Furthermore, our results show a controlled increase in the workfunction up to 0.3 eV with the bromine content. These results should help pave the way for further development of graphene as potentially a highly transparent substitute to other transparent conducting electrodes in optoelectronic devices.

9552-10, Session 2

Thermal instability of field emission from carbon nanotubes studied using multi-physics simulation by considering space charge effect

Ahmad E Islam, Air Force Research Laboratory (United States) and National Research Council (United States) and National Academy of Sciences (United States); Steven B. Fairchild, Benji Maruyama, Air Force Research Lab. (United States)

Thermal stability is an important concern for practical use of high-current field emitters in display, X-ray generation, Hall thruster, and microplasma generation. Carbon nanotubes (CNTs) and their bundles have high thermal conductivity and offers great promise in this aspect, as evident from the wide-scale availability of experiments with CNT-based emitters. Analysis of these experiments is often carried out using – classical Fowler-Nordheim (FN) equation and heat equation with no self-consistency, infinite conductivity for CNT, and a linear potential profile near the emission points. Ideal work-function of CNT is typically assumed during extraction of critical parameters like field enhancement factor, area of emission – making these extractions physically irrelevant. Additionally, the space-charge effect – one of the most important aspect of high-current field emission – is never considered during data analysis.

In this work, we use a self-consistent numerical framework for the first time to study thermal stability of field emission in CNT-based emitters by considering proper electrostatics, quantum-mechanical tunneling (with FN equation as the limiting case), heat flow, and space charge effect. Our self-consistent numerical simulation compares well with the available experimental results. This comparison suggests consideration of finite CNT conductivity and proper workfunction as key for accurate extraction field enhancement factor. Developed framework also offers a unique opportunity to study temperature rise in the emission areas and suggests options for improving thermal stability and hence mitigating thermal runaway. The analysis also identifies the role of impurity in reducing the space charge effect.

9552-11, Session 2

Study of 2D triangular lattice of multiwall carbon nanotube arrays

Xingxing Wu, Mei Wang, Maojin Yun, Weijin Kong, Qingdao Univ. (China)

A triangular lattice photonic crystal is formed with the periodic arrays of multiwall carbon nanotube. With the Drude-Lorentz model, the photonic properties of the designed multiwall carbon nanotube photonic crystal are investigated by means of optical transmission measurements. In order to find the relations between optical properties and different parameters of the photonic crystals, such as radius and intermediate spacing of the nanotube, the transverse electric (TE) and transverse magnetic (TM) waves propagation should be considered respectively. The transmission spectrum and simulation results show that a strong metamaterial cut-off filtering effect at the plasma frequency is obtained with the designed multiwall carbon nanotube photonic crystal. It can be used in high pass filters, waveguides, switches and diffraction gratings which based on the computational analysis.

9552-12, Session 2

Mitigation of charged impurity effects in graphene field-effect transistors with polar organic molecules

Barrett C. Worley, Seohee Kim, Deji Akinwande, The Univ. of Texas at Austin (United States); Peter J. Rossky, Rice Univ. (United States); Ananth Dodabalapur, The Univ. of Texas at Austin (United States)

Recent developments in monolayer graphene production allow its use as the active layer in field-effect transistor technology. Favorable electrical characteristics of monolayer graphene include high mobility, operating frequency, and good stability. These characteristics are governed by such key transport physical phenomena as electron-hole transport symmetry, Dirac point voltage, and charged impurity effects. Doping of graphene occurs during device fabrication, and is largely due to charged impurities located at or near the graphene/substrate interface. These impurities cause scattering of charge carriers, which lowers mobility. Such scattering is detrimental to graphene transistor performance, but our group has shown that coating with fluoropolymer thin films or exposure to polar organic vapors can restore favorable electrical characteristics to monolayer graphene. By partially neutralizing charged impurities and defects, we can improve the mobility by approximately a factor of 2, change the Dirac voltage by fairly large amounts, and reduce the residual carrier density significantly. We hypothesize that this phenomena results from screening of charged impurities by the polar molecules. To better understand such screening interactions, we performed computational chemistry experiments to observe interactions between polar organic molecules and monolayer graphene. The molecules interacted more strongly with defective graphene than with pristine graphene, and the electronic environment of graphene was altered. These computational observations correlate well with our experimental results to support our hypothesis that polar molecules can act to screen charged impurities on or near monolayer graphene. Such screening favorably mitigates charge scattering, improving graphene transistor performance.

9552-13, Session 2

On-chip high power porous silicon lithium ion batteries with stable capacity over 10000 cycles *(Invited Paper)*

Andrew S. Westover, Daniel Freudiger, Zarif Gani, Keith Share, Landon Oakes, Rachel E. Carter, Cary L. Pint, Vanderbilt Univ. (United States)

We demonstrate the operation of a graphene-passivated on-chip porous silicon material as a high rate lithium ion battery anode with over 50x power density and 100x energy density improvement compared to identically prepared on-chip porous silicon supercapacitors. We demonstrate this Faradaic storage behavior to occur at fast charging rates (1-10 mA/cm2) where lithium locally intercalates into the nanoporous silicon, but not underlying bulk silicon material. This prevents the degradation and poor cycling performance that is commonly observed from deep storage in bulk silicon materials. As a result, this device exhibits cycling performance that exceeds 10,000 cycles with capacity above 0.1 mAh/cm2, without notable capacity fade. This work demonstrates a practical route toward high power, high energy, and long lifetime all-silicon on-chip storage systems relevant toward integration of energy storage into electronics, photovoltaics, and other silicon-based technology.

9552-14, Session 3

Two-dimensional material electronics and photonics *(Invited Paper)*

Wenjuan Zhu, Univ. of Illinois at Urbana-Champaign (United States)

Two-dimensional (2D) materials has attracted intense interest in research in recent years. As compared to their bulk counterparts, these 2D materials have many unique properties due to their reduced dimensionality and symmetry. A key difference is the band structures, which lead to distinct electronic and photonic properties. The 2D nature of the materials also plays an important role in defining their exceptional properties of mechanical strength, surface sensitivity, thermal conductivity, tunable band-gap and interaction with light. These unique properties of 2D materials open up broad territories of applications in computing, communication, energy, and medicine. In this talk, I will present our work on understanding the electrical properties of graphene and MoS2, in particular current transport and band-gap engineering in graphene, interface between gate dielectrics and graphene, and gap states in MoS2. I will also present our work on the nano-scale electronic devices (RF and logic devices) and photonic devices (plasmonic devices and photo-detectors) based on graphene and transition metal dichalcogenides.

9552-15, Session 3

Optical selection rule based on valley-exciton locking in monolayer TMDC

Jun Xiao, Ziliang Ye, Ying Wang, Hanyu Zhu, Yuan Wang, Xiang Zhang, Univ. of California, Berkeley (United States)

Layered transition metal dichalcogenide (TMDC) with hexagonal lattice structure has six valleys at corners of the Brillouin zone. The nontrivial Berry curvature distribution renders the adjacent valleys with distinguishable valley angular momentum, which enables itself as an ideal 2D valleytronic platform. Recent studies reported strong excitonic effect in monolayer WS2 and each excitonic state is identified with a well-defined orbital angular momentum, however the anticipated selection rules involve nonlinear optical processes are not clear. Here we show valley angular momentum (VAM) together with exciton angular momentum (EAM) impose different valley-exciton locked selection rules for second harmonic generation (SHG) and two photon luminescence (TPL) in monolayer WS2. Moreover, the two-photon induced valley populations yield net circular polarized photoluminescence after a sub-ps interexciton relaxation. The work demonstrates a new approach to control valley population at different excitonic states for next generation of optical circuits and quantum information computing.

9552-16, Session 3

Second-harmonic generation in an atomic phase-matched nonlinear 2D crystal

Mervin Zhao, Ziliang Ye, Yu Ye, Hanyu Zhu, Yuan Wang, Univ. of California, Berkeley (United States); Yoshihiro Iwasa, The Univ. of Tokyo (Japan); Xiang Zhang, Univ. of California, Berkeley (United States)

The second harmonic generation (SHG) produced from two-dimensional atomic crystals have been utilized recently in studying the grain boundaries and electronic structure of such ultra-thin materials. However, the SHG in many of these crystals, such as transition metal dichalcogenides (TMDCs), only occur in odd numbered layers with limited intensity due to their noncentrosymmetric nature. Here, we probe the SHG from the bulk noncentrosymmetric molybdenum disulfide (MoS2). Whereas the commonly studied 2H crystal phase's anti-parallel nonlinear dipoles in adjacent layers give an oscillatory SH response, the parallel nonlinear dipoles of each atomic layer in the 3R phase constructively interfere to amplify the nonlinear light. Due to this interference, we observed the atomically phase-matched condition yielding a quadratic dependence between the intensity and layer number. Additionally, we probed the layer evolution of the A and B excitonic transitions in 3R-MoS2 using SHG spectroscopy and found distinct electronic structure differences arising from the crystal geometry. These findings demonstrate the dramatic effect of the symmetry and layer stacking of these atomic crystals.

9552-17, Session 3

Monolayer tungsten disulfide laser

Yu Ye, Zi Jing Wong, Univ. of California, Berkeley (United States); Xiufang Lu, Univ. of Science and Technology of China (China); Hanyu Zhu, Yuan Wang, Univ. of California, Berkeley (United States); Xianhui Chen, Univ. of Science and Technology of China (China); Xiang Zhang, Univ. of California, Berkeley (United States)

When transition metal dichalcogenide (TMDC) crystals are thinned to monolayers, they undergo an indirect to direct bandgap transition, enabling rich electroluminescent and photoluminescent behaviors. Coupling and integration of TMDC monolayers with photonic crystal and distributed Bragg reflector microcavities have recently been reported with Purcell enhancement of spontaneous emission and strong light-matter interaction. However, realization of laser – a fundamental building block of optoelectronic system – remains a bottleneck, mainly due to the limited overall materials gain volume and difficulty to design efficient optical confinement structure. In fact, the quantum confinement on these layered d-electron materials leads to layer-dependent evolution of electronic structure with step like density of states for monolayers comparing to their bulk counterparts, Making TMDC monolayers a unique optical gain medium for superior lasing characteristics. Here, we report the first realization of monolayer tungsten disulfide (WS2) laser embedded in a microdisk resonator. To reduce the 2D material lasing threshold, we utilized a whispering gallery mode resonator with a high quality factor. The Si3N4/WS2/HSQ sandwich configuration provides a strong feedback and mode overlap. An excitonic laser emission has bee observed in the visible wavelength. Our work marks a major step towards monolayer-based on-chip active optoelectronics and integrated 2D photonic platforms for new optical communication and computing applications.

9552-18, Session 3

Plasmonic gold nanorods enhance the photoluminescence of a two-dimensional molybdenum disulfide (MoS2) monolayer

Min-Hsiung Shih, Kevin Lee, Yi-Huan Chen, Academia Sinica (Taiwan)

Enhancing the Photoluminescence (PL) of a weak emitter, such as the 2-D atomic layers of molybdenum disulfide (MoS2), is critical for developing the next generation optoelectronic devices such as flexible mobiles, ultrathin light-emitting diodes, and atomically thin phototransistors. MoS2, which is one of the transition metal dichalcogenide (TMD) semiconductors, has received great attention due to its excellent optical and electronic properties and potential applications in field-effect transistors, light emitting and sensing devices. This study presents the enhanced photoluminescence (PL) of a MoS2 monolayer incorporating a MoS2 monolayer in the presence of gold (Au) nanorods. A localized surface plasmon wave of Au nanorods that generated around the MoS2 monolayer can provide resonance wavelength overlapping with that of the MoS2 gain spectrum. These spatial and spectral matches between the localized surface plasmon polariton waves and that from MoS2 emission drastically enhanced the light emission from the MoS2 monolayer. Upon optimizing the Au nanorod density in the system, we obtained more than six-fold intensity enhancement of the PL that was generated from the MoS2 monolayer incorporating Au nanorods, as compared to the intensity of the PL from the pristine MoS2 monolayer. The plasmonic Au nanostructures approach provides a valuable avenue to enhancing the emitting efficiency of the 2-D nano-materials and their devices for the future optoelectronic devices and systems.

9552-20, Session 3

Pulsed laser annealing for advanced performance of mechanically flexible and optically transparent multilayer MoS2 transistors *(Invited Paper)*

Hyuk-Jun Kwon, Univ of California Berkeley (United States); Woong Choi, Kookmin Univ. (Korea, Republic of); Min Suk Oh, Display Convergence Research Center, Korea Electronics Technology Institute (Korea, Republic of); Sunkook Kim, Kyung Hee Univ. (Korea, Republic of); Costas P Grigoropoulos, Univ of California Berkeley (United States)

Laser enables the achievement of superb interfacial characteristics between electrode and semiconducting material contact surface and is also useful for a reduction in contact resistance. The irradiation of a pulsed laser with high energy density and short wavelength onto the electrodes leads to thermal annealing at the locally confined small area that needs high temperature without inflicting thermal damage. This contrasts conventional thermal annealing that affects the entire panel, including unwanted areas in which the annealing process should be excluded.

We demonstrate that mechanically flexible and optically transparent (more than 81% transmittance in visible wavelength) multilayered molybdenum disulfide (MoS2) thin-film transistors (TFTs) in which the source/drain electrodes are selectively annealed using picosecond laser achieve the enhancement of device performance without plastic deformation, such as higher mobility, increased output resistance, and decreased subthreshold swing. Numerical thermal simulation for the temperature distribution, transmission electron microscopy (TEM) analysis, current-voltage measurements, and contact-free mobility extracted from the Y-function method (YFM) enable understanding of the compatibility and the effects of pulsed laser annealing process; the enhanced performance originated not only from a decrease in the Schottky barrier effect at the contact, but also an improvement of the channel interface. Furthermore, these results show that the laser annealing can be a promising technology to build up a high performance transparent and flexible electronics.

9552-21, Session 3

Cavity coupled MoS2 light sources *(Invited Paper)*

Ertugrul Cubukcu, Jason C. Reed, Fei Yi, Hai Zhu, Univ. of Pennsylvania (United States)

Emerging transition metal dichalcogenide (TMDC) materials such as MoS2 exhibit a direct electronic bandgap at the monolayer limit. Besides. this material exhibits giant resonant second order optical nonlinear susceptibility. Here, we utilize these unique properties coupled to optical microcavities. In the first part of this talk, we will show our recent results on a wavelength tunable integrated narrowband light source with a chemically enhanced MoS2 layer integrated into a microdisk cavity with a sub-wavelength notch coupler for easy excitation and light extraction. Here, we fabricate SiO2 micro disk resonators that support high-quality factor whispering gallery modes. These microdisk cavities contain a monolayer of the MoS2 crystal directly embedded as part of the fabrication process. In the second part, we will present our recent results on the optomechanical control of second harmonic generation from monolayer MoS2. This work relies on a one-dimensional Fabry-Perot type microcavity, which is doubly resonant with fundamental and second harmonic beams. We envision that this work will pave the way for nanophotonic light sources with atomically thin active media for next generation optoelectronic sensors and systems.

9552-22, Session 3

Towards graphene electronics *(Invited Paper)*

Eric Borguet, Temple Univ. (United States)

Thirty years ago there were two classic forms of carbon (diamond and graphite). Since then, three new carbon allotropes (buckyballs, carbon nanotubes and graphene), all involving only sp2 carbons, have been discovered. While there is much excitement about graphene, another interesting carbon-based material, graphyne (a two dimensional network of sp and sp2 carbon centers.) has been suggested.

Even though bulk graphyne is not known in nature, it has been the subject of theoretical calculations which suggest exciting properties for graphynes beyond those of graphene. While macroscopic samples of graphyne are not currently available, molecular units of graphyne, called carbo-benzenes, have been synthesized by our collaborators in Toulouse.

We report the single molecule electrical measurements on molecular carbo-benzenes, connected to gold electrodes via amine anchoring groups, determined using scanning tunneling microscope break junction (STM-BJ) methods. Our results show that these highly conjugated macro-aromatics with NH2 metal-anchoring functions are superior in conductivity (~100 nS) compared with molecules of similar length (1.94 nm). These experimental results are rationalized by high level calculations performed by our colleagues at Northwestern. Cutting one side of the macro-aromatic circuit results in a two orders of magnitude smaller junction conductance. Furthermore, single carbo-benzene-mediated junctions exhibit field-effect transistor behavior when an electrochemical gate potential is applied, opening the way for device applications.

9552-23, Session 3

Tin disulfide: large-area growth and characterization

Zafer Mutlu, Mihrimah Ozkan, Cengiz S. Ozkan, Univ. of California, Riverside (United States)

Tin disulfide (SnS2), an emerging two-dimensional (2D) layered metal dichalcogenide semiconductor, has promising potential applications in electronic and optoelectronic devices. Here we demonstrate the large-area growth of atomically thin SnS2 films directly on device-compatible SiO2, MgO and sapphire substrates by a scalable chemical vapor deposition

(CVD) method using pre-deposited Sn films and S powders as the reactants. Growth temperature, pressure and pre-deposited film thickness are found to critically impact the quality of the as grown films. The films grown under optimal conditions are found to be of high structural quality. The compositional analysis of the layers is done by X-ray photo?emission spectroscopy. The thickness and surface roughness of the films are determined by atomic force microscopy. High resolution transmission electron microscopy and Raman spectroscopy indicate that the number of layers range from single layer to a few layers. The charge-carrier mobility is measured through the back-gate field-effect transistor configuration. The growth approach developed here can be now used to build broken-gap hetero-structures of 2D materials stacked in the vertical direction such as SnS2/MoTe2 with ultimate control over their morphology, composition, and dimensionality.

9552-24, Session 3

Control of light-matter interaction in 2D atomic crystals *(Invited Paper)*

Vinod M. Menon, The City College of New York (United States)

In this talk I will review recent efforts at enhancing the interaction of light with excitons in 2D atomic crystals of transition metal dichalcogendeis (TMD) using optical microcavities. Approaches to enhance spontaneous emission using one dimensional dielectric microcavities, two-dimensional photonic crystals and metamaterials will be discussed. Following this, I will discuss the regime of strong coupling between excitons and photons resulting in the formation of microcavity polaritons in these systems. The possibility to exploit the unique properties of 2D atomic crystals such as valley polarization in photonic applications will be briefly addressed. Finally I will discuss some potential applications of such microcavity enhanced 2D atomic crystal based devices.

9552-41, Session 3

Tunable WS2 microfiber saturable absorber as mode-locker and Q-switcher in an all-fiber laser

Reza Khazaeinezhad, Yonsei Univ. (Korea, Republic of); Sahar Hosseinzadeh Kassani, Harvard Medical School (United States); Hwanseong Jeong, Ajou Univ. (Korea, Republic of); Kyung Jun Park, Byoung Yoon Kim, KAIST (Korea, Republic of); Dong-Il Yeom, Ajou Univ. (Korea, Republic of); Kyunghwan Ken Oh, Yonsei Univ. (Korea, Republic of)

Ultrafast lasers are used in a variety of applications, ranging from optical communications to medical diagnostics, biomedical imaging and industrial materials processing. Developments of new gain media and mode-locking technologies have changed the outlook of ultrafast lasers over the past two decades. Saturable Absorber (SA) is a key component in passive mode-locked and Q-switched fiber lasers. Over the past couple of decades, a large range of SA materials have been demonstrated, including toxic dyes, semiconductors with costly fabrication process and narrow spectral band, and carbon materials such as Carbon nano tubes (CNTs) and graphene with diameter and chirality absorption dependent and uses hazardous organic solvents such as dichlorobenzene as well as polymer composites for homogeneous dispersion. Nevertheless, all these SAs have their own drawbacks, and are thus unable to fully satisfy the key SA requirements for ultrafast lasers. These limitations motivate research on new materials for alternative SA materials and novel designs. Recently, Transition Metal Dichalcogenides such as MoS2 and WS2 have been attracted intensive attentions due to their unique characteristics in the field of nonlinear optical materials [1-5]. The reported nonlinear optical absorption of MoS2 through Z-scan measurements confirmed that MoS2 not only has significant saturable absorber performance in broadband wavelengths but also demonstrates a higher saturable absorption response than graphene [6]. In this study, we experimentally demonstrated application of WS2 as a SA in a passively Er-doped fiber laser, successfully achieving tunable ultrafast pulses as well as Q-switching operation. We propose a novel tunable saturable absorber based on the WS2-deposited tapered fiber without using any kind of polymer. The use of polymers has many disadvantages, such as decreasing the damage threshold, increasing the non-saturable loss due to absorption. Tapered fibers were fabricated via the standard flame brushing method and WS2 nano-sheets were prepared using liquid phase exfoliation method. Then, the WS2 nano-sheets were optically deposited along the interaction length of the tapered fibers by evanescent field interactions. Subsequently, we built a ring laser including the fabricated SAs and tunable ultrafast pulses based on waist diameter of tapered fiber and Qswitched pulses were obtained.

Plastic events in soft glass materials *(Keynote Presentation)*

Roberto Benzi, Univ. degli Studi di Roma “Tor Vergata” (Italy)

Many materials around us respond elastically to small applied stresses, but flow once a threshold stress (the yield stress) is exceeded. This is the case for food products, powders, cosmetics, foams, etc... It turns out that understanding the yield stress transition in these materials, often called soft glasses, is a challenging question. Similar to structural glasses, soft glasses exhibit aging and complex dynamics. Also, the size of the elementary building block of a soft glass is usually ranging from 1 micron to 1mm, ruling out the possibility to investigate the problem by molecular dynamics.

Recently, a new approach has been proposed: using a mesoscopic formulation of the system, the dynamics of relative simple soft glasses, like foams or micro emulsions, has been investigated. Numerical simulations allow the computation of several important properties of the systems, such as the yield stress transition. In this talk, I will review the new approach and explain how the complexity of soft glass dynamics may be disentangled in a systematic way.

9552-26, Session 4

A graphene-based non-volatile memory

Loic Loisel, Ecole Polytechnique (France) and Nanyang Technological Univ. (Singapore); Ange Maurice, Nanyang Technological Univ. (Singapore); Bérengère Lebental, Ecole Polytechnique (France) and Institut Francais

des Sciences et Technologies des Transports de l'amenagement et des Reseaux (France); Stefano Vezzoli, Nanyang Technological Univ. (Singapore); Costel-Sorin Cojocaru, Ecole Polytechnique (France); Beng Kang Tay, Nanyang Technological Univ. (Singapore)

We report on the demonstration and characterization of a non-volatile graphene-based memory, where the resistance level can be reversibly modulated with a contrast exceeding 400. We study two-terminal devices consisting of highly crystalline (Raman I(D)/I(G) ≈ 0.2) monolayer CVD-graphene micro-ribbons transferred on SiO2 after growth on Cu. Electrical characterizations right after fabrication show the expected Ohmic behavior with k? resistance level and no memory effect.

A breakdown technique turns the resistive devices into memories: we apply a voltage sweep up to 30V (a few mA). During the sweep, several moderate jumps in resistance are observed, followed by a final rise to a high resistance state (several M?). As evidenced by Raman mapping, the resulting material is highly disordered graphene (I(D)/I(G) ≈ 1.3) covering the whole device width. After breakdown, the resistance can be reversibly set at two well-separated levels (e.g. 0.1 M? and 10 M?) by applying low voltage pulses (10V; 1-100 ?A) in vacuum. Both conductance states feature the Poole-Frenkel conduction mode, as is typical in disordered carbon. No loss of matter or physical gap is observed with either SEM or AFM.

Overall, our results suggest that the reversible switching is mostly due to thermally-induced increase or decrease in sp2 grain size in disordered graphene. This is significantly different from the commonly reported switching mechanism based on conducting filaments bridging a physical gap.

Plasmonic sensing structure of carbon nanotubes and gold nanoparticles for hydrogen detection

Marco Angiola, Univ. degli Studi di Padova (Italy); Chris Rutherglen, Carbonics, Inc. (United States); Kosmas Galatsis, Univ. of California, Los Angeles (United States); Alessandro Martucci, Univ. degli Studi di Padova (Italy)

Large attention has been directed toward carbon nanotubes as material for chemical sensors. However, little attention was paid toward the different behavior of the metallic and semiconductive carbon nanotubes as optical sensing materials.

Semiconductive or metallic Single Wall Carbon Nanotubes (SWCNTs) have been deposited on gold nanoparticles (NPs) monolayer and used as plasmonic based gas sensor.

The coupling between SWCNTs and Au NPs has the aim of combining the reactivity of the nanotubes towards hazardous gases, such as H2, CO, NO2, with the Localized Surface Plasmon Resonance (LSPR) of gold NPs. The LSPR is known to be extremely sensitive to the changes in the dielectric properties of the surrounding medium, a characteristic that has been widely exploited for the preparation of sensing devices. While the use of SWCNTs for gas sensing has been covered in multiple reports, to the best of our knowledge this is the first time that SWCNTs are used as sensing material in an optical sensor for the detection of reducing and oxidizing gases.

Two different techniques, ink-jet printer and dropcasting, were used for depositing the transparent CNTs film on the plasmonic layer. Both the deposition techniques proved to be effective for the development of transparent optical sensing films.

Metallic SWCNTs showed high sensitivity toward H2 at low temperature and an enhancement of performance at 300°C with the detection of low concentration of H2 and NO2. On the contrary, the semiconductive SWCNTs displayed very poor gas sensing properties, especially for the thinner film.

9552-28, Session 4

Perfect extinction of terahertz waves in monolayer graphene over 2-nm-wide metallic apertures *(Invited Paper)*

Hyeong-Ryeol Park, Univ of Minnesota Twin Cities (United States); Seon Namgung, Univ. of Minnesota, Twin Cities (United States); Xiaoshu Chen, Univ of Minnesota Twin Cities (United States); Nathan C Lindquist, Bethel University (United States); Yan Francescato, Vincenzo Giannini, Stefan A Maier, Imperial College London (United Kingdom); Sang-Hyun Oh, Univ of Minnesota Twin Cities (United States)

2D materials such as graphene possess unique electrical and optical properties that are not present in bulk materials. Due to their atomic-scale thickness, however, 2D materials usually interact only weakly with electromagnetic waves, presenting challenges for realizing high-performance optoelectronic devices. This work demonstrates that by confining light into ultra-small metallic gaps, it is possible to dramatically boost this interaction with graphene. As an extreme case, terahertz waves are squeezed into 2-nm-wide gaps, which are ~100000 times smaller than the wavelength, allowing them to interact with 99% efficiency with monolayer graphene. This experiment is made possible by a new technique called atomic layer lithography to define sub-10-nm-wide and millimeter-long gaps in a metal film. Interestingly, while the gaps cover only 0.002% of the surface, 25% of incident THz energy passes through the metal film. The mechanism behind this dramatically enhanced transmission is partly in the shape of the gaps themselves: these annular gaps are able to efficiently funnel the THz waves along the loop. Furthermore, since the annular gaps are so narrow, the energy density becomes very high inside the gap and near the surface. Therefore, by placing graphene at the exit side of these gaps, 99% of the transmission is blocked since the graphene can now efficiently absorb the strongly confined waves. As an application of this strong absorption, we also demonstrate the construction of a high-quality THz modulator. Nanogaps are integrated with an ionic gel gate and the enhanced intraband absorption in the graphene leads to a very large modulation depth of 80% with an operational voltage as low as 1.5 V. Besides graphene, such ultra-strong light-matter interactions mediated by nanogap structures could also benefit many applications involving other 2D materials.

9552-30, Session 4

Materials and other needs for advanced phase change memory *(Invited Paper)*

Norma E. Sosa, IBM Thomas J. Watson Research Ctr. (United States)

Phase change memory (PCM), with its long history, may now hold its brightest promise to date. This bright future is being fueled by the "push" from big data. PCM is a non-volatile memory technology used to create solid-state random access memory devices that operate based the resistance properties of materials. Employing the electrical resistance differences—as opposed to differences in charge stored—between the amorphous and crystalline phases of the material, PCM can store bits, namely one's and zero's. Indeed, owing to the method of storage, PCM can in fact be designed to hold multiple bits thus leading to a high-density technology twice the storage density and less than half the cost of DRAM, the main kind found in typical personal computers. It has been long known that PCM can fill a need gap that spans 3 decades in performance from DRAM to solid state drive (NAND Flash). Furthermore, PCM devices can lead to performance and reliability improvements essential to enabling significant steps forward to supporting big data centric computing. This talk will focus on the science and challenges of aggressive scaling to realize the density needed, how this scaling challenge is intertwined with materials needs for endurance into the giga-cycles, and the associated forefront research aiming to realizing multi-level functionality into these nanoscale programmable resistor devices.

9552-31, Session 4

Photodetector based on carbon nonotubes

Valeri Timoshenkov, National Research Univ. of Electronic Technology (Russian Federation); Alexandr Pavlov, Evgeni Kitsyuk, Roman Ryazanov, Institute of Nanotechnologies of Microelectronics Russian Academy of Sciences (Russian Federation); Yuri Adamov, National Research Univ. of Electronic Technology (Russian Federation)

Photodetector based on carbon nanotubes (CNT) was investigated. Optical sensor (size 2x8mm) was done on quartz susbtrate (size 5x10.5mm). Samples of photodetectors sensors were produced by planar technology. This technology included deposition of first metal layer (AL), lithography for formation of pads, etching, and formation of local catalyst area by inverse lithography. Catalyst layer for selective synthesize was deposited by standard procedure of magnetron sputtering and consist of Ti/Ni (thickness is 10/2 nm). The catalyst photoresist was removed after sputtering. This procedure forms local synthesis area. After cutting a substrate to chips 5x10.5 mm samples were ready to synthesis. Vertically-aligned multi-wall carbon nanotubes were directly synthesized on quartz chips by PECVD method.

The growing of carbon nanotubes started from catalyst nanoclusters. It was performed by oxidizing annealing at 280°C in O2 environment and reducing annealing at 450 ?C in H2 environment. Synthesis of multiwall carbon nanotubes was carried out in gas mixture composition - C2H2, H2 and NH3. Temperature of substrate holder (550 ?C) was controlled by thermo sensor. Plasma energy generator creates of radio frequency (RF) with energies of 20 W and low frequency (LF) with energy 30 W. The operating pressure was 2 Torr.

The morphology of the nanotubes was observed by scanning electron microscopy. Height of CNT array is approximately 2 µm and average diameter is about 40 nm.

Spectrum sensitivity of photodetector was investigated for 0.4u - 0.8u wavelength. Resistivity of CNT layers over temperature was detected in the range of -40 ?C to 150 ?C.

9552-32, Session 5

Wafer-scale single-crystalline graphene and its application for semiconductor layer transfers *(Invited Paper)*

Jeehwan Kim, IBM Thomas J. Watson Research Ctr. (United States); Hongsik Park, Kyungpook National Univ. (Korea, Republic of); Can Bayram, Univ. of Illinois at Urbana-Champaign (United States); Christos D. Dimitrakopoulos, Univ. of Massachusetts Amherst (United States); James Hannon, IBM Thomas J. Watson Research Ctr. (United States)

The performance of optimized graphene devices is ultimately determined by the quality of the graphene itself. Graphene grown on SiC has a single orientation, but its thickness cannot be limited to one layer. We have developed a method for manipulating these graphene layers with a single-atom-thickness precision. A graphene film of one or two monolayers grown on SiC is exfoliated via the stress induced with a nickel film. The excess graphene is selectively removed with a second exfoliation process with a gold film, resulting in a flat, single-oriented, monolayer graphene film.

This single-oriented graphene can be a template for the growth and transfer of single-crystalline films if films can be epitaxially grown on graphene. We, for the first time, demonstrated direct van der Waals growth of high-quality single-crystalline GaN films on this graphene. The GaN film was released and transferred onto Si substrates. The post-released graphene/SiC substrate was reused for multiple growth and transfer cycles of GaN films. This technique will be generally applied for growing other single-crystalline 3D and 2D materials on graphene and transfer.

Metal-assisted exfoliation (MAE): green process for transferring graphene to flexible substrates and templating of sub-nanometer plasmonic gaps *(Invited Paper)*

Aliaksandr V. Zaretski, Brandon C. Marin, Herad Moetazedi, Tyler J Dill, Liban Jibril, Casey Kong, Andrea R. Tao, Darren J. Lipomi, Univ. of California, San Diego (United States)

This paper describes a new technique, termed “metal-assisted exfoliation,” for the scalable transfer of graphene from catalytic copper foils to flexible polymeric supports. The process is amenable to roll-to-roll manufacturing, and the copper substrate can be recycled. We then demonstrate the use of single-layer graphene as a template for the formation of sub-nanometer plasmonic gaps using a scalable fabrication process called “nanoskiving.” These gaps are formed between parallel gold nanowires in a process that first produces three-layer thin films with the architecture gold/single-layer graphene/gold, and then sections the composite films with an ultramicrotome. The structures produced can be treated as two gold nanowires separated along their entire lengths by an atomically thin graphene nanoribbon. Oxygen plasma etches the sandwiched graphene to a finite depth; this action produces a sub-nanometer gap near the top surface of the junction between the wires that is capable of supporting highly confined optical fields. The confinement of light is confirmed by surface-enhanced Raman spectroscopy measurements, which indicate that the enhancement of the electric field arises from the junction between the gold nanowires. These experiments demonstrate nanoskiving as a unique and easy-to-implement fabrication technique that is capable of forming sub-nanometer plasmonic gaps between parallel metallic nanostructures over long, macroscopic distances. These structures could be valuable for fundamental investigations as well as applications in plasmonics and molecular electronics.

9552-34, Session 5

Graphene growth on SiC(0001) and SiC(000-1): effect of substrate termination, hydrogen etching, and growth ambient *(Invited Paper)*

Zachary R. Robinson, Gell Jernigan, Marc Currie, Jennifer Hite, Konrad Bussmann, U.S. Naval Research Lab. (United States); Luke Nyakiti, Texas A&M Univ. (United States); Nelson Garces, Anindya Nath, Virginia Wheeler, Rachael Myers-Ward, James Wollmershauser, Boris Feygelson, U.S. Naval Research Lab. (United States); James Hannon, IBM T.J. Watson Research Laboraotry (United States); D. Kurt Gaskill, Charles Eddy Jr., U.S. Naval Research Lab. (United States)

Graphene of high crystal quality and single-layer thickness can be grown epitaxially by low pressure sublimation (LPS) on SiC(0001). On SiC(000-1), which is the C-terminated polar surface, there has been much less success growing uniform, single-layer films. In this work, a systematic study of

surface preparation by in situ hydrogen etching follow by LPS in an argon ambient was performed. Hydrogen etching is an important first step in the graphene growth process because it removes damage caused by polishing the surface. However, etching at too high of a temperature or for too long can result in pit formation due to the preferential etching of screw dislocations that intersect the surface. It was found that temperatures above 1450 °C in 200mbar of hydrogen result in pitting of the surface, whereas etch temperatures at and below 1450 °C can result in atomically flat terraces of ~1 ?m. Following the hydrogen etch optimization, a systematic study of argon-mediated graphene growth was carried out by varying temperature and pressure. By performing simultaneous growth on the 4H and 6H substrates, it was found that subtle differences in substrate properties can lead to drastic differences in graphene growth morphology and thickness. However, for all of the films the graphene was found to have non-uniform thickness. Further, x-ray photoelectron spectroscopy and low energy electron microscopy measurements reveal that trace amounts of oxygen that may be present during growth significantly affect the graphene growth process. Recent results will be discussed.

9552-35, Session 5

Theoretical insights into multibandgap hybrid perovskites for photovoltaic applications *(Invited Paper)*

Jacky EVEN, Daniel SAPORI, Laurent PEDESSEAU, Alain ROLLAND, Institut National des Sciences Appliquées de Rennes (France); Mikaël KEPENEKIAN, CNRS, Institut des Sciences Chimiques de Rennes (France); Roberto Robles, ICN2 - Institut Catala de Nanociencia i Nanotecnologia (Spain); Shijian Wang, Yong Huang, Alexandre Beck, Olivier Durand, Institut National des Sciences Appliquées de Rennes (France); Claudine KATAN, CNRS, Institut des Sciences Chimiques de Rennes (France)

In this review, we examine recent theoretical investigations on 3D [1] and layered hybrid perovskites (HOP) [2] that combine classical solid-state physics concepts and density functional theory (DFT) simulations as a tool for studying their exceptional photovoltaic and optoelectronic properties. Such an approach allows one to define a new class of semiconductors, where the pseudocubic high temperature perovskite structure plays a central role. A general symmetry analysis of electronic Bloch states, lattice strain, molecular rotations and optical phonons yield new insight into the influence of lattice distortions, including loss of inversion symmetry, as well as spin-orbit coupling. Electronic band folding and degeneracy, phase transitions, effective masses, carrier transport and optical absorption are analyzed. Screening mechanisms related to thermally activated molecular rotations are important for room temperature optical and transport properties of 3D HOP. Concepts of Bloch and envelope functions, as well as confinement potential are discussed. Dielectric confinement in layered HOP is determined and compared to the one in colloidal nanoplatelets [3]. A new method for the numerical computation of dielectric constant and self-energy profiles is proposed. Non-radiative Auger effects are analyzed for the first time close to the electronic band gap of 3D hybrid perovskites. The new theoretical concepts will be compared to recent experimental investigations on the excitonic properties of both 3D and layered HOP [4].

High aspect ratio CNT structures produced by energetic ion bombardment

Gregory A. Konesky, National Nanotech, Inc. (United States)

Earlier research has sought to utilize the exceptional thermal conductivity of CNTs to produce a heat spreader by bulk cross-linking the CNTs into an interpenetrating network. An isotropic thermal conductivity of 2150 W/m-K was measured in a 5 ?m thick MWCNT film which had been subject to argon ion bombardment with an ion energy of 4 keV and a fluence on the order of 10^17 ions/cm2. While energetic ions will randomly bombard the entire CNT network, on occasion, one will strike a junction where two or more CNTs are touching, momentarily disrupting them. CNTs have the remarkable ability to self-heal, and in doing so, the disrupted junction self-heals into a new interpenetrating junction. However, practical heat spreader applications require films at least 100 times thicker than this initial demonstration. In an attempt to achieve this, substantially higher ion energies and fluence were applied. But rather than forming interpenetrating junctions deeper into the bulk of a CNT thick film, an interesting new form of high aspect ratio structure results, where groups of CNTs are now vertically aligned, even though the original CNT thick film was randomly oriented. There is also a sharp transition at the base of these structures from the new aligned form to the original randomly oriented form. We consider various aspects of ion-induced sputter dynamics coupled to the growth processes of CNTs to account for these new aligned high aspect ratio structures. The role of ion channeling within and between CNTs is also considered.

9552-37, Session 5

Synthesis of large-size graphene by chemical vapor deposition

Ruizhe Wu, Yao Ding, Lin Gan, Zhengtang Luo Luo, Hong Kong Univ. of Science and Technology (Hong Kong, China)

The major obstacle for graphene application is the difficulty to obtain graphene of large size while retain the long range structural order. To synthesis single crystal graphene with large dimension, we developed multiple strategies to enlarge the graphene size by controlling the nucleation density during the initiation stage of chemical vapor deposition processes, or through continued growth. Electron diffraction and Raman mapping measurement show that the graphene flakes are single crystal in nature. Electron transport measurement in Hall bar configuration demonstrate that the graphene exhibit high carrier mobility and exceptional electronic properties. Our method allows the production of high quality graphene film of long range electronic connectivity and structure coherence.

9552-38, Session 5

Nanoscale thermocapillarity enabled purification for horizontally aligned arrays of single-walled carbon nanotubes *(Invited Paper)*

Sung Hun Jin, Incheon National Univ. (Korea, Republic of)

Among the remarkable variety of semiconducting nanomaterials that have been discovered over the past two decades, single-walled carbon nanotubes remain uniquely well suited for applications in high-performance electronics, sensors and other technologies. The most advanced opportunities demand the ability to form perfectly aligned, horizontal arrays of purely semiconducting, chemically pristine carbon nanotubes. Here, we present strategies that offer this capability. Nanoscale thermos-capillary flows in thin-film organic coatings followed by reactive ion etching serve as highly efficient means for selectively removing metallic carbon nanotubes from electronically heterogeneous aligned arrays grown on quartz substrates. The

low temperatures and unusual physics associated with this process enable robust, scalable operation, with clear potential for practical use.

Especially for the purpose of selective joule heating over only metallic nanotubes, two representative platforms are proposed and confirmed. One is achieved by selective joule heating associated with thin film transistors with partial gate structure. The other is based on a simple, scalable, large-area scheme through microwave irradiation by using micro-strip dipole antennas of low work-function metals. In this study, based on purified semiconducting SWNTs, we demonstrated field effect transistors with mobility (> 1,000 cm^2/Vsec) and on/off switching ratio (~10,000) with current outputs in the milliamp range. Furthermore, as one demonstration of the effectiveness over large area-scalability and simplicity, implementing the micro-wave based purification, on large arrays consisting of ~20,000 SWNTs completely removes all of the m-SWNTs (~7,000) to yield a purity of s-SWNTs that corresponds, quantitatively, to at least to 99.9925% and likely significantly higher.

9552-6, Session PWed

Study of SWCNT functionalization by means of SERS

Justinas Ceponkus, Martynas Velicka, Milda Pucetaite, Jorinta Jakubauskaite, Valdas Sablinskas, Vilnius Univ. (Lithuania)

Raman spectroscopy is known to provide information about the quality of the SWCNT's. The information is based on the intensity ratio of D and G spectral modes and the frequency of RBM modes. However due to resonance nature of Raman spectrum of the nanotubes this method is not suitable to detect functionalization of the nanotubes.

Surface enhanced Raman spectroscopy (SERS) is known to enhance the Raman bands up to fourteen orders of magnitude. The use of this technique provides possibility to detect even small amounts of chemical groups attached to the SWCNT. Enhancement effect of particular spectral band in the SERS spectra strongly depends on the strength of adsorption of molecule under studies on the metal particle as well as on the distance of particular chemical group from the metal surface. Since preferable adsorption sites of the functionalized nanotube are the functional groups, SERS technique allows detecting small amounts of functional groups despite strong resonance Raman from backbone of SWCNT.

In this study COOH functionalized nanotubes were dispersed in silver colloid and dried on the standard silver plate for Raman measurements.

Spectra of SWCNT without colloid in the spectral range between 50 and 1800 cm-1 exhibit only three main spectral features: G band at 1590 cm-1, D band at 1350 cm-1, and RBM modes between 200 and 400 cm-1. Spectra of SWCNT with the colloid exhibit several additional spectral bands which do not belong to the colloid. These bands attributed to vibrations of C-C-O, C-C and C-O from the functional groups and the carbon atom of the SWCNT attached to the corresponding group. The bands associated with the vibrations involving O atom is an indication that silver nanoparticles interact with the functional group attached to SWCNT.

9552-39, Session PWed

Use of carbon nanotubes as an anti-icing and de-icing material for aircrafts

Ashwin Kumar Kuchibhotla, Kumar Ravi, Badrinath Vadakkapattu Canthadai, B. V. Reddi, Esakkimuthuraju Murugan, Vidya Jyothi Institute of Technology (India)

Anti-icing and De-icing of aircrafts efficiently is essential and also a major concern for safe operation of a flight.

Traditional methods of anti-icing and de-icing of aircrafts such as heating, deicer boot and deicing fluids make use of salts, waxes and fluids which are toxic to the soil and harm aquatic life. These need to be done every time before take-off. The use of carbon nanotubes delivers significant performance improvements. However, the applicability of this technique has not yet been evaluated.

We propose a novel idea which incorporates the use of carbon nanotubes as an anti-icing and de-icing material.

This paper describes the synthesis of carbon nanotubes by carbon vapor deposition process which is used to create a super hydrophobic coating to be coated on the surface of different aircraft parts. It repels the water by reduction of surface energy and prevents formation of ice on the aircraft.

The results of this study introduce the concept of super hydrophobic coatings of carbon nanotubes which may provide an improvised method of anti-icing and de-icing.

9553-1, Session 1

Using electric field manipulation to fabricate nanoscale fibers on large areas: a path to electronic and photonic devices *(Invited Paper)*

Jack L Skinner, Montana Tech (United States)

Traditional fabrication methods used for the integrated circuit (IC) and the microelectromechanical systems (MEMS) industry have been developed specifically for two-dimensional fabrication on planar surfaces. While electrospinning (ES) has been in existence for over 100 years, its full potential as a fabrication technology has not been reached. ES is not currently being used for commercial fabrication of electronic or photonics devices. The focus of this presentation is on computational and experimental methods focused on spatial fiber control with the aim of expediting the adoption of ES as a common-place fabrication method.

Both analytical and numerical methods are used for modeling fiber deposition. Forces leading to fiber formation and deposition are modeled by integrating the electrostatic force acting on the fiber within a circular area at an elevation 1 mm above the collection plate. A shape function is used to estimate the electrostatic field distribution for the surface integral. Experimental depositions of fibers with nominal sizes of 100 nm were compared with analytical results with reasonable agreement. COMSOL Multiphysics was used to estimate the field strength for given configurations of the ES spinneret and collection plate. We also use active field control to align fibers across electrodes and passive electrostatic lenses to confine the electrostatic field to achieve control over fiber deposition. Applications of our fibers range from being directly used as sensors or in subsequent pattern transfer. The strength of ES as a fabrication technology is in rapid patterning of nanoscale features over large areas with inexpensive materials.

9553-2, Session 1

Structural modulation of nanowire interfaces grown over selectively disrupted single crystal surfaces

Elias J Garratt, Babak Nikoobakht, National Institiute of Standards and Technology (United States)

Recent breakthroughs in deterministic approaches to the fabrication of nanowire arrays have demonstrated the possibility of fabricating such networks using low-cost scalable methods. In this regard, we have developed a scalable growth platform for lateral fabrication of nanocrystals with high precision utilizing lattice match and symmetry. Using this planar architecture, a number of homo- and heterostructures have been demonstrated including ZnO nanowires grown over GaN. The latter combination produces horizontal, epitaxially formed crystals aligned in the plane of the substrate containing a very low number of intrinsic defects. We use such ordered structures as model systems in the interests of gauging the interfacial structural dynamics in relation to external stimuli. Using nanosecond pulses of focused ion beams to slightly modify the substrate surface and selectively form lattice disorders in the path of nanowire growth, we examine the nanocrystal, namely: its directionality and lattice defects. High resolution electron and cathodoluminescence microscopies are used to reveal some interesting optical and structural effects; for instance, a minimum threshold of surface defects that can divert nanowires. We also discuss data indicating formation of surface strains and show their mitigation during the growth process as well as high tolerance of such epitaxial systems to the imposed artificial defects.

Silicon-Germanium epitaxy for radial nanowire heterostructures *(Invited Paper)*

Yung-Chen Lin, Jinkyoung Yoo, Los Alamos National Lab. (United States)

Radial epitaxy enables researchers to modulate composition in nanostructures along radial direction precisely. Radial nanowire heterostructures have been considered as suitable building blocks for electronic and photonic devices with three-dimensional architectures for transistors, photovoltaic devices, and energy storages. From the perspective of fundamental understanding o materials behavior radial heterostructure is very interesting platform to study strain relaxation since defect formation in nanowire heterostructure can be occurred in both core and shell regions. Here we report the observation of cross-over of defect formation region from shell to core in silicon (Si)/germanium (Ge) core/shell NW heterostructures, which are technologically important nanomaterials. We observed that stacking faults primarily nucleated around Si/Ge interface and extended to the Ge shell. As the Ge shell thickness increases, stacking faults can be found in the Si core. Furthermore we will discuss the carrier transport characteristics of Si/Ge radial heterostructures with various growth sequences.

Absorption enhancement and carrier diffusion in single lead sulfide nanowire Schottky solar cells *(Invited Paper)*

Yiming Yang, Xingyue Peng, Steven Hyatt, Dong Yu, Univ. of California, Davis (United States)

Light trapping in sub-wavelength semiconductor nanowires (NWs) offers a promising approach to simultaneously reducing material consumption and enhancing photovoltaic performance. Nevertheless, the absorption efficiency of a NW, defined by the ratio of optical absorption cross section

to the NW diameter, lingers around 1 in existing NW photonic devices, and the absorption enhancement has suffers from a narrow spectral width. The degree of absorption enhancement is expected to substantially scale up with material refractive indices. Here, we show that the absorption efficiency can be significantly improved in NWs with higher refractive indices, by an direct experimental observation of up to 350% external quantum efficiency (EQE) in lead sulfide (PbS) NW resonators, a 3-fold increase compared to Si NWs. Furthermore, broadband absorption enhancement is achieved in single tapered NWs, where light of various wavelengths is absorbed at segments with different diameters analogous to a tandem solar cell. Overall, the single NW Schottky junction solar cells benefit from optical resonance, near bandgap open circuit voltage, and long minority carrier diffusion length, demonstrating power conversion efficiency (PCE) comparable to single Si NW coaxial p-n junction cells, but with much simpler fabrication processes.

9553-7, Session 2

Ordered arrays of bottom-up III-nitride core-shell nanostructures *(Invited Paper)*

Daniel F. Feezell, Ashwin K. Rishinaramangalam, Rhett Eller, Saadat Mishkat Ul Masabih, Michael Fairchild, Darryl M. Shima, Ganesh Balakrishnan, Steven R. J. Brueck, The Univ. of New Mexico (United States)

III-nitrides are the preferred materials for high-brightness light-emitting diodes (LEDs) for solid-state lighting and diode lasers for high-density optical data storage. However, III-nitrides grown on the conventional polar c-plane using sapphire substrates suffer from polarization-related electric fields and high dislocation densities. Growth on nonpolar/semipolar free-standing GaN substrates is one option to address these issues, although the high costs associated with this approach are a concern. Another option is to realize nonpolar/semipolar active regions using nanoscale bottom-up selective-area epitaxy (SAE) on sapphire substrates. The SAE technique results in three-dimensional GaN nanostructure cores with large nonpolar/semipolar surface areas and low dislocation densities on inexpensive substrates. Subsequent growth of InGaN shells on the core templates can be used to fabricate nonpolar/semipolar quantum-well active regions. In this work, we use bottom-up SAE and catalyst-free metal organic chemical vapor deposition (MOCVD) to fabricate ordered arrays of various core-shell nanostructures, including GaN-InGaN nanowalls, pyramidal nanostripes, and nanowires. Scanning electron microscopy, cross-sectional transmission electron microscopy, and micro-photoluminescence are utilized to examine the dependence of geometry, surface morphology, and quantum-well emission on epitaxial growth conditions. Progress toward applying these nanostructures to electrically injected LEDs for solid-state lighting and nanophotonics will also be discussed.

9553-11, Session 3

Template-assisted synthesis of III-nitride and metal-oxide nano-heterostructures using low-temperature atomic layer deposition for energy, sensing, and catalysis applications *(Invited Paper)*

Necmi Biyikli, Cagla Ozgit-Akgun, Hamit Eren, Ali Haider, Tamer Uyar, Fatma Kayaci, Mustafa Ozgur Guler, Ruslan Garifullin, Ali K. Okyay, Gamze M. Ulusoy, Eda Goldenberg, Bilkent Univ. (Turkey)

Recent experimental research efforts on developing functional nanostructured III-nitride and metal-oxide materials via low-temperature atomic layer deposition (ALD) will be reviewed. Ultimate conformality, a unique propoerty of ALD process, is utilized to fabricate core-shell and hollow tubular nanostructures on various nano-templates including electrospun nanofibrous polymers, self-assembled peptide nanofibers, metallic nanowires, and multi-wall carbon nanotubes (MWCNTs). III-nitride and metal-oxide coatings were deposited on these nano-templates via thermal and plasma-enhanced ALD processes with thickness values ranging from a few mono-layers to 40 nm.

Metal-oxide materials studied include ZnO, TiO2, HfO2, ZrO2, and Al2O3. Standard ALD growth recipes were modified so that precursor molecules have enough time to diffuse and penetrate within the layers/pores of the nano-template material. As a result, uniform and conformal coatings on high-surface area nano-templates were demonstrated. Substrate temperatures were kept below 200C and within the self-limiting ALD window, so that temperature-sensitive template materials preserved their integrity III-nitride coatings were applied to similar nano-templates via plasma-enhanced ALD (PEALD) technique. AlN, GaN, and InN thin-film coating recipes were optimized to achieve self-limiting growth with deposition temperatures as low as 100C. BN growth took place only for >350C, in which precursor decomposition occured and therefore growth proceeded in CVD regime. III-nitride core-shell and hollow tubular single and multi-layered nanostructures were fabricated.

The resulting metal-oxide and III-nitride core-shell and hollow nano-tubular structures were used for photocatalysis, dye sensitized solar cell (DSSC), energy storage and chemical sensing applications. Significantly enhanced catalysis, solar efficiency, charge capacity and sensitivity performance are reported. Moreover, core-shell metal-oxide and III-nitride materials showed promise to be used in applications where flexibility is critical like functional membranes, textile and flexible electronic applications.

Simultaneous optical and structural investigation of nanomaterials and nanostructures for LEDs *(Invited Paper)*

Marcus Mueller, Otto-von-Guericke Univ. Magdeburg (Germany); Frank Bertram, Gordson Schmidt, Jürgen Christen, Otto-von-Guericke-Univ. Magdeburg (Germany)

In the past few years, tremendous progress has been achieved on epitaxial growth and processing of group III nitride nano- and microrods. Furthermore, these growth improvements have allowed the fabrication of optoelectronic devices based nanorods as active elements, i.e. light emitting diodes (LEDs). However, their efficiency is still far behind the performance of conventional GaN-based light emitting diodes.

The controlled growth of GaN nanorods offers a potential benefit for achieving higher efficiencies of III-Nitride based optoelectronic devices due to a high surface to volume ratio. Nanorods have a very large active area compared to their footprint. Since the active region is wrapped around the three-dimensional core (for core shell structures), the active layer scales with the rod's aspect ratio (i.e. the ratio of height and diameter). Therefore, by controlling their density, diameter and height, a tremendous increase of active surface can be achieved. Additionally, the low defect density in nanorods allows the characterization of single extended defects which is of high interest for a clear understanding of the formation of these defects.

In this study we present a direct nano-scale correlation of the optical properties with the actual real crystalline structure of single GaN nanorods using low temperature CL spectroscopy in a scanning transmission electron microscope (STEM). We concentrate on the crystalline quality, local In incorporation, n- and p-layer quality and defects of the complete structures.

Sonochemically grown 1D ZnO nanostructures and their applications *(Invited Paper)*

Yavuz Bayam, Gediz Univ. (Turkey); Debora Rodrigues, Univ. of Houston (United States); Rukayya K. Bala, Gediz Üniv. (Turkey); Tugba O. Okyay, Univ. of Houston (United States); Enis E. Tural, Sinem Duyar, Gediz Üniv. (Turkey)

Upon irradiation of liquid with high intensity of sound, the alternate expansion and compression of the acoustic wave create bubbles. These bubbles oscillate and accumulate ultrasonic energy and grow until they reach an unstable size. They eventually collapse and release the concentrated energy stored. The implosive collapse of bubbles generate a hot spot with very high temperature of 5000 K and pressure of 1000 atm, with high heating and cooling rate above 1010 K/s. This phenomenon causes high energy chemical reactions within a short time.

ZnO nanorods of different size were synthesized by sonochemical method. The long sonication period at the maximum amplitude produced the best result, with ZnO nanorods densly grown on the substrate.

The surface morphology, crystal structure and elemental analysis of the grown nanorods sample were observed by optical microscope, SEM, EDS and Raman Spectroscopy.

The antibacterial properties of the sonochemically synthesized ZnO nanorods toward E.coli and B.subtilis was investigated. It was found that the sample sonicated for long period at the maximum amplitude exhibited the highest antibacterial properties.

Gas sensing measurements of sonochemically grown ZnO nanorod network in between Au interdigitated electrodes were carried out for the gas sensing characterization. The gas sensing measurements were carried out for two oxidizing gases (O2 and CO2) and five reducing gases (CO, C2H5OH, C3H7OH, CHCl3, CH2Cl2). Same device has also been utilized and tested as humidity sensor. The results suggest that sonochemical method is a very good candidate for production of high performing, low cost gas and humidity sensors.

9553-14, Session 4

Imaging local electrical and optical responses in nanostructured devices *(Invited Paper)*

Marina S. Leite, Univ. of Maryland, College Park (United States)

If one had the option to resolve the local electrical and optical responses of nanostructured devices at the nanometer scale, this would enable unprecedented correlation between the structural properties of materials and carriers' recombination and collection, allowing for the design of next generation devices with improved performance. Currently, macroscopic electrical and optical characteristics of low-dimensional systems is very well understood, however, a direct correlation between the local electrical and optical responses is still missing. Here we combine scanning probe microscopy techniques to map the voltage and the current generated by optoelectronic devices. By implementing a variant of Kelvin probe force microscopy (KPFM) we map the open-circuit voltage (Voc) of working devices with spatial resolution < 100 nm by measuring the difference between the contact potential difference under illumination and in the dark, which is equal to the photo-generated voltage of the device (and is proportional to the Fermi level splitting). By applying scanning photocurrent microscopy we image local variations in photocurrent, also with nanoscale resolution. We combine these methods to resolve recombination and collection within polycrystalline devices with high spatial resolution. Moreover, we quantify the contribution of (i) increased scattering, (ii) field enhancement, and (iii) waveguiding to solar cells' performance improvement caused by metallic nanostructures. We decorate the solar cells with noble metal and alloyed nanoparticles, and spectrally resolve the effect of scattering enhancement, and the waveguiding contribution by varying the periodicity of the NPs array, and measuring the local changes in Voc as a function of wavelength.

9553-15, Session 4

Latest advances in low-cost solar water splitting nanodevices *(Invited Paper)*

Lionel Vayssieres, Xi'an Jiaotong Univ. (China)

The demand of low cost materials has become one of the major challenges scientists face to address critical contemporary issues such as sustainable energy sources. For instance, one of the promising alternatives for the transition of fossil fuel-based energy to a clean and renewable technology relies on the widespread implementation of solar-related energy systems, however, the high cost of energy production poses an intrinsic limitation. In this context, low cost materials development is required to balance the necessary increase in power generation and conversion efficiency and the costs of implementation and operation. Furthermore, a better comprehensive understanding of materials growth and properties relationships using quantum confinement and nanoscale strategies to raise the theoretical limits by changing the fundamental physics and chemistry is the key to success. Such ideas will be demonstrated by the thermodynamic modeling and low-cost design of crystalline arrays of quantum rods- and dots-based oxides with controlled orientation, size, and shape onto various substrates at nano-, meso-, and micro-scale by aqueous chemical growth at low-temperature. Tailored dimensionality effects on their surface chemistry, electronic structure, and energetics for a low cost and sustainable generation of hydrogen from the two most abundant and geographically-balanced free resources available on this planet, that is the sun and seawater will also be presented.

Resonant spectroscopy of individual CdSe quantum dots containing single Mn2+ ions in (Zn,Cd)Se barrier

Justyna Piwowar, Wojciech Pacuski, Tomasz Smolenski, Mateusz Goryca, Aleksander M. Bogucki, Andrzej Golnik, Piotr Kossacki, Jan Suffczynski, Univ. of Warsaw (Poland)

We present design, a Molecular Beam Epitaxy growth, and results of polarization resolved, resonant spectroscopy of CdSe Quantum Dots (QDs) embedded in Zn1-xCdxSe (x up to 30%) barrier, innovative with respect to, e.g, our previous studies[1-2].

Micro-Photoluminescence at 1.7 K-300 K temperatures range reveals the QDs energy emission shifted to 1.9 – 2.3 eV from 2.3 – 2.5 eV, proper for CdSe QDs in ZnSe barrier. A typical pattern of excitonic emission spectrum of a single CdSe/(Zn,Cd)Se QD is determined.

Photoluminescence Excitation (PLE) measurements on individual QDs are performed using a tunable Rhodamine 590 dye laser operating at 2.05-2.20 eV as the excitation source. Sharp (FWHM down to 200 ueV) maxima are found in PLE spectra, reflecting the resonant transfer of photoexcitation to the emitting QD state. Effects of optical control of confined exciton spin[2] are studied through polarization resolved PLE. In particular, transfer of optical polarization between absorbing and emitting states with 18% efficiency is found.

The CdSe/(Zn,Cd)Se QDs are suitable for implementation as temperature robust non-classical light sources or as building blocks for lasers operating at the short wavelength transmission window of plastic optical fibers. Incorporation of single Mn2+ ions makes them promising for efficient optical single ion spin orientation. The QD transitions energy below energy of Mn2+ ion internal transition (2.1 eV) is beneficial for high quantum yield of magnetooptical devices involving CdSe/(Zn,Cd)Se QDs doped with many Mn2+ ions.

Photoluminescence study of the increased hole confinement in CdTe quantum dots

Malgorzata M. Pilat, Univ. of Warsaw (Poland); Lukasz Klopotowski, Piotr Wojnar, Krzysztof Fronc, Grzegorz Karczewski, Tomasz Wojtowicz, Jacek Kossut, Institute of Physics (Poland)

At low temperature single CdTe quantum dot (QD) photoluminescence (PL) spectra contains four transitions resulting from the ground state, s-shell carriers recombination: the neutral exciton (X0), positively and negatively charged excitons (X+ and X-, respectively), and the biexciton (2X). With increasing temperature these PL peaks redshift, broaden, and decrease the intensity. The redshift is related to the bandgap shrinkage, while increased exciton-acoustic phonon coupling results in peaks broadening. The quenching of the PL intensity comes from thermal activation of carriers to other QDs or to excited states within the same dot.

To define the confinement conditions in the conduction and valence band separately we investigated the influence of temperature on particular charge state (X+ and X-). For CdTe QDs in ZnTe barriers, we find that the PL vanishes at about 65 K. Importantly, we observe decreasing of the normalized X+ intensity, while the X- intensity remains approximately constant. On the contrary, for CdTe QDs in ZnMgTe barriers, the PL is visible up to 115 K and the decrease of the normalized X+ intensity is substantially slower. These results point out that Mg incorporation in the barrier increases the hole confinement along the growth axis. As a consequence, the hole states are moved further apart in energy compared to those in CdTe dots in ZnTe barriers, inhibiting the thermal activation of s-shell carriers to excited states. Our result demonstrate that a proper design of the valence band structure should lead to room temperature emission from CdTe QDs.

HgTe colloidal quantum dot LWIR infrared photodetectors

Richard E. Pimpinella, Anthony Ciani, Sivananthan Labs., Inc. (United States); Philippe Guyot-Sionnest, The Univ. of Chicago (United States); Christoph H. Grein, Univ. of Illinois at Chicago (United States)

The majority of modern infrared imaging devices are based on epitaxially grown bulk semiconductor materials. Colloidal quantum dot (CQD) based infrared devices provide great promise for significantly reducing cost as well as significantly increased operating temperatures of infrared imaging systems. In addition, CQD based infrared devices greatly benefit from band gap tuning by controlling the CQD size rather than the composition. LWIR Photoresponsive thin films were fabricated by synthesizing HgTe quantum dots through colloidal synthesis similar to the fabrication process for MWIR HgTe CQDs [1,2]. We will describe the optical response of the HgTe CQD in the 8-12 μm cutoff range as a function of temperature.

Novel quantum dot cascade laser

Ning Zhuo, Feng-Qi Liu, Institute of Semiconductors (China)

Quantum cascade lasers are semiconductor laser sources based on intersubband transitions in multiple quantum well systems. Their unique operation principle and good performance have established themselves as the leading tunable coherent semiconductor source in the infrared and terahertz ranges of the electromagnetic spectrum. In principle, such lasers are restricted in broad tunability, surface emission, and high wallplug efficiency. Theoretical works have predicted that these issues can be raveled out in a quantum dot cascade laser, in which quantum well active region is replaced by quantum-dot active region. By making use of self-assembled quantum dots in the Stranski–Krastanow growth mode and two-step strain-compensation active region design, an unambiguous quantum dot cascade laser based on InAs/InGaAs/InAlAs heterostructure is directly proven.

Fatigue analysis of optimized chevron with Z shape arms

Margarita Tecpoyotl-Torres, Ramón Cabello-Ruiz, Jose Gerardo Vera-Dimas, Jose Alfredo Rodriguez-Ramirez, J. Jesús Escobedo-Alatorre, Alejandra Ocampo Díaz, Univ. Autónoma del Estado de Morelos (Mexico)

Micro-Electromechanical Systems have been widely used in military applications, radio frequency systems, pressure sensors, automotive industry, among several others. Due to the diversity and multiple energy domains involved, MEMS devices are vulnerable to several mechanical

failures such as fatigue. Most MEMS devices contain moving parts that are subjected to cyclic loading, which degrade device´s efficiency. Due to the high importance of MEMS in various applications, it is necessary to know the lifetime of them to prevent any damage or process discontinuity to which the system is subject. There have been several investigations in particular on the fatigue analysis in presence of cracks, however in terms of lifetime under cycling load, information is not abundant. The fatigue analysis can be performed for characterizing the ability of a material to support many cycles that a device component experiences during its usable lifetime. In this paper, a theoretical fatigue analysis of an optimized chevron with Z shape arms is shown. Simulations are made to validate calculations, using Ansys 15.0, to obtain the arms lifetime of the component. Especial attention is given on arms because they are subjected to greater efforts in the presence of cyclic loading.

Structural and electrical properties of zinc oxide doped with aluminium oxide thin films prepared via atomic layer deposition

Baojun Yan, Shulin Liu, Institute of High Energy Physics (China)

Zinc oxide (ZnO) doped with aluminum oxide (Al2O3) and pure Al2O3 thin films were grown on Si (100), quartz and porous substrates by atomic layer deposition at 200ºC using diethylzinc, trimethylaluminium, and deionized water as precursors. All prepared samples thicknesses are varied nominally from 80 nm to 250 nm with a varying number of alternating ZnO and Al2O3 layers. Samples thickness and ellipsometric spectra were measured using a spectroscopic ellipsometer (SE), and the parameters determined by computer simulation matched with the experimental results well. The morphologies of all samples were clearly shown by scanning electron microscopy (SEM). The element distribution measured by energy dispersive x-ray (EDX) was evenly distributed implied the film composition is uniform. The data from x-ray diffraction (XRD) suggest that layer growth appears to be substrate sensitive and film thickness and deposition temperature also have influences on the crystallization of films. The surface chemical states of deposited samples were investigated by x-ray photoemission spectrum (XPS) and the results show the carbon atom contamination is apparent in the films growth which has probably severe influence on the electrical properties. The effects of nano oxide thin film thicknesses on the electrical properties of samples prepared on porous substrate were studied. Before electrical measurement, electrodes were fabricated by electron beam evaporation method firstly. By applied high direct voltages (DC 800 V) on the two ends of the samples measured at vacuum condition, the I-V curves and resistances can be obtained precisely. The resistance jitter phenomenon of samples was observed and we proposed a current transport model within the oxide layers to elucidate the experimental phenomenon.

9553-45, Session PWed

Charge trapping and recombination in Ge nanoislands grown on Si (001)

Anastasiia A. Mykytiuk, Sergey V. Kondratenko, National Taras Shevchenko Univ. of Kyiv (Ukraine); Yu. N. Kozyrev, Chuiko Institute of Surface Chemistry (Ukraine); Volodymyr S. Lysenko, V.E. Lashkaryov Institute of Semiconductor Physics (Ukraine)

In nanosize semiconductor heterostructures quantum size effects can result in changes of the electron spectrum.

In our sample Ge was deposited on boron doped p-Si(100) substrate with temperature of 600 degrees centigrade. For in-plane photoconductivity studies ohmic contacts were formed by annealing of Au at 370 degrees centigrade into the planar surface normal to the epitaxial layers.

Transient in-plane photocurrent of the Ge-Si heterostructure with Ge nanoislands on p-Si (001) upon exposing with different photon energies at 120 K were studied. When only nanoislands were excited we observed a comparably fast relaxation. When the temperature drops to 120 K the long-term relaxation of the photocurrent is observed.

Using the Kelvin probe method we recorded the fluctuations of the electrostatic potential in the Si-Ge heterostructures with Ge nanoclusters.

It was shown that Ge nanoislands can accumulate positive charge, which affects the contact-potential difference (CPD) within the nanoisland by varying it by 5 to 10 mV depending on the size of the nanoisland. The CPD increases with the increasing of the nanoisland diameter.

The recombination efficiency of the electron-hole pairs involving quantum confinement states in nanoislands is higher in comparison with the rate of recombination of the carriers photogenerated in Si substrate. It was found that when we have selective photoexcitation, recombination of electron-hole pairs in SiGe nanoislands is defined by spatial separation of nonequilibrium charge carriers, when the holes are captured in the valence band states of SiGe nanoislands and electrons are in silicon environment.

Logic gates based on nonlinear light interaction in subwavelength discrete systems

Gregorio Mendoza González, Erwin A. Martí Panameño, Benemérita Univ. Autónoma de Puebla (Mexico)

We study the dynamics of nonlinear propagation and interaction of two optical fields in arrays of dielectric subwavelength waveguides of circular and square cross section. Applying the finite difference time-domain method, we numerically solve the Maxwell's equations considering real values for the constitutive relations. The arrays under study are formed by a finite number of parallel waveguides with identical parameters: a subwavelength dimension in cross section, Kerr nonlinearity, length of tens of micrometers and the separation between the waveguides is constant. In our study, we focus on the determination of specific values of the physical parameters before mentioned, to obtain light self-trapping. For this, we also determine the properties of the incident optical fields: complex amplitude, wavelength, angle of incidence and phase difference. As a result we observe the dependence of the total energy output to the parameters of phase difference and angle of incidence. This allows us to conclude about the possibility to control the nonlinear interaction properties of two optical fields, generating a single output beam, whose position can be controlled by the selection of the system parameters. These results allow us to reproduce the behavior of an AND gate.

Raman spectroscopy studying of guanajuatite (Bi2Se3): natural topological insulator

Malgorzata M. Pilat, Katarzyna Golasa, Magdalena Grzeszczyk, Adam Babinski, Univ. of Warsaw (Poland)

Topological insulators are a new class of materials which are semiconducting in bulk but conducting on their surface. One of its representatives is bismuth selenide (Bi2Se3), which occurs naturally as a mineral called guanajuatite. Bi2Se3 has a layered structure consisting of quintuples – alternating mono-atomic layers of bismuth and selenium in the stoichiometric ratio. While atoms inside the quintuple are strongly bounded, individual quintuples interact with each other only via relatively weak van der Waals effect. We present micro-Raman spectroscopy studies of the natural Bi2Se3. Four Raman active phonon modes (two each A1g and Eg corresponding to vibrations crosswise and along quintuple respectively) are studied in a wide range of temperature (4-300 K) and the results are compared with spectra obtained on a synthesized material. A linear temperature dependence of active Raman modes energy enables us to determine the first order temperature coefficient of the phonons. Results span the range from 1.01 to 1.71 cm-1/K depending on the mode, which is in accord with previous

works on Bi2Se3. It is shown that the widths of the observed Raman peaks in guanajuatite are similar to the corresponding values in the synthesized Bi2Se3 confirming the quality of natural crystals.

9553-21, Session 6

Physics of artificially-engineered AlGaN and InGaN based digital alloys

Wei Sun, Chee-Keong Tan, Nelson Tansu, Lehigh Univ. (United States)

The pursuit of III-Nitride based semiconductor in optoelectronic application has been primarily driven by the attribute of broadband coverage through the use of AlN and InN materials. However, the phase separation in growing high Al/In-content ternary alloy has been one of the largest barriers in applying the application of nitride-based ternary semiconductor. Meanwhile, the large built-in polarization induced by the strain effect within the active region also causes significant charge separation issue. Thus, a new approach in extending the bandgap coverage and suppressing charge-separation in nitride-based alloy needs to be pursued.

In this work, we propose novel artificially-engineered AlGaN and InGaN based digital alloys to overcome the limitations presented by the epitaxy of phase-separated III-Nitride ternary material and the carrier separation issue in the polarized material system. The proposed digital alloy structure is a short period superlattice that is formed by desired thin film alloy layers alternately, in which the thickness of each layer is represented by a number of monolayer (ML). By adjusting the thickness of GaN layer (m ML) and AlN or InN layer (n ML), the Al/In-content and the band structure of AlGaN or InGaN digital alloy can be engineered correspondingly. Due to the usage of thin film GaN and InN/AlN layers, the large quantum coupling and suppressed charge separation could increase the wavefunction overlap of carriers significantly. The use of this digital alloy demonstrated the suitability of this method in extending the bandgap coverage and suppressing charge separation in nitride-based semiconductors.

9553-22, Session 6

Electrical generation and control of valley carrier in monolayer TMDC

Yu Ye, Xiaobo Yin, Univ. of California, Berkeley (United States); Hailong Wang, Institute of Semiconductors (China); Ziliang Ye, Hanyu Zhu, Yuan Wang, Univ. of California, Berkeley (United States); Jianhua Zhao, Institute of Semiconductors (China); Xiang Zhang, Univ. of California, Berkeley (United States)

Electrical control of the flow of charges is at the heart of modern electronics. The spintronics exploits the spin degree of freedom (DOF) of electrons for information processes such as magnetoresistive random-access memory. Recently, the atomic membrane of transition metal dichalcogenides (TMDCs) was found possesses a nonequivalent carrier distribution in crystal momentum valley space, which makes the valley index of electrons a new DOF for information processing. A variety of valleytronic devices such as valley filters and valves have been proposed, and optical valley excitation has been observed. However, to realize its potential in electronics, one has to electrically control of valley DOF, which remains the critical challenge to date. Here, we experimentally demonstrate electrically valley generation and control. Valley polarization is achieved through spin injection via a diluted ferromagnetic semiconductor and measured by the helicity of electroluminescence using the unique spin-valley locking. We also report a new scheme of electronic devices combining both the spin and valley DOFs. Such a direct electrical generation and control of valley carriers opens the new dimension in utilizing both spin and valley for next-generation electronics and computing.

9553-23, Session 6

Optical study of interlayer coupling and stacking-dependent electronic structure in MoS2

Ze-Xiang Shen, Jiaxu Yan, Juan Xia, Zheng Liu, Nanyang Technological Univ. (Singapore)

The optical and electronic structures of two dimensional transition metal dichalcogenide (2DTMD) materials often show very strong layer-dependent properties. Detailed understanding of the inter-layer interaction will help greatly in tailoring the properties of 2D TMD materials for applications. Raman/Photoluminescence (PL) spectroscopy and imaging have been extensively used in the study of nano-materials and nano-devices. They provide critical information for the characterization of the materials such as electronic structure, optical property, phonon structure, defects, doping and stacking sequence.

In this talk, we use Raman and PL techniques to study few-layer MoS2 samples. The Raman and PL spectra show clear correlation with layer-thickness and stacking sequence. Our ab initio calculations reveal that difference in the electronic structures mainly arises from competition between spin-orbit coupling and interlayer coupling in different structural configurations.

9553-24, Session 6

The role of ultra-thin SiO2 layers in metal-insulator-semiconductor (MIS) photoelectrochemical devices *(Invited Paper)*

Daniel V. Esposito, Columbia Univ. (United States)

Solid-state junctions based on a metal-insulator-semiconductor (MIS) architecture are of great interest for a number of optoelectronic applications such as photovoltaics, photoelectrochemical cells, and photodetection. One major advantage of the MIS junction compared to the closely related metal-semiconductor junction, or Schottky junction, is that the thin insulating layer (1-3 nm thick) that separates the metal and semiconductor can significantly reduce the density of undesirable interfacial mid-gap states. The reduction in mid-gap states helps “un-pin” the junction, allowing for significantly higher built-in-voltages to be achieved. A second major advantage of the MIS junction is that the thin insulating layer can also protect the underlying semiconductor from corrosion in an electrochemical environment, making the MIS architecture well-suited for application in (photo)electrochemical applications.

In this presentation, discontinuous Si-based MIS junctions immersed in electrolyte are explored for use as i.) photoelectrodes for solar-water splitting in photoelectrochemical cells (PECs) and ii.) position-sensitive photodetectors. The development and optimization of MIS photoelectrodes for both of these applications relies heavily on understanding how processing of the thin SiO2 layer impacts the properties of nano- and micro-scale MIS junctions, as well as the interactions of the insulating layer with the electrolyte. In this work, we systematically explore the effects of insulator thickness, synthesis method, and chemical treatment on the photoelectrochemical and electrochemical properties of these MIS devices. It is shown that electrolyte-induced inversion plays a critical role in determining the charge carrier dynamics within the MIS photoelectrodes for both applications.

9553-26, Session 6

Functional 2-dimensional nanomaterial inks for photonics and (opto)electronics *(Invited Paper)*

Tawfique Hasan, Univ. of Cambridge (United Kingdom)

Layered nanomaterial crystals with interesting electronic and optical properties are an attractive proposition for flexible photonic and optoelectronic devices. The most widely investigated layered material is graphene, which heralds the possibility of truly flexible and perhaps, transparent electronics. Other graphene-like layered nanomaterials, for example, semiconducting metal dichalcogenides complementary (opto) electronic properties, strengthening the offering from layered materials. Together, graphene and related layered materials thus represent a family of materials attractive for next generation flexible electronic components, devices and systems.

For large area applications, growth of layered materials typically requires high temperature (~1000 C). This is further complicated during their transfer deposition on to the target substrates. An alternative and economic approach is to use inks of exfoliated layers from their chemically untreated bulk crystals. This process can be carried out at room temperature and does not involve harsh chemicals. More importantly, the inks offer device fabrication and integration strategy through different processes, such as polymer composites, digital and lithographic printing as well as roll-to-roll (R2R) and spray coating over large area.

I will discuss several photonic and (opto)electronic applications using graphene, the most established ink platform to date. This will include ultrafast lasers, transistors, hybrid nanomaterial transparent and non-transparent conductors and electrodes on silicon/glass, plastic and paper substrates. I will briefly address other layered material inks and their printability. I will conclude with a short perspective in terms of materials, printing technologies and devices that may evolve from this materials technology platform.

9553-27, Session 7

Synthesis of one-dimentional nanostructures for gas sensing and photovoltaic applications *(Invited Paper)*

Hakan Karaagac, Elif Peksu, M. Saif Islam, Istanbul Technical Univ. (Turkey)

In recent years, ZnO,(TiO2 and Silicon (Si) nanowires (NWs) have attracted a significant attention due to their unique properties which can be employed for many applications including field ionization gas sensors, photodetectors, and solar cells. In this work, three-dimentional p-n heterojunctions were used for the fabrication of field ionization gas sensors and solar cells. P-Si micro-pillars/ZnO NWs, n-TiO2-nanorod/p-CdTe and n-Si-NW/p-Ag(Ga,In)Se2(AGIS) material combinations were preferred for the construction field-ionization gas sensor, a core-shell and a thin-film embedded type of solar cells, respectively. Well-aligned Si NWs were derived from a silicon (100) wafer by using Ag-assisted electroless etching technique. The synthesized Si-NWs embedded into a sputter deposited chalcopyrite thin film (AGIS) to fabricate a thin film embedded solar cell. High aspect ratio well oriented silicon micropillars (MPs) were synthesized using the deep reactive ion Etching process with the BOSCH recipe. Field ionization gas sensor based on p-Si-MPs/n-ZnO-NWs was fabricated from growing hydrothermally dense arrays of ZnO nanowires onto the high aspect ratio vertically oriented silicon MPs. The constructed structure was tested for many target gases including He, N2, NH3 and O2, which showed very promising results. It was observed that nanowires with controlled doping of metal offer unique advantage for FI applications due to high density of surface states associated with the impurities. Especially, unoccupied local states formed by doping Si-NWs with gold resulted in a nearly 5 order of magnitude enhancement in field ionization current. In this talk, the performance of all the fabricated devices will be presented in detail.

9553-28, Session 7

Flexible and stackable non-volatile resistive memory for high integration *(Invited Paper)*

Shawkat Ali, Jinho Bae, Chong Hyun Lee, Jeju National Univ. (Korea, Republic of)

"N/A": However, I filled in the box to help understand our idea.

Organic and printed electronics have been initiated and developed since various electronic applications have been substantially demanded for flexible electronic technology, good prototyping, mass production with low cost, and eco-friendly fabrication process. In these flexible electronic systems, a research of the flexible memory for high integration becomes an important topic. In order to produce a memory of high data storage capacity, it introduces constraints of low power consumption, high read/write speed, and decreasing device size in higher memory density. For the last decade, resistive crossbar array architectures suitable for easy fabrication and low power consumption are being considered to solve these constraints. However, it reveals several problems such as sneak path, crosstalk, and power requirement, which limits the memory size and performance as the memory integration increases. In this paper, we propose a novel flexible and stackable resistive random access memory (ReRAM) array with multi-layered crossbar structures, which comprises of small size printed resistive switching elements and printed pull-up resistors. With the architecture of the proposed memory, the basic memory block of ReRAM is based on one resistor and multi-layered column memristor (1R-MCM) structure, which can be easily extended to 3 dimensional columns. Especially, it can be applied for higher memory density because it has 3 dimensional structure with multiple memory layers on a same area. For a high integration, the proposed memory device is also fabricated on polyethyleneterephthalate (PET) flexible substrate by using direct-printed technology, electrohydrodynamic (EHD) system printable to micrometer scale patterns at room temperature and normal air pressure. To fabricate the proposed memory device, the materials, silver (Ag) for top and bottom electrodes, PVP for memristor, and (MEH:PPV and PMMA in acetonitrile) for pull-up resistors are used. In random access of the proposed memory device, zero detection error was obtained in reading a logic data, and cell to cell interference was not occurred. Lower power consumption realized by the low current memristive elements with high OFF/ON ratio and higher retention time by flexible encapsulation were achieved. The proposed ReRAM based on 1R-MCM also demonstrated as high read/write speed as the data writing with a short delay time and data reading without delay. To overcome several limitations of flexible memory devices including, high speed, low power easy fabrication, the proposed memory device can create a new approach to be used in electronic applications.

Nanoscale characterization and modeling of the variability in metal oxide resistive switching memory *(Invited Paper)*

Matthew J. Marinella, David R. Hughart, Patrick R. Mickel, Stephen W. Howell, Ed Bielejec, George Vizkelethy, Jose L. Pacheco, Rudeger H.T. Wilke, Sapan Agarwal, Conrad D. James, Sandia National Labs. (United States)

Metal oxide based resistive switching memory is a promising device technology for advanced memory and neuromorphic computing. However, the key hurdle in moving this technology forward as a memory and analog circuit element is the significant variability in electrical characteristics. This electrical variability can be categorized by (1) device to device variation, (2) cycle to cycle, or temporal write variation, and (3) read noise. The goal of this work is to correlate nanoscale physical properties of the switching film and electrodes with electrical variability. First, we will present methodologies used to electrically assess the temporal variability and the read noise. These results are then correlated with the results of nanoscale characterization of morphological, and electrical properties of the switching films using conducting atomic force microscopy (CAFM). In addition, we will present spatial maps of switching regions in the oxide produced by probing the switching film with a nanoscale ion beam while correlating the beam position with in situ electrical response (indicating the filament region). We will then present density functional theory (DFT) modeling, which provides further evidence of the origins of variability. Finally, we will discuss how methods to improve the electrical variability of devices, and the feasibility of using transition metal oxide memories for analog computation.

Sandia National Laboratories is a multi-program laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000.

Extended defect structures observed in (AlxGa1-x)0.5In0.5P light emitting diodes grown by MOVPE *(Invited Paper)*

Andreas Rudolph, OSRAM Opto Semiconductors GmbH (Germany)

Scanning transmission electron microscopy (STEM) annular dark field (ADF), high angle annular dark field (HAADF), cathodoluminescence (CL) and energy-dispersive X-ray spectroscopy (EDX) analysis were carried out to investigate the structural and optical properties of (AlxGa1-x)0.5In0.5P light emitting diodes (LEDs). Extended defect structures were observed in the LED active region, which exhibit defect emission that is shifted by 0.25 eV relative to the multi quantum well (MQW) emission. The morphology and composition of the defect structures was elucidated and the results confirmed by growth experiments and photoluminescence (PL) measurements.

Optoelectronics in two-dimensional semiconductor alloys *(Invited Paper)*

François Léonard, Sandia National Labs. (United States)

Two -dimensional transition-metal dichalcogenides (2D-TMDs) have attracted attention for applications in electronics and photonics, as well as for the wealth of new scientific phenomena that arise at low dimensionality. Recently, the ability to grow 2D-TMDs by chemical vapor deposition has opened the path to large area devices, but also to the synthesis of semiconductor alloys with tunable bandgaps. In this presentation, I will discuss our recent experimental work in exploring the optoelectronic properties of 2D MoS_2(1-x)Se_2x alloys spanning the compositional range. In particular, we report the observation of a new regime of operation where the photocurrent depends superlinearly on light intensity. We use spatially-resolved photocurrent measurements on devices consisting of CVD-grown monolayers to show the photoconductive nature of the photoresponse, with the photocurrent dominated by recombination and field-induced carrier separation in the channel. Time-dependent photoconductivity measurements show the presence of persistent photoconductivity for the S-rich alloys, while photocurrent measurements at fixed wavelength for devices of different alloy compositions show a systematic decrease of the responsivity with increasing Se content associated with increased linearity of the current-voltage characteristics. A model based on the presence of different types of recombination centers is presented to explain the origin of the superlinear dependence on light intensity, which emerges when the non-equilibrium occupancy of initially empty fast recombination centers becomes comparable to that of slow recombination centers.

Observation of direct electron-electron interaction in suspended MQW structures

Iman Hassani Nia, Sung Jun Jang, Hooman Mohseni, Northwestern Univ. (United States)

Suspended structures have been used not only for a wide range of Micro Electro Mechanical systems (MEMs) but also particularly for highly sensitive bolometers. The advantage of using such devices is that they provide a very high thermal isolation to the environment which makes it possible to detect any physical phenomenon by its temperature signature. On the other hand, by carefully designing Multiple Quantum Well (MQW) structures, scientists have been able to tailor the electronic energy levels in such a way to obtain the desired performance for lasers and detectors in particular. Inspired by the virtue of the suspended structures and MQWs, we have fabricated pristine suspended MQW structures with minimal damage to the active region using a novel method. We furthermore measured the temperature of these devices using ultra-accurate micro-thermometers. By using two separate lasers and performing heterodyne detection of the resulting change in the temperature, we observed direct signature of electron and electron interaction in our devices. We attribute these effects to various recombination mechanisms in the III-V MQW structure. To have a better understanding of these phenomena, we have performed our experiments from 78 K up to room temperature. The results have been interpreted by rigorous self-consistent solution of Poisson and Schrodinger equations and also solving the carrier rate equations. We believe that our findings will open up new aspects of III-V semiconductors physics and particularly its applications for sensing.

9553-38, Session 9

Chemical modification approaches for improved performance of Na-ion battery electrodes

Bryan Byles, Mallory Clites, Ekaterina Pomerantseva, Drexel Univ. (United States)

Recent concerns in regards to the long-term sustainability of lithium has shifted the focus of energy storage research towards utilizing other charge carrying ions in intercalation based metal-ion batteries. Sodium has received much attention as an alternative to lithium due the fact that it is more abundant and less expensive. However, there are limited numbers of electrochemically active Na-ion battery electrode materials. We present chemical approaches that results in the improved performance of materials known to reversibly intercalate sodium ions through the modification of materials composition. In this work, we study two different chemical modification processes. The first approach is based on the chemical pre-intercalation of sodium ions. Vanadium pentoxide was used as a model "host" material to investigate this process. By varying the Na:V ratio in the precursors, more than one sodium ion per vanadium oxide unit cell was inserted and reversibly cycled in electrochemical tests. The second chemical modification approach we investigated involved post-synthesis treatments, including hydrothermal treatment and annealing of sodium pre-intercalated vanadium oxides. These methods have proven to improve performance through enhancing capacity and capacity retention, respectively. An alternative post-synthesis treatment involves the reaction of electrode materials with acids. To study this method we used nanostructured manganese oxides. Formation of defects during acid leaching resulted in facilitated diffusion of Na ions into the crystal structure of the material and improved its electrochemical performance. Overall, these pre- and post-synthesis approaches prove to be an efficient means of improving performance of Na-ion batteries.

9553-39, Session 9

Deposition and characterizations of ultrasmooth silver thin films assisted with a germanium wetting layer

Junce Zhang, David M. Fryauf, Matthew P. Garrett, Univ. of California, Santa Cruz (United States); Logeeswaran Veerayah Jayaraman, Univ. of California, Davis (United States); Atsuhito Sawabe, Aoyama Gakuin Univ. (Japan); M. Saif Islam, Univ. of California, Davis (United States); Nobuhiko P. Kobayashi, Univ. of California, Santa Cruz (United States)

The structural properties of thin (15nm) silver (Ag) films deposited on SiO2/Si(100) substrates with a germanium (Ge) wetting layer were studied. The Ag thin films with different Ge wetting layer thicknesses were characterized by cross-sectional transmission electron microscopy (XTEM), reflection high energy electron diffraction (RHEED), X-ray diffractometry (XRD), grazing incidence X-ray diffractometry (GIXRD), X-ray reflection (XRR) and Fourier transform infrared spectroscopy (FTIR). The surface of Ag thin films was found to be significantly smoothened by introducing a Ge wetting layer with a thickness in the range of 1-2nm. However, as the Ge wetting layer thickness increased beyond 2nm, the surface roughness increased concomitantly. The role of 1-2nm Ge wetting layer in the Ag film deposition is discussed by the surface energy of Ge, the bond dissociation energy of Ag-Ge, and the deposition mechanisms of Ag thin films on a given characteristic Ge wetting layer. Additionally, Ge island formation, precipitation of Ge from Ag-Ge alloys and penetration of Ge into SiO2 are suggested for the Ge beyond 2nm. This demonstration of ultrasmooth Ag thin films would offer an advantageous material platform with scalability for applications such as molecular anchors, optical metamaterials, plasmonic devices, and several areas of nanophotonics.

9553-40, Session 9

Thin film thermoelectric metal-organic framework with high Seebeck coefficient and low thermal conductivity

Kristopher J. Erickson, Francois Leonard, Vitalie N. Stavila, Michael E. Foster, Catalin D. Spataru, Reese Jones, Sandia National Labs. (United States); Brian Foley, Patrick Hopkins, Univ. of Virginia (United States); Mark D. Allendorf, A. Alec Talin, Sandia National Labs. (United States)

Inorganic, low bandgap semiconductors such as Bi2Te3 have adequate efficiency for some thermoelectric energy conversion applications, but have not been more widely adopted because they are difficult to deposit over complex and/or high surface area structures, are not eco-friendly, and are too expensive. As an alternative, conducting polymers have recently attracted much attention for thermoelectric applications motivated by their low material cost, ease of processability, non-toxicity, and low thermal conductivity. Metal-organic frameworks (MOFs), which are extended, crystalline compounds consisting of metal ions interconnected by organic ligands, share many of the advantages of all-organic polymers including solution processability and low thermal conductivity. Additionally, MOFs and Guest@MOF materials offer higher thermal stability (up to ~300

oC in some cases) and have long-range crystalline order which should improve charge mobility. A potential advantage of MOFs and Guest@MOF materials over all-organic polymers is the opportunity for tuning the electronic structure through appropriate choice of metal and ligand, which could solve the long-standing challenge of finding stable, high ZT n-type organic semiconductors. In our presentation, we report on thermoelectric measurements of electrically conducting TCNQ@Cu3(BTC)2 thin films deposited using a room-temperature, solution-based method, which reveal a large, positive Seebeck coefficient. Furthermore, we use time-dependent thermoreflectance (TDTR) to measure the thermal conductivity of the films, which is found to have a low value due to the presence of disorder, as suggested by molecular dynamics simulations. In addition to establishing the thermoelectric figure of merit, the thermoelectric measurements reveal for the first time that holes are the majority carriers in TCNQ@Cu3(BTC)2.

Super-resolution imaging of plasmonic nanostructures *(Invited Paper)*

Katherine A. Willets, Temple Univ. (United States)

Noble metal nanoparticles have attracted significant attention due to their ability to support localized surface plasmons, which generate local electromagnetic field enhancements, produce strong environmentally-sensitive nanoparticle color, lead to localized heating, and even produce energetically excited (or hot) electrons. In order to impart additional function to these materials, hybrid nanostructures, in which organic or inorganic materials are covalently attached to the nanoparticle surface, have been synthesized, allowing plasmonic nanoparticles to be used in biosensing, drug delivery, and photonic applications. One challenge is knowing the nature of the assembly of these molecules onto the surface of the nanoparticles, which is complicated by their small size and lack of contrast in traditional surface characterization techniques, such as electron microscopy. This talk will describe super-resolution optical imaging of fluorescently-labeled molecules covalently attached to the surface of gold nanorods, highlighting some of the unique challenges of performing super-resolution imaging on plasmonic nanostructures, as well as providing insight into local binding heterogeneity.

Expanding the horizon of plasmon-enhanced Raman spectroscopy: from SERS to SHINERS, TERS, and EERS *(Invited Paper)*

Jian-Feng Li, Yi-Fan Huang, Song-Yuan Ding, Zhi-Lin Yang, De-Yin Wu, Bin Ren, Zhong-Qun Tian, Xiamen Univ. (China)

In the about four decades, surface-enhanced Raman scattering (SERS) has gone through a tortuous pathway to develop into a family of plasmon-enhanced Raman spectroscopy (PERS). Surface plasmons (SPs) or surface plasmon resonance (SPR), either localized surface plasmons or propagating surface plasmons, can significantly increase the intensity of Raman scattering from a molecule adsorbed at or close to the nanostructures. Although SERS is comparable to the sensitivity of fluorescence, there are two significant drawbacks to the commonplace application of SERS: a lack of substrate/molecule generality and a lack of morphology generality. To bypass these obstacles, many groups including ours have utilized different nanostructures to invent Tip-enhanced Raman spectroscopy (TERS) and shell-isolated nanoparticle-enhanced Raman spectroscopy (SHINERS). High-quality Raman spectra were obtained on various molecules adsorbed at Pt, Au and Rh single-crystal surfaces and from Si surfaces with hydrogen monolayers. Very recently we employed electron-enhanced Raman spectroscopy (EERS) to expend the study from surface reaction active sites to the electronic jellium at electrode-electrolyte interfaces. PERS have significantly expanded the versatility of Raman spectroscopy in surface science and trace analysis on complex systems, for wide applications in surface, materials and life sciences, as well as for molecular electronics, inspection of food safety and drug. In the PERS family each member with its own operation mode has its strength and limitations, their features will be summarized and correlated. Finally, an outlook on further developments of PERS will be given with emphasis on the emerging methodology.

9554-7, Session 2

Photo induced force microscopy: nanoscale imaging of optical polarizability *(Invited Paper)*

Hemantha K. Wickramasinghe, Univ. of California, Irvine (United States)

We review the application of Atomic Force Microscopy (AFM) for mapping optical near-fields with nanometer resolution. By detecting the optical force between a gold coated AFM probe and its image dipole on a glass substrate, we profile the electric field distributions of tightly focused laser beams with different polarizations. The experimentally recorded focal force maps agree well with theoretical predictions . We experimentally estimate the aspect ratio of the apex of gold coated AFM probe using only optical forces. We show that the optical force between a sharp gold coated

AFM probe and a sample can be used to map the spatial distribution of polarizability. Recent results using this method will be presented. Photo Induced Force Microscopy (PIFM) allows for background free, thermal noise limited mechanical imaging of optical phenomenon over wide range of wavelengths from Visible to RF with detection sensitivity limited only by AFM performance.

9554-8, Session 2

Experimental correlation of electric fields and Raman signals in SERS and TERS *(Invited Paper)*

Zachary D. Schultz, Hao Wang, Daniel T. Kwasnieski, James M. Marr, Univ. of Notre Dame (United States)

Enhanced Raman scattering from plasmonic nanostructures associated with surface enhanced (SERS) and tip enhanced (TERS) is seeing a dramatic increase in applications from bioimaging to chemical catalysis. The importance of gap-modes for high sensitivity indicates plasmon coupling between nanostructures plays an important role. However, the observed Raman scattering can change with different geometric arrangements of nanoparticles, excitation wavelengths, and chemical environments; suggesting differences in the local electric field.(1, 2) Our results indicate that molecules adsorbed to the nanostructures are selectively enhanced in the presence of competing molecules. This selective enhancement arises from controlled interactions between nanostructures, such as an isolated nanoparticle and a TERS tip.(3, 4) Complementary experiments suggest that shifts in the vibrational frequency of reporter molecules can be correlated to the electric field experienced by the molecule.(5) Here we present a strategy that utilizes the controlled formation of coupled plasmonic structures to experimentally measure both the magnitude of the electric fields and the observed Raman scattering.

9554-9, Session 2

Nano-antenna-controlled tunable enhancement in tip-enhanced Raman spectroscopy

Prabhat Verma, Osaka Univ. (Japan)

Tip-enhanced Raman spectroscopy (TERS) utilizes a nano-tip as plasmonic nano-antenna for enhancement and confinement of light for nano-spectroscopy and nano-imaging. Usually, the tips for TERS are prepared by evaporating metal on an AFM cantilever tip to form a thin layer of metallic nanoparticles on the surface. By controlling the shape and size of these metallic nanoparticles, one can tunably control the surface plasmon resonance, and hence the enhancement in TERS. I will show some results of numerical simulations and will demonstrate how we can tune the enhancement in TERS by precisely truncating the length of silver on the tip.

9554-10, Session 3

Nanospectroscopy for nano-chemistry and nanostructures *(Invited Paper)*

Debdulal Roy, National Physical Lab. (United Kingdom)

The first part of the talk will focus on measuring nanochemistry in catalysis. Chemical mapping of a photocatalytic reaction with nanoscale spatial resolution is demonstrated for the first time using tip-enhanced Raman spectroscopy (TERS). An ultrathin alumina film applied to the Ag-coated TERS tip blocks catalytic interference whilst maintaining near-field electromagnetic enhancement, thus enabling spectroscopic imaging of catalytic activity on nanostructured Ag surfaces.

The second part focuses on detects in graphene. Defects in a 2D material, like graphene, directly impact its key performances including high electrical conductivity, high tensile strength and chemical inertness. Measuring single defect in few nanometres length scale has not been realised without the help of high resolution transmission electron microscopy. Here we present a simple and elegant way of measuring single defects, 0D point defects and 1D line defects in the 2D plane of single layer of atoms in graphene using tip-enhanced Raman spectroscopy. Spectroscopic measurements provide great deal of information ranging from fundamental light scattering from defects to measuring the extent that a defect influences the properties of a 2D material.

9554-11, Session 3

Seeing molecular vibrations: chemical imaging for biomedicine *(Invited Paper)*

Wei Min, Columbia Univ. (United States)

Here we discuss an emerging chemical imaging platform, stimulated Raman scattering (SRS) microscopy, which can enhance the otherwise feeble spontaneous Raman eight orders of magnitude by virtue of stimulated emission. When coupled with stable isotopes (e.g., deuterium and 13C) or bioorthogonal chemical moieties (e.g., alkynes), SRS microscopy is well suited for probing in vivo metabolic dynamics of small bio-molecules which cannot be labeled by bulky fluorophores. Physical principle of the underlying optical spectroscopy and exciting biomedical applications such as imaging lipid metabolism, protein synthesis, DNA replication, protein degradation, RNA synthesis, glucose uptake, drug trafficking and tumor metabolism will be presented.

9554-12, Session 3

Infrared near-field nanospectroscopy: chemical identification, nanoellipsometry, and nanotomography *(Invited Paper)*

Alexander A. Govyadinov, CIC nanoGUNE Consolider (Spain)

Scattering-type scanning near-field optical microscopy (s-SNOM) brings the power of infrared imaging and spectroscopy to the nanometer scale. The spatial resolution of about 10 - 20 nm opens a new era for modern applications in analytical chemistry, materials and bio sciences. After a brief overview of fundamentals and applications of s-SNOM, this talk will present recent achievements in broadband infrared nanospectroscopy (nano-FTIR) of polymers and proteins. Particularly, it will show how nanoscale chemical identification and quantitative recovery of local dielectric properties can be achieved. Finally, our progress towards near-field nanotomography will be discussed.

9554-13, Session 3

Investigation of surface plasmons in nano-squares using electron energy loss spectroscopy

Yue Zhang, Rice Univ. (United States); Edson Bellido Sosa, McMaster Univ. (Canada); Alejandro Manjavacas, Yang Cao, Rice Univ. (United States); Gianluigi A. Botton, McMaster

Univ. (Canada); Peter Nordlander, Rice Univ. (United States)

Electron energy-loss spectroscopy (EELS) has great advantages to study surface plasmon. This method allows us to image surface plasmon with nanometer spatial resolution. Furthermore, EELS perfectly identifies dark modes in addition to bright modes. Here, we present an experimental and theoretical study of silver nano-squares. EELS performed in a scanning transmission electron microscope (STEM-EELS) is used to acquire spectra and maps of plasmon resonances of lithographically patterned silver nano-squares. The simulations give EELS spectra and photonic local density of states (LDOS) maps at plasmon resonances, using Finite-Difference Time-Domain (FDTD). The simulation and experiment are in good agreement, and observed modes that are not captured by optical measurements: besides multipolar bright and dark modes, plasmonic modes confined to the center of the structures are also successfully found. Our study fully explains the optical properties of nano-squares.

9554-14, Session 4

Accelerating beams for advanced imaging in biomedicine *(Invited Paper)*

Kishan Dholakia, Univ. of St. Andrews (United Kingdom)

I will describe the use of shaped light fields namely propagation invariant ('non-diffracting') light fields and complex beam shaping for advanced studies in imaging. Propagation invariant light fields, as the name suggests retain their transverse intensity profile upon propagation. Bessel light fields and Airy light fields are prime examples of such beams. In terms of imaging, single plane illumination (light sheet) microscopy (SPIM) offers a myriad of unique advantages. Detection orthogonal to the illumination allows rapid imaging of large, three-dimensional, samples of living tissue. Illumination with a thin sheet of light ensures high contrast by minimizing the fluorescent background. Moreover, by restricting the sample exposure to a single plane, photo-bleaching and damage are minimized. This is crucial when imaging photo-sensitive samples over a larger period of time. Recent enhancements to the original technique attempt to overcome the inherent trade off between axial resolution and field-of-view of conventional light sheet microscopy. Until recently, this was only achieved by compromising on one or more of its key advantages: high contrast, time-resolution, or minimal sample exposure. I will discuss the use of propagation invariant light fields for the enhancement within this imaging modality particularly Airy modes. The extension to combining this approach with super-resolution will be described.

9554-15, Session 4

Nanophotonic measurement of the dark fraction in red fluorescent proteins *(Invited Paper)*

Jord C. Prangsma, Robert Molenaar, Christian Blum, Univ. Twente (Netherlands); Vinod Subramaniam, FOM Institute for Atomic and Molecular Physics (Netherlands)

All complex fluorophores such as fluorescent proteins display a fraction of the population that absorb light but do not emit fluorescence. Accurate measurement of this 'dark' fraction is of critical importance for quantitative microscopy in cell biology. We used a nanophotonic method to measure the dark fraction of several frequently used red fluorescent proteins. The results we obtain show that most RFPs have a considerable 30% fraction of absorbing but not emitting fluorophores. Our findings have direct implications in quantitative microscopy such as in the interpretation of intensity-based FRET measurements, and prove an important bottleneck in the development of enhanced fluorescent proteins.

9554-16, Session 4

Supercritical angle fluorescence for absolute super-localization nanoscopy *(Invited Paper)*

Nicolas Bourg, Institut des Sciences Moléculaires d'Orsay (France); Guillaume Dupuis, Sandrine Lécart, Univ. Paris-Sud 11 (France); Emmanuel Fort, Institut Langevin (France); Sandrine Lévêque-Fort, Institut des Sciences Moléculaires d'Orsay (France)

We propose to take advantage of Supercritical Angle Fluorescence (SAF) emission, also called forbidden light, to obtain an isotropic and absolute 3D localization precision in superlocalization microscopy. When a fluorophore is located in the vicinity of the coverslip interface, its near-field component can become propagative and emitted above the critical angle. As this SAF emission decreases exponentially with the dye/interface distance, absolute nanometric axial position of each fluorescent dye can be extracted. An isotropic 3D localization precision of 20nm within an axial range of ~150 nm above the coverslip can be achieved, allowing to observe the 3D hollowness of microtubules.

9554-17, Session 4

Optical coherence tomography for nanoparticles quantitative characterization

Michal Trojanowski, Maciej Kraszewski, Marcin R. Str?kowski, Jerzy Pluci?ski, Gdansk Univ. of Technology (Poland)

The unique features of nanocomposite materials depend on the type and size of nanoparticles, as well as their placement in the composite matrices. Therefore the nanocomposites manufacturing process requires inline control over certain parameters of nanoparticles such as dispersion and concentartion. Keeping track of nanoparticles parameters inside a matrix is currently a difficult task due to lack of a fast, reliable and cost effective way of measurement that can be used for large volume samples. Currently used methods like scanning electron microscopy and transmission electron microscopy (SEM, TEM) are costly, time consuming and invasive. To overcome those difficulties we propose the usage of Low Coherence Interferometry (LCI) based methods such as Optical Coherence Tomography (OCT). OCT is an optical measurement method which is a non-destructive and non-invasive technique. It is capable of creating tomographic images of inner structure by gathering depth related backscattered signal from scattering particles. OCT can analyse, in a single shot, area of the micrometre range. To increase OCTs measurement capabilities we are using additional system extensions such as Spectroscopic OCT (SOCT) and Polarization Sensitive (PS-OCT). With such additions we are able to measure several parameters such as extinction coefficient, absorption coefficient, scattering spectra and polarization. Those parameters allow us to quantitatively estimate nanoparticles, size, orientation and dispersion. Gaining those information allows to calculate volume concentration of nanoparticles. In addition we analyse different types of particles, metallic and oxides. To fully characterize nanoparticles it is necessary to find and differentiate those that are single particles from agglomerated ones. In this contribution we present our research results on using the LCI based measurement techniques for evaluation of materials with nanoparticles. The laboratory system and signal processing algorithms are going to be shown in order to express the usefulness of this method for inline constant monitoring of the nanocomposite material fabrication.

9554-18, Session 4

Microscopic ellipsometry image of microspheres on a substrate

Fu-Chen Hsiao, Yu-Da Chen, Buu Trong H. Ngo, Huai-Yi Xie,

Yia-Chung Chang, Academia Sinica (Taiwan)

We performed experimental measurements and theoretical simulation based on an efficient half-space Green's function method[1,2] to investigate the diffraction patterns of light scattering from silicon and ZnO microspheres on a substrate. The microscopic ellipsometry image for s- and p-polarized reflectance and their phase difference (Rs, Rp, and ?) was taken by a modified Optrel MULTISKOP system with rotating compensator configuration for various angles of incidence and wavelengths ranging from 450nm to 750nm. An 80X objective was used and the pixel size for our image is around 200nm. The images obtained display clear diffraction patterns, which is analyzed by an efficient full-wave simulation. By expanding the electromagnetic fields within the microsphere in terms of spherical harmonics[2,3] and use the half-space Green's function method to solve the scattered field, we obtain accurate near-filed distributions on the focal plane. The near-field distributions are then converted to images observed by the CCD camera via a near-field to far-field transformation. The simulated images are then compared with experimental results to gain deep understanding of these diffraction patterns. Mode profiles of the resonant cavity modes are observed and identified theoretically.

Nanoscopy of thick specimens using adaptive optics *(Invited Paper)*

Martin J. Booth, Univ. of Oxford (United Kingdom)

Optical nanoscopes provide nanometric resolution of specimens through combinations of optical and photophysical effects. Their performance is however often compromised by aberrations, especially when imaging deep into cells or tissues. We present advances in adaptive optics for compensation of aberrations in STED and single molecule switching (STORM/PALM) microscopy. Aberration correction permits 3D STED microscopy tens of micrometres inside inhomogeneous tissue. Adaptive STORM microscopy leads to significant increases in the number of detected emitters and localization precision. We also show that aberration correction is necessary to avoid localization errors in 3D STORM microscopes.

9554-19, Session 5

Optimizing STED and single-molecule switching nanoscopy for biological applications *(Invited Paper)*

Edward Allgeyer, Xiang Hao, Fang Huang, Emil Kromann, Yu Lin, Mary Grace Velasco, Yongdeng Zhang, Joerg Bewersdorf, Yale Univ. (United States)

This presentation will provide an overview over our current method developments in STED and single-molecule switching nanoscopy (FPALM, PALM, STORM, GSDIM, dSTORM, ...) towards routine application in cell biology, in particular in living cells. We will discuss, in particular, recent advances in speeding up SMS nanoscopy with sCMOS camera detection and novel algorithms, and the use of recently developed live-cell compatible fluorophores for multicolor STED as well as SMS nanoscopy.

9554-20, Session 5

Quantitative high spatiotemporal resolution imaging of biological processes *(Invited Paper)*

Joseph S. Borbely, Jason Otterstrom, Nitin Mohan, Carlo Manzo, Melike Lakadamyali, ICFO - Institut de Ciències Fotòniques (Spain)

In the recent years, super-resolution microscopy has emerged as a powerful tool to image cells at the nanoscale, giving important insights into biological processes at the molecular level. These methods have been so revolutionary that their impact has recently been recognized by the Nobel Prize in Chemistry. While exciting developments over the last decade have significantly advanced the capabilities of super-resolution microscopy, important challenges remain in pushing its applications in biology. One limitation is the compromise between spatial and temporal resolution that make these methods poorly suited to study dynamic processes. Another challenge is our limited capability to extract quantitative information from the super-resolution images, which is confounded by the photophysics of the fluorophores. I will show how we are developing new approaches to overcome these challenges and demonstrate two novel biological applications of super-resolution microscopy. In the first part of my talk, I will summarize our ongoing efforts to use a combination of single particle tracking and super-resolution microscopy to study how molecular motors such as dynein and kinesin overcome road blocks to transport their cargo. In the second part of my talk, I will show how we are using highly quantitative approaches to decipher the nanoscale organization of chromatin inside intact nuclei at the single cell level. Overall, I will demonstrate that quantitative, high spatio-temporal resolution imaging holds great promise for solving important mysteries in biology.

9554-21, Session 5

Optical nanoscopy to reveal structural and functional properties of liver cells *(Invited Paper)*

Peter McCourt, UiT The Arctic Univ. of Norway (Norway); Thomas R. Huser, Univ. Bielefeld (Germany); Karen K. Sørensen, Cristina I. Øie, UiT The Arctic Univ. of Norway (Norway); Viola Mönkemöller, Univ. of Bielefeld (Germany); Balpreet S. Ahluwalia, UiT The Arctic Univ. of Norway (Norway)

The advent of optical nanoscopy has provided an opportunity to study fundamental properties of nanoscale biological functions, such as liver sinusoidal endothelial cells (LSEC) and their fenestrations. The fenestrations are nano-pores (50-200 nm) on the LSEC plasma membrane that allow free passage of molecules through cells. The fenestrated LSEC also hase a voracious appetite for waste molecules, viruses and nanoparticles. LSEC daily remove huge amounts of waste, nanoparticles and virus from the blood. Pharmaceuticals also need to pass through these fenestrations to be activated (e.g. cholesterol reducing statins) or detoxified by hepatocytes. And, when we age, our LSEC fenestrations become smaller and fewer. Today, we study these cells and structures using either conventional light microscopy on living cells, or high-resolution (but static) methods such as transmission and scanning electron microscopy on fixed (i.e. dead) tissue. Such methods, while very powerful, yield no real time information about the uptake of virus or nanoparticles, nor any information about fenestration dynamics. Therefore, to study LS-SEC, we are now using optical nanoscopy methods, and developing our own, to map their functions in 4 dimensions. Attaining this goal will shed new light on the cell biology of the liver and how it keeps us alive. This paper describes the challenges of studying LS-SEC with light microscopy, as well as current and potential solutions to this challenge using optical nanoscopy.

9554-22, Session 5

Chip-based optical microscopy for imaging membrane sieve plates of liver scavenger cells

Øystein I. Helle, Cristina I. Øie, Peter McCourt, Balpreet S. Ahluwalia, UiT The Arctic Univ. of Norway (Norway)

Liver sinusoidal scavenger endothelial cells (LSECs) are engaged in blood clearance activity. LSECs are uniquely characterized structurally with fenestration (nano-holes of ~50-200 nm diameter) grouped in sieve plates, which allows small soluble material, but not larger particles to pass through the sinusoidal wall. As fenestrations and sieve plates are present only on the cell membrane, TIRF (total internal reflection microscopy) configuration is preferred over epi- fluorescence. In TIRF microscopy surface evanescent field is used to excite the sample. Here, we use the evanescent field on top of optical waveguides to image cell membrane network and sieve-plates (holes in the membrane) of liver cells. In waveguide excitation, the evanescent field is dominant only near the surface (~100-150 nm) providing default optical sectioning and illuminating fluorophores that are in close proximity to the surface and thus benefiting higher signal-to-noise ratio. This method represents an integrated, on-chip optical microscopy approach, with a possible extension towards super-resolution imaging methods. Waveguide platform is compatible with fast optical fiber components (couplers, adapters, switches) allowing easy multiplexing to different wavelengths. In this paper, we will discuss the challenges and opportunities provided by integrated optical microscopy for imaging cell membranes.

9554-23, Session 5

Nanoscopic lithography and applications

Jaroslaw Jacak, Richard Wollhofen, Thomas A. Klar, Johannes Kepler Univ. Linz (Austria)

STED-lithography is a powerful tool for maskless two and three dimensional structuring far below the diffraction limit of any desired geometry [1]. Similar to STED-microscopy [2, 3], optically excited starters of polymerization are depleted by a second laser beam which confines the excitation volume. An appropriate beam shaping reduces the volume, where initiators of polymerization are in the excited state, which initiates the polymerization in the adjacent region of the focal spot.

Using a 110 fs pulsed laser (780 nm) for multy-photon polymerization (MPP) and a 532 nm CW laser for STED, we are able to obtain structure sizes of 55 nm in all three dimensions (?/14 for 780 nm excitation) and manufacture two separated lines with 120 nm lateral distance, which marks the best resolution in STED lithography reported so far [5, 6].

Various two-and three-dimensional acrylate nanostructures are fabricated on glass supports with precisely controlled size, geometry and chemical properties. Tuning the polymer properties, we are able to create structures allowing an easy biofunctionalization with proteins approaching the single protein level [7]. In contrast, we can also inhibit adhesion of proteins or cells to the structures by using another composition of the polymer. We use direct stochastic optical reconstruction microscopy (dSTORM) and statistical fluorescence analysis methods to determine the protein density on nanoscopic structures fabricated via STED-lithography.

Visualisation of plasmonic fields at the nanoscale with single molecule localisation microscopy *(Invited Paper)*

Christian Steuwe, KU Leuven (Belgium) and Univ. of Cambridge (United Kingdom); Miklos Erdelyi, Univ. of Cambridge (United Kingdom); Gabor Szekeres, Mária Csete, Univ. of Szeged (Hungary); Jeremy J. Baumberg, Univ. of Cambridge (United Kingdom); Sumeet Mahajan, Univ. of Southampton (United Kingdom); Clemens F. Kaminski, Univ. of Cambridge (United Kingdom)

In this paper we demonstrate a novel method for combining surface enhancement on nanostructures with high resolution localisation microscopy [1] for in situ imaging of plasmonic hotspots in three dimensions [2]. We show that this technique allows for the characterisation of surfaces on the nanoscale enabling visualization of plasmon active areas, hence offering complementary information to results obtained by optical scattering or other far-field optical methods. The data is amenable for comparison with simulations obtained by boundary element and finite difference time-domain methods. For performing surface enhanced localisation microscopy (SELM) on metal surfaces we place fluorophores at precisely defined distances away from the surface to obtain the best field enhancement and overcome quenching. Using this technique we characterise plasmonic 'hotspots' on two types of substrates previously used in surface enhanced Raman spectroscopy such as Klarite®, a pyramidally pitted material [3] and sphere segment void (SSV) nanostructured substrates which can offer tunable plasmonic properties [4][5].

Furthermore, we investigate the photo-switching behaviour of fluorophores in the vicinity of the enhanced optical field of the metal and demonstrate the possibility of switching fluorophores between a dark and bright state thus obviating the need of any oxidising or reducing agents usually required for photoswitching superresolution methods [1].

Visible-wavelength two-photon excitation microscopy *(Invited Paper)*

Katsumasa Fujita, Masahito Yamanaka, Kumiko Uegaki, Yoshiyuki Arai, Kenta Saito, Nicholas I. Smith, Yasuo Yonemaru, Kentaro Mochizuki, Satoshi Kawata, Takeharu Nagai, Osaka Univ. (Japan)

We proposed and investigate the use of visible light for two-photon excitation of fluorescent proteins. We found that various kinds of fluorescent proteins can be excited by absorbing two photons at the wavelength of 525 nm to emit fluorescence. We used an OPO system pumped by 200-fs pulsed laser oscillating at 400 nm to produce 525 nm pulsed laser light for the visible-wavelength two-photon excitation and successfully demonstrated the simultaneous observation of four fluorescent protein, Sirius, mseCFP,

mTFP1, and EGFP expressed in HeLa cells. The fluorescence signal we have obtained from the fluorescent proteins was more than 100 times stronger than that of autofluorescence from endogenous molecules. We have confirmed that Sirius, mseCFP, mTFP1, and EGFP shows fluorescence response quadratic to the excitation intensity of pulsed laser light at 525 nm. We also measured the excitation spectra, and the results indicate the contribution of resonant two-photon excitation to the result of imaging with low autofluorescence background. With using 100-nm diameter fluorescence beads with fluorescnece emission at 440 nm, we have confirmed that the spatial resolutions of 120 nm and 280 nm can be obtained for the lateral and axial directions, respectively, with two-photon excitation at 500 nm. Finally, we have applied the visible-wavelength two-photon excitation in multifocus confocal microscopy and successfully demonstrated the video-rate two-color fluorescence imaging with high spatial resolution.

9554-26, Session 6

Resolution enhancement in a double-helix phase engineered scanning microscope (RESCH microscope) *(Invited Paper)*

Alexander Jesacher, Monika Ritsch-Marte, Medizinische Univ. Innsbruck (Austria); Rafael Piestun, Univ. of Colorado at Boulder (United States)

Recently we introduced RESCH microscopy [1] – a scanning microscope that allows slightly refocusing the sample after the acquisition has been performed, solely by performing appropriate data post-processing. The microscope features a double-helix phase-engineered emission point spread function in combination with camera-based detection. Based on the principle of transverse resolution enhancement in Image Scanning Microscopy [2,3], we demonstrate similar resolution improvement in RESCH. Furthermore, we outline a pathway for how the collected 3D sample information can be used to construct sharper optical sections.

Nonlinear fluorescence probe using photoinduced charge separation

Kentaro Mochizuki, Lanting Shi, Shin Mizukami, Masahito Yamanaka, Osaka Univ. (Japan); Mamoru Tanabe, FUJIFILM Corp. (Japan); Wei-Tao Gong, Almar F. Palonpon, Shogo Kawano, Satoshi Kawata, Kazuya Kikuchi, Katsumasa Fujita, Osaka Univ. (Japan)

Two-photon excitation microscopy (TPEM) provides spatial resolution beyond the optical diffraction limit using the nonlinear response of fluorescent molecules. One of the strong advantages of TPEM is that it can be performed using a laser-scanning microscope without a complicated excitation method or computational post-processing. However, TPEM has not been recognized as a super-resolution microscopy due to the use of near-infrared light as excitation source, which provides lower resolution than visible light. In our research, we aimed for the realization of nonlinear fluorescence response with visible light excitation to perform super-resolution imaging using a laser-scanning microscope. The nonlinear fluorescence response with visible light excitation is achieved by developing a probe which provides stepwise two-photon excitation through photoinduced charge separation. The probe named nitro-bisBODIPY consists of two fluorescent molecules (electron donor: D) and one electron acceptor (A), resulting to the structure of D-A-D. Excited by an incident photon, nitro-bisBODIPY generates a charge-separated pair between one of the fluorescent molecules and the acceptor. Fluorescence emission is obtained only when one more incident photon is used to excite the other fluorescent molecule of the probe in the charge-separated state. This stepwise two-photon excitation by nitro-bisBODIPY was confirmed by detection of the 2nd order nonlinear fluorescence response using a confocal microscope with 488 nm CW excitation. The physical model of the stepwise two-photon excitation was investigated by building the energy diagram of nitro-bisBODIPY. Finally, we obtained the improvement of spatial resolution in fluorescence imaging of HeLa cells using nitro-bisBODIPY.

9554-28, Session 6

A new method of single-particle spectroscopy with optical microresonators

Kevin Heylman, Randall H. Goldsmith, Kassandra A. Knapper, Erik Horak, Univ. of Wisconsin-Madison (United States)

Single-particle spectroscopy is a powerful technique for characterizing disordered materials, individual nanoparticles, and plasmonic nanostructures. This type of spectroscopy is typically performed via luminescence; however, important target systems such as plasmonic nanoparticles and conducting polymers typically cannot be made to luminesce. Absorption spectroscopy not only lacks this drawback, it offers additional information; in particular, the electronic structure and orientation of single nanoparticles can be determined. Previous efforts have typically employed photothermal microscopy, where the absorbing particle dissipates nanowatts of heat to its local environment through non-radiative relaxation after optical excitation. The extension of this technique to objects with small absorption cross-sections has been hampered by the intrinsically low sensitivity of existing methods for reading out this small heat flux.

In this work we employ ultrahigh-quality-factor optical microresonators to detect this dissipated heat, substantially augmenting the sensitivity and versatility of photothermal absorption spectroscopy. Tuning the excitation wavelength and measuring the resulting variation in dissipated heat leads to an absorption spectrum of a single nano-object. Finite-element simulations in COMSOL Multiphysics are used to correlate the observed resonance shift to an absolute absorption cross-section at each wavelength. Rotating the linear polarization angle of the excitation light, by contrast, gives information about the transition dipole of the absorber. This single-particle linear dichroism can be used to determine the orientation of anisotropic plasmonic nanoparticles, or the degree of crystallinity of organic nanoparticles. Combining the information content of optical absorption spectroscopy with the specificity of single-particle imaging provides a valuable new tool for nanospectroscopy.

Electrochemical tip-enhanced Raman spectroscopy *(Invited Paper)*

Zhicong Zeng, Shengchao Huang, Tengxiang Huang, Maohua Li, Bin Ren, Xiamen Univ. (China)

Tip-enhanced Raman spectroscopy (TERS) can not only provide very high sensitivity but also high spatial resolution, and has found applications in various fields, including surface science, materials, and biology. Most of previous TERS studies were performed in air or in the ultrahigh vacuum. If TERS study can be performed in the electrochemical environment, the electronic properties of the surface can be well controlled so that the interaction of the molecules with the substrate and the configuration of the molecules on the surface can also be well controlled.

However, the EC-TERS is not just a simple combination of electrochemistry with TERS, or the combination of EC-STM with Raman. It is a merge of STM, electrochemistry and Raman spectroscopy, and the mutual interference among these techniques makes the EC-TERS particularly challenge: the light distortion in EC system, the sensitivity, the tip coating to work under EC-STM and retain the TERS activity and cleanliness.

We designed a special spectroelectrochemical cell to eliminate the

distortion of the liquid layer to the optical path and obtain TER spectra of reasonably good signal to noise ratio for surface adsorbed molecules under electrochemical potential control. For example, potential dependent TERS signal have been obtained for adsorbed aromatic thiol molecule, and much obvious signal change compared with SERS has been found, manifesting the importance of EC-TERS to reveal the interfacial structure of an electrochemical system.

We further extended EC-TERS to electrochemical redox system, and clear dependence of the species during redox reaction can be identified.

Tip-enhanced Raman spectroscopy in graphene and GaN nanostructures *(Invited Paper)*

Janina Maultzsch, Technische Univ. Berlin (Germany)

Application of tip-enhanced Raman spectroscopy (TERS) to nanostructured materials can give valuable information about local deformations, disorder, as well as nm-scale variations in composition, strain, and doping. Here we present examples for carbon and semiconductor nanomaterials. TERS measurements on approximately 10nm wide graphene folds show the differences in strain and substrate-induced doping levels between the fold and the unfolded graphene. In GaN layers we investigate the different enhancement in TERS for different Raman modes, as well as polarization-dependent selection rules.

9554-32, Session 7

Polarization analysis in near-field Raman spectroscopy *(Invited Paper)*

Yuika Saito, Toshihiro Mino, Prabhat Verma, Osaka Univ. (Japan)

TERS has emerged over the past decade as a powerful tool for Raman spectroscopy that shows high sensitivity and capability of nano-scale imaging with high spatial resolution. TERS utilizes a metallic nano-tip, which confines and enhances the propagating light into near-field in the close vicinity of the apex. Besides the nano-scale spatial resolution, polarization analysis in TERS is of tremendous advantage, as it allows one to study highly directional intrinsic properties of a sample at the nanoscale. In this study, we have developed a method to analyze the polarization of near-field light in TERS from the scattering pattern produced by the induced dipole in the metallic tip. Under dipole approximation, we measured the image of the dipole at a plane away from the focal plane, where the information about the direction of the dipole oscillation was intact. The direction of the dipole oscillation was determined from the defocused pattern, and then the polarization of near-field light was evaluated from the oscillation direction by calculating the intensity distribution of near-field light We used those evaluated tips to measure nano-images from single-walled carbon nanotubes and confirmed that the contrast of the TERS image depended on the oscillation direction of the dipole, which were also found in excellent agreement with the calculated TERS images, verifying that the polarization of the near-field was quantitatively estimated by our technique.

9554-33, Session 7

Fast reproducible TERS imaging for real world applications

Dmitry Evplov, Vasily Gavrilyuk, Andrey Krayev, Sergey Saunin, AIST-NT Inc. (United States)

Since the discovery in 2000 Tip Enhanced Raman Scattering (TERS) has been a subject of great scientific interest due to the huge potential of the nanoscale chemical imaging. For number of reasons, both fundamental and engineering, successful TERS measurements were achieved in very limited number of the laboratories around the world. The real-life application of TERS as an analytical method has been hampered by the complexity of the experimental setups, poor reproducibility and extremely long acquisition times, measured in hours, required for collection of reasonably high pixel density TERS maps.

We report successful chemically specific high pixel density, high speed (less than 10 minutes per map) TERS imaging of complex samples comprised of Graphene oxide, Carbon nanotubes of different chirality , fullerene and self-assembled layers of organic molecules. The spatial resolution routinely obtained in such chemically specific TERS maps is in the 15 - 20 nm range, with the best resolution achieved being 7 nm.

The ease of use of the TERS imaging system and high speed TERS imaging capability enabled by advanced hardware and software move TERS closer to become a real life analytical method for chemically specific imaging at the nano scale.

9554-34, Session 8

Molecule-to-nanoantenna coupling investigated by polarization-sensitive SERS *(Invited Paper)*

Pietro G. Gucciardi, Consiglio Nazionale delle Ricerche (Italy)

When molecules are near-field coupled with optical nanoantennas their scattering properties are strongly affected by the radiation properties of the nanoantenna itself. In Surface Enhanced Raman Scattering (SERS) the Raman scattering cross section is greatly enhanced, the field orientation and polarization are modified by the nanoantenna radiation modes. Here we discuss how the polarization of the Raman field, inelastically scattered by molecules in SERS, is modified by the interaction with optical nanoantennas in a model beyond the E^4 approximation. The polarized SERS intensity is discussed for different nanoantenna geometries. Insights on how to recover information on the Raman polarizability tensor based on the SERS measurements are given.

9554-35, Session 8

Multi-targeting SERS bio-imaging *(Invited Paper)*

Aiguo Shen, Jiming Hu, Wuhan Univ. (China)

Surface-enhanced Raman scatter (SERS) technique has been fully demonstrated to be highly suitable for multi-targeting assay and bioimaging since due to its high sensitivity and multiolex etection capability. Herein, we describe recent advances in this domain including the design and synthesis of SERS substrates and tags, label-free/separation-free SERS assay and in vitro/in vivo SERS bio-imaging in our group. Especially, a focusing introduction is given on novel SERS active micropipettes for micro-area sampling and quantitative, separation-free detection of multiple organic residues, and the multi-targeting SERS imaging of a live cell which allow simutaneous label-free imaging of nuclear and label imaging of membrane in the process of drug induced cellular apoptosis.

9554-36, Session 8

Fan-shaped gold nanoantennas above reflective substrates for surface-enhanced infrared absorption (SEIRA)

Xiao Yang, Lisa V. Brown, Ke Zhao, Bob Y. Zheng, Peter Nordlander, Naomi J. Halas, Rice Univ. (United States)

Surface-enhanced infrared absorption (SEIRA) has been gaining substantial attention by using plasmonic nanoantennas to amplify near-field intensities so that it can extend IR spectroscopy to zeptomolar quantities and ultimately to the sigle-molecule level. Here we report a new nanoantenna for SEIRA detection, consisting of a fan-shaped Au structure positioned at a well-specified distance above a reflective plane with an intervening silica spacer layer. This antenna can be easily tuned to overlap vibrational modes within a broad spectral range from the near-IR into terahertz regimes. Our finite difference time domain (FDTD) simulations reveal a maximum SEIRA enhancement factor of 105 in the antenna junction area, which is corresponding to the experimental detection of 20-200 zeptomoles of octadecanethiol, using a standard commercial FTIR spectrometer. Our optimized antenna exhibits an order of magnitude greater SEIRA sensitivity than previous record-setting designs, which opens new opportunities for using infrared spectroscopy to analyze exceptionally small quantities of molecules.

9554-37, Session 8

Shell-isolated nanoparticle-enhanced Raman spectroscopy: principle and applications

Jian-Feng Li, Zhong-Qun Tian, Xiamen Univ. (China)

Surface-enhanced Raman spectroscopy (SERS) is a powerful technique that yields fingerprint vibrational information with ultra-high sensitivity. However, only roughened Ag, Au and Cu surfaces can generate strong SERS effect. The lack of materials and morphology generality has severely limited the breadth of SERS practical applications on surface science, electrochemistry and catalysis.

Shell-isolated nanoparticle-enhanced Raman spectroscopy (SHINERS) was therefore invented to break the long-standing limitation of SERS. In SHINERS, Au@SiO2 core-shell nanoparticles were rationally designed. The gold core acts as plasmonic antenna and encapsulated by an ultra-thin, uniform and pinhole-free silica shell, can provide high electromagnetic field to enhance the Raman signals of probed molecules. The inert silica shell acts as tunneling barrier prevents the core from interacting with the environment.

SHINERS has already been applied to a number of challenging systems, such as hydrogen and CO on Pt(hkl) and Rh(hkl), which can't be realized by traditional SERS. Combining with electrochemical methods, we has investigated the adsorption processes of pyridine at the Au(hkl) single crystal/solution interface, and in-situ monitored the surface electro-oxidation at Au(hkl) electrodes. These pioneering studies demonstrate convincingly the ability of SHINERS in exploring correlations between structure and reactivity as well as in monitoring intermediates at the interfaces. SHINERS was also explored from semiconductor surface for industry, to living bacteria for life science, and to pesticide residue detection for food safety. The concept of shell-isolated nanoparticle-enhancement is being applied to other spectroscopies such as infrared absorption, sum frequency generation and fluorescence.

9554-38, Session 8

Dynamic placement of plasmonic hotspots for super-resolution chemical imaging

Nathan C. Lindquist, Christopher T. Ertsgaard, Rachel M. McKoskey, Isabel S. Rich, Bethel Univ. (United States)

We demonstrate dynamic placement of plasmonic "hotspots" for super-resolution chemical imaging via Surface Enhanced Raman Spectroscopy (SERS). A silver nanohole array surface was first coated with various biological samples and illuminated with a laser. After optical filtering, the SERS hotspots could be imaged over a wide field of view on a CCD camera. Due to the large plasmonic field enhancements, blinking behavior of the SERS hotspots was observed and processed using a Stochastic Optical Reconstruction Microscopy (STORM) algorithm enabling localization of the hotspots to within 10 nm. However, illumination of the sample with a single static laser beam (i.e., a slightly de-focused Gaussian beam) only produced SERS hotspots in fixed locations on the surface, leaving noticeable gaps in any final super-resolution STORM image. But, by using a spatial light modulator (SLM), the illumination profile of the beam could be altered, shifting any hotspots across the nanohole array surface in sub-wavelength steps (i.e., shift a hotspot's position by <100 nm with an illumination wavelength of 660 nm). Therefore, by properly structuring an illuminating light field with the SLM, we show the possibility of positioning plasmonic hotspots over a metallic nanohole surface on-the-fly. Using this and our SERS-STORM imaging technique, we show potential for high-resolution chemical imaging without the noticeable gaps that were present with static laser illumination. Interestingly, even illuminating the surface with randomly shifting SLM phase profiles was sufficient to completely fill in a wide field of view for super-resolution SERS imaging of a single strand of collagen protein fibrils.

9554-39, Session 9

Nanospectroscopy of hybrid metallic-inorganic and metallic-organic systems *(Invited Paper)*

Monika Fleischer, Eberhard Karls Univ. Tübingen (Germany)

Plasmonic nanostructures acting as optical antennas are employed to locally create electrical near-fields and concentrate energy. Through the nanostructures' plasmon resonances the enhancement effects are spectrally dependent. The nanostructure material and geometry can be tailored to match either an exciting wavelength, or particular transitions of a nanosystem that is coupled to the nanoantenna. Such hybrid structures present interesting systems for near-field enhancement studies, single nanoemitter spectroscopy, for the modification of polarization and radiation characteristics, or for sensors and device applications.

In this presentation different hybrid nanostructures are introduced. Plasmonic nanostructures are fabricated by electron beam lithography, either in a lift-off process or by etch-mask transfer techniques. The geometry and plasmonic modes of the metallic nanostructures are thoroughly characterized by scanning electron microscopy, atomic force microscopy, numerical simulations, and nanospectroscopy [1-4]. To prepare hybrid systems based on these structures, nanoscale control over the positioning of nanoemitters within the high near-field regions of the plasmonic nanoantennas, or nanoscale thickness control over organic layer deposition are required. Firstly, strategies for the self-aligned fabrication of nanocone-nanoemitter structures by back-etching, dry ablation, and dielectrophoresis are demonstrated [4]. Secondly, nanogratings coupled to organic thin-films are discussed [3]. The respective hybrid systems are investigated by microscopy, dark-field scattering, extinction and Raman spectroscopy.

Live cell imaging using Au-NNP (Nanobridged Nanogap Particles) *(Invited Paper)*

Yung Doug Suh, Korea Research Institute of Chemical Technology (Korea, Republic of)

Single-particle tracking Live-Cell imaging using Au-NNP(Nanobridged Nanogap Particles) will be presented. Due to a stable plasmonic amplification of Raman signal from the intra-nanogap of Au-NNP, we have a stable and strong Raman signal enough for single particle imaging of Au-NNP in live cell. Multiplex imaging by encoding different Raman dyes into this nanogap and its application will be also discussed.

9554-41, Session 9

Morphologically controlled devices for SERS/TERS-like applications at the nanoscale *(Invited Paper)*

Remo Proietti Zaccaria, Istituto Italiano di Tecnologia (Italy)

Top-down fabrication allows for the realization of morphologically controlled micro/nano devices down to few nanometers scale. We investigate a number of applications based on this fabrication technique, with special emphasis towards nanoplasmonics. In particular, we shall focus on quasi-2D and 3D SERS devices, to move on with TERS structures especially designed to provide superfocusing characteristic. This feature, besides having tremendous impact in improving the TERS spatial resolution, is at the core of a new kind of nanoscopy technique based on hot-electrons transfer.

Finally, we shall provide a flavor of a new paradigm, namely the magnetic field enhancement and concentration from 2D SERS-like nanodevices.

9554-42, Session 9

Magnetic plasmonic Fano resonance at optical frequency *(Invited Paper)*

Zheyu Fang, Yanjun Bao, Peking Univ. (China)

We demonstrate a purely magnetic plasmon Fano resonance at optical frequency with Au split ring hexamer nanostructure excited by an azimuthally polarized incident light. Collective magnetic plasmon modes induced by the circular electric field within the hexamer and each of the split ring can be controlled and effectively hybridized by designing the size and orientation of each ring unit. With control of the magnetic Fano resonance, the split ring hexamer configuration can be further extended to obtain a double Fano resonance, which shows potential in the narrow line-shape engineering and low-loss magnetic plasmon resonance applications.

9554-43, Session 9

Metallic nanorods array for magnified subwavelength imaging

Yoshiro Ohashi, Bikas Ranjan, Yuika Saito, Prabhat Verma, Osaka Univ. (Japan)

Earlier, our group proposed a lens made of metallic nanorods, stacked in 3D arrays tapered in a conical shape. This nanolens could theoretically realize super-resolution color imaging in the visible range. The image could be magnified and transferred through metallic nanorods array. Lithography or self-assembly are common ways to fabricate such nanostructured devices. However, to precisely arrange nanorods is challenging due to the limitations to scale down components, and to increase accuracy of assembling particles in large area.

Here we experimentally demonstrated 2D nanolens with long chains of metallic nanorods placed at tapered angles in a fan-like shape to magnify images. In the fabrication, we chemically synthesized gold nanorods coated with CTAB surfactant to ensure a 10 nm gap between the rods for the resonance control of nanolens. And we prepared trenches patterned by FIB lithography on a PMMA coated glass substrate. The different hydrophobicity of PMMA and CTAB coats enabled to optimize capillary force in gold nanorod solution and selectively assemble nanorods into hydrophilic trenches. Finally, we obtained 2D nanolens after lift-off of the PMMA layer.

We numerically estimated the resonance property of nanorods chain and found a broad peak in the visible range located at a wavelength of 727 nm. The broadness of this peak (~178 nm) confirms that a broad range of wavelength can be resonant with this structure. This phenomenon was also confirmed experimentally by optical measurements. These results show that the combination of lithography and self-assembly has the potential to realize plasmonic nanolens.

9554-44, Session 10

Raman identification of edge misalignment of bilayer graphene down to the nanometer scale *(Invited Paper)*

Ping-Heng Tan, Institute of Semiconductors (China)

No Abstract Available

9554-45, Session 10

Space and time localization of the Raman scattering in graphene systems *(Invited Paper)*

Ado Jorio, Univ. Federal de Minas Gerais (Brazil)

This work focuses on the localization aspects of Raman spectroscopy. The materials under study are graphene related systems. Spatial localization is considered in tip-enhanced Raman spectroscopy (TERS), with focus on the specific aspects of TERS in two-dimensional systems. Time localization is considered in the correlation between the Stokes (S) and anti-Stokes (aS) scattering events, which leads to corrections in the broadly used relation between the S/aS ratio and the boson statistics. This phenomenon is shown to be special for low-dimensional systems under specific resonance conditions.

9554-46, Session 10

Nonlinear photo-oxidation of graphene and carbon nanotubes probed by four wave mixing imaging and spectroscopy *(Invited Paper)*

Mika Pettersson, Jukka Aumanen, Andreas Johansson, Juha Koivistoinen, Pasi Myllyperkiö, Univ. of Jyväskylä (Finland)

Graphene has high potential for becoming the next generation material for electronics, photonics and optoelectronics. However, spatially controlled modification of graphene is required for applications. Here, we report patterning and controlled tuning of electrical and optical properties of graphene by laser induced non-linear oxidation. We use four wave mixing (FWM) as a key method for imaging graphene and graphene oxide patterns with high sensitivity. FWM produces strong signal in monolayer graphene and the signal is highly sensitive to oxidation providing good contrast between patterned and non-patterned areas. We have also performed photo-oxidation and FWM imaging for air suspended carbon nanotubes.

9554-48, Session PWed

Multiplexed label-free detection of single proteins

Aleksandar Sebesta, Alexander Weigel, Philipp Kukura, Univ. of Oxford (United Kingdom)

Optical detection of single molecules usually relies on the fluorescent properties of the molecule or a label. Samples like proteins are purely refractive in the visible and near infrared, and thus not detectable by fluorescence without additional labelling. Recent alternative approaches used the local refractive index sensitivity of surface plasmon resonances to sense proteins as small as 53 kD even without any labels. 1,2

So far, all of these methods relied on the subsequent readout of one gold nanoparticle at a time. We present a novel wide-field detection scheme, which allows us to simultaneously monitor the surface plasmon resonance of multiple gold nanorods. The setup is based on a home-built ultrasensitive darkfield microspectroscope, which was shown to be 2 orders of magnitude more sensitive than the current state of the art, and capable of detecting and characterising 10 nm diameter gold nanospheres.3 Here, we directly recorded 2-dimensional, spectrally dispersed images of a gold nanorod array. The spectral positions were referenced with additional monochromatic illumination, allowing us to use the full 2D space of the sensor without any slit in the detection path. We present simultaneous readout traces of multiple gold nanorods with single-protein sensitivity. The technique not only increases the number of detected events for a given bulk concentration, but also allows us to distinguish general fluctuations and correlated noise from particle-specific protein binding steps. Together with the simple experimental implementation, our approach paves the way towards routine and efficient label-free detection down to the single molecule level.

Spectral analysis of photonic nanojet and exploring different microstructures with jet-like photonic beam for imaging applications

Mohsen Rezaei, Alireza Bonakdar, Hooman Mohseni, Northwestern Univ. (United States)

Resolution in all imaging devices using conventional photonics is limited on Abbe diffraction limit. Overcoming this limit has frequently been the goal to achieve high resolution -beyond diffraction limit- imaging or lithography. In this work we evaluate the photonic jet (PJ) which is essentially light confinement beyond diffraction limit using dielectric microspherers. In PJ evanescent and propagative field are contributing, and resulting in confined optical mode beyond the diffraction limit. PJ has received a tremendous attention within the last decade, with numerous applications in imaging, lithography and enhancing light matter interaction. The main problem in using PJ for lithography and imaging is its severe aberration due to curvature of the microspheres. We proposed a new “hourglass” structure, which can produce a jet like focusing, but with a planar focal plane. We will evaluate the spectral and spatial quality of the jet of light produced in this structure, and compare it with those produced by microspheres.

9554-50, Session PWed

Photo-induced magnetic force using nano probes

Caner Guclu, Univ of California Irvine (United States); Venkata A. Tamma, H. Kumar Wickramasinghe, Filippo Capolino, Univ. of California, Irvine (United States)

A theoretical investigation of the photo-induced magnetic force between nanostructures is presented as an initial assessment of the strength of magnetic field - matter interactions at optical frequencies. Atomic Force Microscopy (AFM) using static magnetism is an established method; whereas optical magnetic effects have not been of use in AFM due to vanishing natural magnetism in molecules and nanostructures at optical frequencies. Nevertheless, recently it has been shown that artificial magnetism can be established in engineered nanostructures and here we report that it can lead to detectable magnetic force levels. In particular we consider two examples of nanoprobes, namely a Si nanosphere and a circular cluster of plasmonic nanospheres. Both structures, either via a Mie magnetic resonance or by a collective plasmonic resonance, respectively, exhibit strong magnetic polarizability. These structures can be used as nanoprobes to detect magnetic fields and forces at optical frequencies. In particular we investigate the case of two nanoprobes interacting with each other, as an exemplary interacting structure, and the dependence of force magnitude and direction on the inter-probe disposition. We report forces in piconewton range when the nanoprobes are illuminated with a LASER beam intensity of 133 W/cm^2. Results show that Scanning Probe Microscopy (SPM) can be based on photo-induced magnetic nanoprobe for the investigation of artificial magnetism and weak magnetic-dipole transitions at optical frequencies. Such nanoprobes can enhance magnetic transitions and even lead to detection by force microscopy with nanoscale precision.

Shell-isolated silver nanoparticles for plasmon-enhanced spectroscopies

Chaoyu Li, Meng Meng, Shaorong Huang, Jianfeng Li, Zhongqun Tian, Xiamen Univ. (China)

In 2010, our group has invented a novel strategy called Shell-Isolated Nanoparticle-Enhanced Raman Spectroscopy (SHINERS) to overcome the substrate and surface generalities of surface-enhanced Raman scattering (SERS). The SERS-active Au nanospheres are coated with the ultrathin silica shell to prevent the interference from the environment, while the Au cores can provide strong electromagnetic (EM) field to enhance the probe molecules nearby. In-situ SHINERS technology has already been applied to a number of challenging systems.

In plasmonics, silver nanostructures have plenty of advantages over other noble metals due to its special dielectric property in visible and near-infrared regions. Herein, we use silver nanoparticles as cores instead of gold ones in the synthesis of SHINERS particles so that we can obtain a much stronger localized optical field in the applications of plasmon-enhanced spectroscopies, such as Raman, fluorescence, and etc.

The Ag nanospheres are synthesized by the seed-mediated growth method in which citrate ions acts as surface protection ligands.The as-prepared Ag@SiO2 nanoparticles could be introduced as signal amplifier to probe the surface adsorbates on the well-defined substrate, monitor the surface catalytic reactions and bear great potentials on plasmon mediated photo-catalysis.

Nanodiamonds as cellular marker for super-resolution STED-TEM correlative microscopy

Neeraj Prabhakar, Åbo Akademi Univ. (Finland)

We describe a correlative STED-TEM method and application of nanodiamonds (ND) as a unique dual purpose label for TEM and STED. NDs have excellent photostability, no-blinking, far red emission and fluorescence

originating from NDs has been shown to be depleted by STED laser allowing it to be resolved up to 6 nm, thus making an ideal super-resolution optical probe. Moreover, the electron dense nature of nanodiamonds allows it to be detected by TEM. First, we used nanogold (Au NP) ink pattern printed coverslips to grow MDA-MB-231 cells. Cells were then labeled with NDs and detected by live cell imaging. Au NP printed coverslips served as a landmark to mark and locate the position of cells with respect to intracellular fluorescent NDs. Therefore, this technique acted as a sophisticated method to precisely localize any cell of interest. Second, once the cell of interest was identified and fixed, nano-gold patterns allowed the re-identification in the block face, thus led to embedding and sectioning of the same cell. 70 nm thin sections of ND containing cells were prepared and imaged with TEM. ND allowed cells to be detected in TEM along with sub-cellular features. Finally, the TEM section was imaged with STED microscope exploiting NDs. as dual. The images obtained from both modalities were correlated with nanometer precision using our open source software. The current work demonstrates the potential of achieving correlative optical resolution with respect to TEM resolution.

Solar-blind photodetectors and focal plane arrays based on AlGaN

Ryan McClintock, Northwestern Univ. (United States)

III-Nitride material system (AlGaInN) possesses unique optical, electrical and structural properties such as a wide tunable direct bandgap, inherent fast carrier dynamics; good carrier transport properties, high breakdown fields; and high robustness and chemical stability. Recent technological advances in the wide bandgap AlGaN portion of this material system have led to a renewed interest in ultraviolet (UV) photodetectors. These detectors find use in numerous applications in the defense, commercial and scientific arenas such as covert space-to-space communications, early missile threat detection, chemical and biological threat detection and spectroscopy, flame detection and monitoring, UV environmental monitoring, and UV astronomy. Back illuminated detectors operating in the solar blind region are of special interest. Back illumination allows the detector to be hybridized to a silicon read-out integrated circuit, epi-side down, and still collect light through the back of the transparent sapphire substrate. This allows the realization of solar blind focal plane arrays (FPAs) for imaging applications. Solar-blind FPAs are especially important because of the near total absence of any background radiation in this region.

In this talk, we will present our recent back-illuminated solar-blind photodetector, mini-array, and FPA results. By systematically optimizing the design of the structure we have realized external quantum efficiencies (EQE) of in excess of 89% for pixel-sized detectors. Based on the absence of any anti-reflection coating, this corresponds to nearly 100% internal quantum efficiency. At the same time, the dark current remains below ~2 ? 10-9 A/cm2 even at 10 volts of reverse bias. The detector has a very sharp falloff starting at 275 with the UV-solar rejection of better than three orders of magnitude, and a visible rejection ratio is more than 6 orders of magnitude. This high performance photodetector design was then used as the basis of the realization of solar-blind FPA. We demonstrated a 320x256 FPA with a peak detection wavelength of 278nm. The operability of the FPA was better than 92%, and excellent corrected imaging was obtained.

9555-3, Session 1

Growth of AlGaN on silicon substrates: a novel way to make back-illuminated ultraviolet photodetectors *(Invited Paper)*

Ryan McClintock, Manijeh Razeghi, Northwestern Univ. (United States)

AlGaN, with its tunable wide-bandgap is a good choice for the realization of ultraviolet photodetectors. AlGaN films tend to be grown on foreign substrates such as sapphire, which is the most common choice for back-illuminated devices. However, even ultraviolet opaque substrates like silicon holds promise because, silicon can be removed by chemical treatment to allow back-illumination, and it is a very low-cost substrate which is available in large diameters up to 300 mm. However, Implementation of silicon as the solar-blind PD substrates requires overcoming the lattice-mismatch (17%) with the AlxGa1-xN that leads to high density of dislocation and crack-initiating stress.

In this talk, we report the growth of thick crack-free AlGaN films on (111) silicon substrates through the use of a substrate patterning and mask-less selective area regrowth. This technique is critical as it decouples the epilayers and the substrate and allows for crack-free growth; however, the masking also helps to reduce the dislocation density by inclining the growth direction and encouraging dislocations to annihilate. A back-illuminated p-i-n PD structure is subsequently grown on this high quality template layer. After processing and hybridizing the device we use a chemical process to selectively remove the silicon substrate. This removal has minimal effect on the device, but it removes the UV-opaque silicon and allows back-illumination of the photodetector. We report our latest results of back-illuminated solar-blind photodetectors growth on silicon.

9555-4, Session 1

Ultraviolet avalanche photodiodes

Ryan McClintock, Manijeh Razeghi, Northwestern Univ. (United States)

The III-Nitride material system is rapidly maturing; having proved itself as a material for LEDs and laser, and now finding use in the area of UV photodetectors. However, many UV applications are still dominated by the use of photomultiplier tubes (PMT). PMTs are capable of obtaining very high sensitivity using internal electron multiplication gain (typically ~106). It is highly desirable to develop a compact semiconductor-based photodetector capable of realizing this level of sensitivity. In principle, this can be obtained in III-Nitrides by taking advantage of avalanche multiplication under high electric fields – typically 2.7 MV/cm, which with proper design can correspond to an external reverse bias of less than 100 volts.

In this talk, we review the current state-of-the-art in III-Nitride solar- and visible-blind APDs, and present our latest results on GaN APDs grown on both conventional sapphire and low dislocation density free-standing c- and m-plane GaN substrates. Leakage current, gain, and single photon detection efficiency (SPDE) of these APDs were compared. The spectral response and Geiger-mode photon counting performance of UV APDs are studied under low photon fluxes, with single photon detection capabilities as much as 30% being demonstrated in smaller devices. Geiger-mode operation conditions are optimized for enhanced SPDE

9555-5, Session 2

Colloidal quantum dots for mid-infrared detection *(Invited Paper)*

Philippe Guyot-Sionnest, The Univ. of Chicago (United States)

Colloidal quantum dots present an opportunity as infrared and liquid processed materials. Initial results in 2011 showed mid-infrared detection with HgTe colloidal quantum dots in the mi-IR range, 3-5 microns. This has been now extended to the long-wave IR, 8-12 microns. The infrared response from the HgTe colloidal quantum dots arises from the absorption of light across the gap created by the confinement. The large dots absorbing the LWIR are about 20 nm in size and the size dispersion will need improvements. While Interband absorption requires the material to be zero or small-gap semiconductors, intraband transitions have no such limitations. However, this requires doped colloidal quantum dots. Two colloidal quantum dot materials, the small gap (0.6 eV) b-HgS and the zero-gap HgSe turn out to be stably doped with electrons. This has led to the observation of Mid-IR intraband photoconduction in both systems and alternative materials for IR detection.

There are several basic challenges, besides fabrication and reliability. The proximity of the surface from the excitation leads to very short excited lifetimes due to nonradiative processes. Controlling the surface will be the avenue to lengthen the lifetime, while plasmonic coupling may lead to shorter radiative lifetime. Since the surface is easily chemically modified, it also leads to strong changes in the Fermi level and this will need to be controlled.

In this talk, I will describe my understanding of the potential and limitations of this material approach to infrared detection, while discussing aspects of transport, photoluminescence, doping and photovoltaic responses.

9555-6, Session 2

Colloidal quantum dot Vis-SWIR imaging: demonstration of a focal plane array and camera prototype *(Invited Paper)*

Ethan J. D. Klem, Christopher W. Gregory, Dorota S. Temple, Jay S. Lewis, RTI International (United States)

RTI has developed a photodiode technology based on solution-processed PbS colloidal quantum dots (CQD). These devices are capable of providing low-cost, high performance detection across the Vis-SWIR spectral range. At the core of this technology is a heterojunction diode structure fabricated using techniques well suited to wafer-scale fabrication, such as spin coating and thermal evaporation. This enables RTI's CQD diodes to be processed at room temperature directly on top of read-out integrated circuits (ROIC), without the need for the hybridization step required by traditional SWIR detectors. Additionally, the CQD diodes can be fabricated on ROICs designed for other detector material systems, effectively allowing rapid prototype demonstrations of CQD focal plane arrays at low cost and on a wide range of pixel pitches and array sizes.

We will show the results of fabricating CQD arrays directly on top of commercially available ROICs. Specifically, the ROICs are a 640 x 512 pixel format with 15 μm pitch, originally developed for InGaAs detectors. We will show that minor modifications to the surface of these ROICs make them suitable for use with our CQD detectors. Once completed, these FPAs are then assembled into a demonstration camera and their imaging performance is evaluated. In addition, we will discuss recent advances in device architecture and processing resulting in devices with room temperature dark currents of 2-5 nA/cm^2 and sensitivity from 350 nm to 1.7 μm.

This combination of high performance, dramatic cost reduction, and multi-band sensitivity is ideally suited to expand the use of SWIR imaging in current applications, as well as to address applications which require a multispectral sensitivity not met by existing technologies.

9555-7, Session 2

Colloidal quantum dot photodetectors *(Invited Paper)*

Valerio Adinolfi, Edward H. Sargent, Univ. of Toronto (Canada)

Colloidal quantum dots (CQDs) are emerging solution processed materials combining low cost, easy deposition on large and flexible substrates, and bandgap tunability. The latter feature, which allows spectral tuning of the absorption profile of the semiconductor, makes these materials particularly attractive for light detection applications. Lead sulfide (PbS) CQDs, in particular, have shown astonishing performance as a light sensitive material operating at visible and infrared (IR) wavelengths. Early studies of PbS CQDs used as a photosensitive resistor (photoconductor) showed an impressive responsivity – exceeding 1000 A/W – and a detectivity (D*) higher then 10^13 Jones. This impressive D* was preserved in the successive development of the first PbS CQD photodiode, showing the possibility to realize fast – f_3db > 1Mhz – and sensitive IR detectors. Currently, the field is moving toward the development of hybrid devices and phototransitors. PbS CQDs have been combined in field effect transistors (FETs) with graphene and MoS2 channels, showing ultra-high gain (exceeding 10^8 electrons/photons) and high D*. Recently a photo-junction FET (photo-JFET) has been reported that breaks the inherent dark current/gain/bandwidth compromise affecting photoconductive light detectors. With this presentation we offer a broad overview on CQD photodetection highlighting the past achievements, the benefits, the challenges and the prospects for the future research on this field.

9555-8, Session 2

Superlattice infrared photodetector research at the jet propulsion laboratory *(Invited Paper)*

Sarath D. Gunapala, David Z. Y. Ting, Alexander Soibel, Sir B. Rafol, Arezou Khoshakhlagh, Linda Höglund, Cory J. Hill, Sam A. Keo, John K. Liu, Jason M. Mumolo, Edward M. Luong, Jet Propulsion Lab. (United States)

Recently, 320x256 pixel focal plane arrays (FPAs) with 30?m pixel pitch were fabricated with LWIR CBIRD material by dry etching through the top contact, hole-barrier superlattice (SL), photosensitive absorber SL, electron-barrier SL into the 0.5μm thick doped GaSb detector common layer. Some imagery was performed at a temperature of 78 K. The measured mean NE?T was 18.6 mK at a flat plate blackbody temperature of 300K with f/2 cold stop. The experimentally measured FPA quantum efficiency is 45%. The horizontal and vertical modulation transfer functions (MTFs) at Nyquist frequency based on pixel pitch, a, (= 1/2a, a = 30?m) ~16.67cycles/mm are about ~0.49 and ~0.52, respectively. The image quality of the natural scene attests to the very good MTF behavior at low and high frequencies. The FPA MTF can be separated into the product of two components. The geometric aperture MTF is related to the pixel size and the diffusion MTF related to electro-optical properties. The diffusion MTF depends on the diffusion length and geometry. The CBIRD pixels are delineated down to the bottom contact and it is expected that no lateral carrier diffusion into the next neighbor can occur. The disadvantage is that the fill factor is less than 100%. Shorter wavelengths on the other hand can be absorbed near the top surface and can diffuse to the next neighbor. In CBIRD FPA, the only channel left for the charge carriers to diffuse to an adjacent pixel is through the thin detector common layer of the FPA.

9555-9, Session 2

Identification of point defect candidates in strained-layer type-II superlattices for infrared detectors: ab initio electronic structure studies *(Invited Paper)*

Nicholas Kioussis, California State Univ., Northridge (United States)

The InAs/GaSb and InAs/InAsSb type-II strain-layer superlattices (T2SLS) are of great importance and show great promise for mid-wave and long-wave infrared (IR) detectors for a variety of civil and military applications. The T2SLS offer several advantages over present day detection technologies including suppressed Auger recombination relative to the bulk MCT material, high quantum efficiencies, and commercial availability of low defect density substrates. While the T2SLS detectors are approaching the empirical Rule-07 benchmark of MCT's performance level, the dark-current density is still significantly higher than that of bulk MCT detectors. One of the major origins of dark current is associated with the Shockley-Read- Hall (SRH) process in the depletion region of the detector.

I will present results of ab initio electronic structure calculations of the stability of a wide range of point defects [As and In vacancies, In, As and Sb antisites, In interstitials, As interstitials, and Sb interstitials] in various charged states in bulk InAs, InSb, and InAsSb systems and T2SLS. I will also present results of the transition energy levels. The calculations reveal that compared to defects in bulk materials, the formation and defect properties in InAs/InAsSb T2SLS can be affected by various structural features, such as strain, interface, and local chemical environment. I will present examples which demonstrate that the effect of strain or local chemical environment shifts the transition energy levels of certain point defects either above or below the conduction band minimum, thus suppressing their contribution to the SRH recombination.

9555-10, Session 3

III-V strain layer superlattice based band engineered avalanche photodiodes *(Invited Paper)*

Sid Ghosh, Raytheon Space and Airborne Systems (United States)

Laser detection and ranging (LADAR)-based systems operating in the Near Infrared (NIR) and Short Wave Infrared (SWIR) have become popular optical sensors for remote sensing, medical, and environmental applications. Sophisticated laser-based radar and weapon systems used for long-range military and astronomical applications need to detect, recognize, and track a variety of targets under a wide spectrum of atmospheric conditions. Infrared APDs play an important role in LADAR systems by integrating the detection and gain stages in a single device. Robust silicon-APDs are limited to visible and very near infrared region (< 1 um), while InGaAs works well up to wavelengths of about 1.5um. Si APDs have low multiplication or excess noise but are limited to below 1um due very poor quantum efficiency above 0.8um. InGaAs and Ge APDs operate up to wavelengths of 1.5um but have poor multiplication or excess noise due to a low impact ionization coefficient ratio between electrons and holes. For the past several decades HgCdTe has been traditionally used in longer wavelength (> 3um) infrared photon detection applications. Recently, various research groups (including Ghosh et. al.) have reported SWIR and MWIR HgCdTe APDs on CdZnTe and Si substrates. However, HgCdTe APDs suffer from low breakdown fields due to material defects, and excess noise increases significantly at high electric fields.

During the past decade, InAs/GaSb Strain Layer Superlattice (SLS) material system has emerged as a potential material for the entire infrared spectrum because of relatively easier growth, comparable absorption coefficients, lower tunneling currents and longer Auger lifetimes resulting in enhanced detectivities (D*). Band engineering in type II SLS allows us to engineer avalanche properties of electrons and holes. This is a great advantage over bulk InGaAs and HgCdTe APDs where engineering avalanche properties is not possible.

The talk will discuss the evolution of superlattice based avalanche photodiodes and some of the recent results on the work being done at Raytheon on SWIR avalanche photodiodes.

9555-12, Session 3

Recent progress in high gain InAs avalanche photodiodes *(Invited Paper)*

Seth Bank, Scott J. Maddox, The Univ. of Texas at Austin (United States); Wenlu Sun, Univ. of Virginia (United States); Hari P. Nair, The Univ. of Texas at Austin (United States); Joe C. Campbell, Univ. of Virginia (United States)

InAs possesses nearly ideal material properties for the fabrication of near- and mid-infrared avalanche photodiodes (APDs), which result in strong electron-initiated impact ionization and negligible hole-initiated impact ionization [1]. Consequently, InAs multiplication regions exhibit several appealing characteristics, including extremely low excess noise factors and bandwidth independent of gain [2], [3]. These properties make InAs APDs attractive for a number of near- and mid-infrared sensing applications including remote gas sensing, light detection and ranging (LIDAR), and both active and passive imaging. Here, we discuss our recent advances in the growth and fabrication of high gain, low noise InAs APDs. Devices yielded room temperature multiplication gains >300, with much reduced (~10x) lower dark current densities. We will also discuss a likely key contributor to our current performance limitations: silicon diffusion into the intrinsic (multiplication) region from the underlying n-type layer during growth. Future work will focus on increasing the intrinsic region thickness, targeting gains >1000. This work was supported by the Army Research Office (W911NF-10-1-0391).

9555-13, Session 3

Evaluation of different processing steps on the dark current of electron-injection detectors

Mohsen Rezaei, Sung Jun Jang, Hooman Mohseni, Northwestern Univ. (United States)

Our recently published results show a much reduced dark current and enhanced speed from our second-generation electron-Injection detectors, due to the introduction of an isolation method. However, these results have been limited to single-element detectors. A natural next step is to incorporate these new devices into a focal plane array (FPA), since we have already achieved very attractive results from an FPA based on the first-generation devices. Despite the high-performance characteristics of second generation devices, isolation introduces new processing steps and a robust procedure is required for realization of focal plane arrays (FPA) with good uniformity and yield. Here we report our systematic evaluation of the processing steps, and in particular the effect of the processing temperature, on the device dark current and uniformity. Our goal is to produce ultra-low dark current FPA based on isolated electron-injection detectors, and to approach single-photon sensitivity.

9555-14, Session 3

Effect of temperature on superconducting nanowire single-photon detector noise

Andrea Bahgat Shehata, Alessandro Ruggeri, Franco Stellari, Alan J. Weger, Peilin Song, IBM Thomas J. Watson Research Ctr. (United States); Kristen Sunter, Karl K. Berggren, Massachusetts Institute of Technology (United States); Vikas Anant, Photon Spot, Inc. (United States)

Today Superconducting Nanowire Single-Photon Detectors (SNSPDs) are commonly used in different photon-starved applications, including testing and diagnostics of VLSI circuits. Detecting very faint signals in the near-infrared wavelength range requires not only good detection efficiency, but also very low Dark Count Rate (DCR) and jitter. For example, low noise is crucial to lower the Bit Error Rate (BER) in Quantum Key Distribution (QKD), or to enable ultra-low voltage optical testing of integrated circuits. In this paper we study the effect of temperature on the noise of superconducting single-photon detectors made of NbN meanders. We show that two different regimes can be identified in the DCR vs. bias current characteristics. At high bias the dark count rate is dominated by the intrinsic noise of the detector that depends on its switching current, while at low bias current it is dominated by the detection of stray photons that get onto the SNSPD. Changing the detector temperature changes its switching current and only affects the high bias branch of the characteristics: a reduction of the DCR can be achieved by lowering the SNSPD base temperature. On the other hand, changing the temperature of the single-photon light source (in our case VLSI circuits) only affects the low bias regime: a lower target temperature leads to a smaller DCR.

9555-15, Session 4

IR CMOS: near infrared enhanced digital imaging *(Invited Paper)*

Martin U. Pralle, James E. Carey, Thomas Joy, Chris J. Vineis, Chintamani Palsule, SiOnyx Inc. (United States)

SiOnyx has demonstrated imaging at light levels below 1 mLux (moonless starlight) at video frame rates with a 720P CMOS image sensor in a compact, low latency camera. Low light imaging is enabled by the combination of enhanced quantum efficiency in the near infrared together with state of the art low noise image sensor design. The quantum efficiency enhancements are achieved by applying Black Silicon, SiOnyx's proprietary ultrafast laser semiconductor processing technology. In the near infrared, silicon's native indirect bandgap results in low absorption coefficients and long absorption lengths. The Black Silicon nanostructured layer fundamentally disrupts this paradigm by enhancing the absorption of light within a thin pixel layer making 5 microns of silicon equivalent to over 300 microns of standard silicon. This results in a demonstrate 10 fold improvements in near infrared sensitivity over incumbent imaging technology while maintaining complete compatibility with standard CMOS image sensor process flows. Applications include surveillance, nightvision, and 1064nm laser see spot. Imaging performance metrics will be discussed.

Demonstrated performance characteristics:

Pixel size : 5.6 & 10 um

Array size: 720P/1.3Mpix

Frame rate: 60 Hz

Read noise: 2 ele/pixel

Spectral sensitivity: 400 to 1200 nm (with 10x QE at 1064nm)

Daytime imaging: color (Bayer pattern)

Nighttime imaging: moonless starlight conditions

1064nm laser imaging: daytime imaging out to 2Km

9555-16, Session 4

Si based mid-infrared GeSn photo detectors and light emitters on silicon substrates *(Invited Paper)*

Shui-Qing Yu, Wei Du, Benjamin R. Conley, Seyed A. Ghetmiri, Aboozar Mosleh, Thach Pham, Perry Grant, Yiyin Zhou, Huong Tran, Sattar Al Kabi, Univ. of Arkansas (United States); Amjad Nazzal, Wilkes Univ. (United States); Greg Sun, Richard A. Soref, Univ. of Massachusetts Boston (United States); Joe Margetis, John Tolle, ASM America Inc. (United States); Baohua Li, Arktonics, LLC (United States); Hameed A. Naseem, Univ. of Arkansas (United States)

The Ge1-xSnx alloy is a promising material for active and passive photonics on Si due to its identified direct bandgap, industry scalable growth, compatibility with complementary metal–oxide–semiconductor (CMOS) process, capability of monolithic integration on Si and broad wavelength coverage in infrared. The GeSn-based optoelectronic devices can be widely used in Si photonic applications such as active imaging, sensing, Ladar signal processing and high speed optical interconnects, et al.

In this work, high performance GeSn photoconductor and light emitting diodes (LED) have been demonstrated. For the photoconductor, the high responsivity was achieved due to high photoconductive gain, which is attributed to the novel optical and electrical design. A side by side comparison of spectral detectivity with other mature photo detectors indicates that the GeSn photoconductor is comparable with commercially available detectors such as InGaAs, InAs and Ge. The longwave cutoff at 2.4 ?m was also observed at room temperature. For LED, temperature-dependent study was conducted. The electroluminescence (EL) spectra at different temperatures were obtained and EL peak shift was observed. Moreover, the emission power at different temperatures was measured. High power emission at 2.1 ?m was achieved.

9555-17, Session 4

Optical absorption in 3D topological insulator Bi2Te3 with applications to THz detectors

Parijat Sengupta, Enrico Bellotti, Boston Univ. (United States)

Topological insulators (TI) are a new class of materials that have an energy gap in bulk but possess gapless states bound to the sample surface or edge that have been theoretically predicted and experimentally observed [1]. The topological state in Bi2Te3 is characterized by a linear dispersion and a Dirac cone at the ?point. The optical absorption on the surface of a TI is given by the standard graphene-like ?ϖ/2 when a linear dispersion is assumed. Realistically, at k-points away from ?, higher order cubic terms in k that represent the underlying hexagonal symmetry [2] of the crystal dominate and give rise to warping of bands. The optical absorption of a ferromagnetic coated gapped 3D TI film with warping terms considered is longer ?ϖ/2 but significantly modified. We demonstrate, by using wave functions from a continuum-Hamiltonian and Fermi-golden rule, the absorption spectrum on the surface of a TI as a function of the chemical potential, film-thickness and incident photon energy. A linear response theory based calculation is also performed using the Kubo formula to determine the longitudinal optical conductivity whose real part gives absorption as a function of photon frequency. The absorption in materials with Dirac fermions which is significantly higher than in normal THz detectors [3] can be further modulated in a TI by explicitly including the warping term making them highly efficient and tunable photodetectors.

Design tradeoffs of II-VI and III-V superlattices for VLWIR sensing *(Invited Paper)*

Gail J. Brown, Frank Szmulowicz, Air Force Research Lab. (United States)

There are three leading options for creating superlattice materials to cover the very long wavelength infrared (VLWIR) sensing range: InAs/InGaSb, InAs/InAsSb and HgTe/CdTe. Each of these material systems has some advantages and disadvantages in the very narrow band gap regime, i.e. 100 to 50 meV. The results of an analysis of the design tradeoffs for these three superlattice materials will be presented. Areas to be discussed are: sensitivity to variations in layer widths and composition, absorption coefficient, carrier mobilities and lifetimes. Comparisons to experimental results, where available, will also be performed to support the design analysis. A review of the state-of-the-art for these three superlattice materials for VLWIR sensing will also be covered.

9555-19, Session 5

Full-band structure modeling of the radiative and non-radiative properties of semiconductor materials and devices *(Invited Paper)*

Enrico Bellotti, Hanqing Wen, Benjamin Pinkie, Masahiko

Matsubara, Boston Univ. (United States); Francesco Bertazzi, Politecnico di Torino (Italy)

Understanding the radiative and non-radiative properties of semiconductor materials is a prerequisite for optimizing the performance of existing light emitters and detectors and for developing new device architectures based on novel materials. Due to the ever increasing complexity of novel semiconductor systems and their relative technological immaturity, it is essential to have design tools and simulation strategies that include the details of the microscopic physics and their dependence on the macroscopic (continuum) variables in the macroscopic device models. Towards this end, we have developed a robust full-band structure based approach that can be used to study the intrinsic material radiative and non-radiative properties and evaluate the same characteristics of low-dimensional device structures. A parallel effort is being carried out to model the effect of substrate driven stress/strain and material quality (dislocations and defects) on microscopic quantities such as non-radiative recombination rate. Using this modeling approach, we have extensively studied the radiative and non-radiative properties of both elemental (Si and Ge) and compound semiconductors (HgCdTe, InGaAs, InAsSb and InGaN). In this work we outline the details of the modelling approach, specifically the challenges and advantages related to the use of the full-band description of the material electronic structure. We will present a detailed comparison of the radiative and Auger recombination rates as a function of temperature and doping for HgCdTe and InAsSb that are two important materials for infrared detectors and emitters. Furthermore we will discuss the role of non-radiatiave Auger recombination processes in explaining the performance of light emitter diodes. Finally we will present the extension of the model to low dimensional structures employed in a number of light emitter and detector structures.

9555-20, Session 5

Three-dimensional numerical modeling for ultra-sensitive noninvasive size-dependent nanoparticle detection technique using subwavelength silicon microcavities

Jeffrey P. Dionne, Lyuba Kuznetsova, San Diego State Univ. (United States)

Resonant microcavities that use whispering gallery modes (WGMs) allow sensitivity to a single bonding event [1] that makes silicon microcavity a promising candidate for a compact, label-free biosensor. The fact that the microdisk's size is comparable with a wavelength is extremely important because the fraction of the light that is absorbed per pass when interacting with a biological molecule is inversely proportional to the cross-sectional area of the optical mode. In addition, it has been recently proposed [2] that silicon is a promising material for mid-IR because of its low loss that opens up an opportunity for the detection of many biological nanoparticles.

In this work we use the three-dimensional finite-difference time-domain numerical simulations (COMSOL Multiphysics) to investigate a system, consisting of a silicon microdisk cavity (1?m radius, 250nm thickness), for the detection of different viruses of the same type by observing the effects that a spherical nanoparticle has on the frequency resonances of the silicon microdisk's WGMs. Numerical simulations show that the observed spectral shift for a nanoparticle with radius R=200 nm is significantly higher for the lower order modes (TM15 mode at ~1960nm) compare to the higher order modes at ~1130 nm. The observed spectral shift varies between 1.4-1.9 nm for the TM15 mode with an attached nanoparticle with radiuses between 100-300 nm. This frequency shift size-dependence makes it possible for the mature and immature HIV-1 viruses to be identified by the resonant frequency change in the transmission spectrum.

9555-21, Session 5

Electro-optical characteristics of p+n In0.53Ga0.47As photodiodes in large format dense focal plane arrays *(Invited Paper)*

Roger E. DeWames, FulcrumIT (United States); Kyle Witte, Patrick G. Maloney, U.S. Army Night Vision & Electronic Sensors Directorate (United States); Adam R. Wichman, Enrico Bellotti, Boston Univ. (United States); Manijeh Razeghi, Northwestern Univ. (United States)

This paper is concerned with focal plane array (FPA) data and applying analytical and three dimensional (3D) numerical simulation methods to capture the right physical effects and processes limiting performance. For shallow homojunction p+n designs, T <300K, in the analytical model the variations from bulk G-R dark current behavior are modeled with a perimeter dependent shunt current conjectured to be of origin at the InP/InGaAs interface. A major result of the device's 3D numerical simulation is the prediction of a perimeter G-R current not associated with the properties of the metallurgical interface. For junctions positioned in the larger band gap InP cap layer, the QE is bias dependent and relatively large reverse bias ≥ 0.9 volts are needed for the QE to saturate to the shallow homojunction value; at this bias voltage the dark current is larger than the shallow homojunction value. The 3D numerical and analytical models agree in predicting and explaining the measured radiatively limited diffusion current of origin in the n-side of the junction; the calculation of the area dependent G-R current is also in agreement. Substrate removal extends the quantum efficiency (QE) spectral band into the visible; dead layer effects limit the QE to 10% at a wavelength of 0.5 ?m.

9555-22, Session 5

Real-time baseline correction technique for MWIR and LWIR time-resolved photoluminescence spectroscopy

Zhi-Yuan Lin, Yong-Hang Zhang, Arizona State Univ. (United States)

The time-resolved photoluminescence (TRPL) measurement provides rich information about carrier dynamics and recombination mechanisms. However, TRPL measurements are quite challenging in mid-wave infrared (MWIR) and long-wave infrared (LWIR) regimes due to noise in photodetectors and data acquisition systems. Our analysis and experimental results show that the noise in a conventional TRPL system using a traditional averaging method is dominated by 1/f noise from 10 Hz to 3 kHz. The signal is also mixed with sub-Hertz noise associated with the boxcar baseline oscillation, commonly known as the "baseline drift" issue which results from numerous fluctuations in the system. A real-time baseline correction method is proposed and demonstrated to suppress these low frequency noise sources. The real-time baseline correction method is realized by modulating the signal. The modulation can be achieved by either electrical, mechanical, or optical approaches. Analysis indicates that the noise of this method is proportional to the noise spectral density at the modulation frequency, this argument is confirmed by the simulation results. The simulated noise achieved by the real-time baseline correction method is much lower than the traditional method. Experimental results show that the low frequency baseline oscillations associated with the traditional TRPL experiments are absent using the real-time baseline correction technique, and the noise of the measurement is significantly reduced. This work establishes a more efficient experimental method for TRPL measurements on weak MWIR and LWIR PL signals, such as the InAs/InAsSb type-II superlattice samples which are used here to demonstrate the proposed method.

9555-23, Session 6

Benefits of small pixel focal plane array technology *(Invited Paper)*

John T. Caulfield, Jon Paul Curzan, Cyan Systems (United States)

There are known limits in undersampled and critically sampled sensors regarding resolution and aliasing. Improved imaging systems using smaller sub diffraction sized pixels have shown good initial imaging results. Oversampling the image using sub-diffraction size pixels offers much more than improved resolution, smaller FPAs, optics, and dewar systems. Oversampled pixels results in processing techniques for smaller pixels that enable a number of related systems benefits such as improved Instantaneous Field of View (IFOV), Noise Equivalent Power (NEP), False Alarm Rate, and detection range, as well as other system level benefits.

Cyan Systems has developed and recently demonstrated a small pixel ROIC/FPA that demonstrates these advanced resolutions features.

We will show data from the first 2.4 Megapixel 5 micron pitch ROIC and demonstrate that spatial oversampling can improve aliasing, sensitivity, and drive reductions in False Alarms through oversampled correlated processing. Oversampled pixels allow larger format FPAs and smaller optics, resulting in reductions in size, power, and weight. Oversampled IR sensors will also improve detection and acuity in turbulent and hazy conditions over larger pixel IR focal plane array sensors.

We will review the phenomena of smaller pixels having improved SNR, and how using temporal and spatial oversampling can compensate and effectively increase SNR lost with smaller pixels. We will quantify the limits of performance of Oversampling based on theory, and also with Monte Carlo type analysis using realistic parameters such as shot noise and thermal noise. We will show quantitative data to illustrate the improvements in resolution, NEP, detection range, and false alarm suppression of the oversampled IR sensor as the temporal and spatial oversampling are increased.

Design methodology: ASICs with complex in-pixel processing for pixel detectors

Farah Fahim, Hooman Mohseni, Northwestern Univ. (United States); Grzegorz Deptuch, James R. Hoff, Alpana Shenai, Fermi National Accelerator Lab. (United States); Bruce Cauble, Cadence Design Systems, Inc. (United States)

The development of Application Specific Integrated Circuits (ASIC) for pixel detectors with complex in-pixel processing using Computer Aided Design (CAD) tools that are, themselves, mainly developed for the design of conventional digital circuits requires a specialized approach. Mixed signal pixels often require parasitically aware detailed analog front-ends and extremely compact digital back-ends with more than 1000 transistors in small areas below 100μm x 100μm. These pixels are tiled to create large arrays, which have the same clock distribution and data readout speed constraints as in, for example, micro-processors. The methodology uses a modified mixed-mode on-top digital implementation flow to not only harness the tool efficiency for timing and floor-planning but also to maintain designer control over compact parasitically aware layout.

The design methodology of two pixel detector ASICs for two diverse applications is discussed. It proposes the modification of the standard approach and uses an iterative design flow, which needs to be adapted based on the area constraints of the digital pixel and the peripheral functionality for the ASIC. Custom digital layouts require parasitic information to be extracted using Assura QRC and subsequently using Encounter in timing mode to extract the timing and delay files. Adapting the design flow of EDI primarily developed for high-speed microprocessor layouts, allows the designer of pixel detector ASICs to distribute high-speed clocks with low jitter across a large array.

9555-25, Session 6

Fusion: ultra-high-speed and ir image sensors *(Invited Paper)*

Takeharu Goji Etoh, Ritsumeikan Univ. (Japan)

It has been thought that there is no need to develop IR ultra-high-speed video cameras, since movement of heat is slower than motions. However, most of targets of ultra-high-speed video cameras operating at more than 1 Mfps, such as combustion, crack propagation, collision, laser plasma, discharge, a tire under a sudden brake and an air bag, generate sudden heat. Researchers in these fields require tools to measure the motion and the heat simultaneously.

Ultra-high frame rate imaging is achieved by an in-situ storage image sensor. Each pixel of the sensor is equipped with multiple memory elements to record a series of image signals simultaneously at all pixels. Image signals stored in each pixel are read out after an image capturing operation. In 2002, we developed an in-situ storage image sensor operating at 1 Mfps. However, the fill factor of the sensor was only 15% due to a light shield covering the wide in-situ storage area. Therefore, in 2011, we developed a backside illuminated in-situ storage image sensor to increase the sensitivity with 100% fill factor and a very high quantum efficiency. The sensor also achieved a much higher frame rate,16.7 Mfps, thanks to the wiring on the front side with more freedom.

This paper proposes development of an ultra-fast IR image sensor in combination of advanced nano-technology for IR imaging and the BSI in-situ storage image sensor technology, and discuss the relating fundamental issues

9555-26, Session 6

Infrared detectors based on InAs/GaSb superlattice materials *(Invited Paper)*

Sanjay Krishna, The Univ. of New Mexico (United States)

Heteroengineered structures with unipolar barriers such as nBn, CBIRD, M-structure, N-structure, pBiBn and cascade structures have taken advantage of the unique bandstructure engineering properties of the 6.1A InAs/GaSb/AlSb family. In this talk, I will review some of the approaches that we have developed in our group nBn, pBiBn and interband cascade detectors. The performance characteristics of these detectors will be discussed in detail in the presentation.

9555-42, Session PWed

Tunable sensitivity phase detection of multichannel transmitted-type guided-mode resonance (GMR) sensor

Wen-Kai Kuo, National Formosa Univ. (Taiwan)

We report a multichannel transmitted-type guided-mode resonance (GMR) sensor by utilizing a phase-shift interferometer (PSI) for phase detection with tuning sensitivity. The GMR sensor grating structure was fabricated by nano-imprinting technique and a thin titanium dioxide (TiO2) film was coated onto the grating surface by sputtering process. In our system, a cylindrical lens with focal length of 60 mm to form a V-shaped convergent beam with incident angles ranging from 12 degree to 16 degree. Two liquid-crystal modulators (LCM) able to produce over one wavelength retardation were used to produce five-step phase shift in the PSI system. A low-cost web-camera with 130 Mega pixels was used to capture these phase shift images of the multichannel GMR sensor and then the five-step phase-shift reconstruction algorithm can obtain spatial phase-shift information. Because intensity and phase curves of the transmitted light, the phase detection sensitivity can be tuned by rotating a polarizer in front of the web-camera. Experimental result shows that the detection sensitivity tuning approximately from 10E-5 to 10E-7 RIU can be obtained in our system. In conclusion, this tunable sensitivity phase detection functions can provide

a more flexible GMR sensor detection method. Moreover, the multichannel scheme can provide low-cost and high throughput detection.

Ellipsoid type microchannel plate photomultiplier tube for neutrino center detector

Shulin Liu, Baojun Yan, Institute of High Energy Physics (China)

In order to determine neutrino mass hierarchy and precisely measure oscillation parameters, Chinese scientists will establish super large neutrino experimental station in Jiangmen city, Guangdong province. The central detector in the experimental station needs 18000 surround 20" photomultiplier tubes (PMTs) with high detection efficiency. In order to develop and implement mass production of the large size PMTs, project group use the ellipsoid type high borosilicate glass as vacuum bulbs which were smelted and blown with low background materials and adopt gradual transition of glass section to achieve Kovar metal sealing. Choose the bialkali photocathode which is easy to make and its spectral range is the best matching with emission spectra of liquid scintillator. By optimizing the process, a kind of new photocathode is fabricated which has high quantum efficiency, low noise and good uniformity. Microchannel plate (MCP) electron multiplier is made of two MCPs which have high open area ratio and high gain. By adjusting the two pieces of MCP position and the corresponding gap voltage, the overall gain of MCPs is about 107 with good single photoelectron peak to valley ratio. The measured signal quality is good by excellent designing of the anode and the signal lead wire. At current process, the performance of ellipsoid type 20" MCP-PMT are quantum efficiency ~30%, collection efficiency more than 80%, photoelectron transit time spread less than 20 ns and the single photoelectron peak to valley ratio greater than 3. Further optimization of MCP-PMTs can meet the needs of Jiangmen Underground Neutrino Observatory (JUNO).

9555-44, Session PWed

Whispering-gallery microresonators and microlasers for nanoscale sensing and beyond

Sahin Kaya Ozdemir, Lan Yang, Washington Univ. in St. Louis (United States)

Optical sensors based on Whispering-Gallery-Mode (WGM) resonators have emerged as front-runners for label-free, ultra-sensitive detection of nanoscale materials and structures due to their superior capability to significantly enhance the interactions of light with the sensing targets. A WGM resonator traps light in circular orbits in a way similar to a whisper, i.e., a sound wave, traveling along a circular wall, an effect found in the whispering gallery of a cathedral dome. The basis for resonator sensors is that the physical associations and interactions of nanomaterials on the surface of a high-Q optical WGM resonator alter the trajectory and lifetime of photons in a way that can be measured and quantified. I will first present the discovery of using ultra-high-Q microresonators for ultra-sensitive self-referencing detection and sizing of single virion, dielectric and metallic nanoparticles. I will introduce sol-gel process as a convenient and efficient method to incorporate optical gain dopants into silica resonators, providing a route to achieve arrays of microlasers on silicon wafer with emission spectral windows from visible to infrared. Then I will discuss using optical gains in a microlaser to improve the detection limit beyond the reach of a passive microresonator. These recent advancements in WGM microresonators will enable a new class of ultra-sensitive and low-power sensors for investigating the properties and kinetic behaviors of nanomaterials, nanostructures, and nanoscale phenomena. In the end, I will discuss exploration of nanoparticles as nanocouplers introducing a new channel to harvest light from free space into high-Q WGM resonators.

9555-45, Session PWed

Modeling and analysis of hybrid pixel detector deficiencies for scientific applications

Farah Fahim, Hooman Mohseni, Northwestern Univ. (United States); Grzegorz Deptuch, Fermi National Accelerator Lab. (United States); James R. Hoff, Fermi National Accelerator Lab. (United States)

Semiconductor hybrid pixel detectors often consist of a pixellated sensor layer bump bonded to a matching pixelated readout integrated circuit (ROIC). The sensor can range from high resistivity Si to III-V materials, whereas a Si CMOS process is typically used to manufacture the ROIC. Independent, device physics and electronic design automation (EDA) tools are used to determine sensor characteristics and verify functional performance of ROICs respectively with significantly different solvers. Some physics solvers provide the capability of transferring data to the EDA tool. However, single pixel transient simulations are either not feasible due to convergence difficulties or are prohibitively long. A simplified sensor model, which includes a current pulse in parallel with detector equivalent capacitor, is often used; even then, spice type top-level (entire array) simulations range from days to weeks.

In order to analyze detector deficiencies for a particular scientific application, accurately defined transient behavioral models of all the functional blocks is required. Furthermore, various simulations, such as transient, noise, Monte Carlo, inter-pixel effects, etc. of the entire array need to be performed, within a reasonable time frame without trading off accuracy. This work uses, Cadence Wreal, a mathematical real number modeling language, to model the sensor and the analog front-end of the pixel as complex mathematical functions. Parasitically aware digital timing is extracted in a standard delay format (sdf) from the pixel digital back-end layout as well as the periphery of the ROIC. For any given input, detector level worst-case and best-case simulations are performed using the Cadence Incisive environment to determine the output. Each top-level transient simulation takes no more than 10-15 minutes. The impact of changing key parameters such as sensor poissonian shot noise, analog front-end bandwidth, jitter due to clock distribution etc. can be accurately analyzed to determine ROIC architectural viability and bottlenecks. Hence the impact of the detector parameters on the scientific application can be studied.

9555-27, Session 7

High grain, low noise organic and nanoelectronic photodetectors *(Invited Paper)*

Jinsong Huang, Univ. of Nebraska-Lincoln (United States)

The dramatically reduction of cost of photodetectors without comprising their performance will enable new applications in many fields. In this talk, I will brief our progress in the development of sensitive photodetectors/ photon counters using low-cost solution processable organic and nano-electronic materials. Four types of device structures will be compared in terms of device gain, noise, sensitivity, response speed and linear dynamic range: 1) traditional diode structure, 2) a structure combine the photodiode and photoconductor through the interface trap triggered secondary charge injection, 3) an organic phototransistor that has combined photoconductive gain and photovoltaic gain, and 4) quantum dots modulated transistor channel conductance. Broad response spectrum from UV to NIR will be demonstrated, and active material limited performance will be discussed.

Solution-Processed Nanoparticle Super-Float-Gated Organic Field-Effect Transistor as Un-cooled Ultraviolet and Infrared Photon Counter

Dielectrophoresis based integration of nanostructures and their sensorial application

Christian Leiterer, Macquarie Univ. (Australia); Gerald Brönstrup, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany); Steffen Berg, Norbert Jahr, Institut für Photonische Technologien eV (Germany); Wolfgang Fritzsche, Leibniz-Institut für Photonische Technologien e.V. (Germany)

This presented work deals with utilization of bottom-up nanostructures in the field of optical basic research, optoelectronic and chemoresistive sensing and their microintegration using AC electrical fields. It focuses on three types of nanostructured materials in particular: DNA/DNA-superstructures, gold nanoparticle and semiconducting nanowire e.g. silicon, gallium arsenide, zinc oxide.

The focus of DNA micro integration lies hereby in determining conditions allowing the handling of single DNA molecules on a microelectrode substrate in a stretched conformation, which enables subsequent investigation and experimenting on single DNA molecules in an organized and ordered fashion. The micro integration based on dielectrophoresis of gold nanoparticles and silicon nanowires focuses on applying contact to these nanostructures in order to use them as optoelectronic or chemo resistive sensors. In order to achieve this, a micro integration process was developed to apply contact to silicon nanowires and gold nanoparticles as basis for their sensorial application. The contacted nanostructures were characterized electrically to optimize the integration procedure to acquire best possible sensing capabilities. Silicon nanowires were demonstrated to work as wavelength sensitive optical sensors and gold nanoparticle as chemo resistive sensor.

9555-29, Session 7

Spectrometer with nanophotonic structure based on compressive sensing

Zhu Wang, Zongfu Yu, Univ. of Wisconsin-Madison (United States)

This talk will introduce a new method of spectral analysis based on compressive sensing, which is based on nanophotonic structures and thus has the potential to achieve high resolution in a compact device size. This method will solve the common problems that exist in traditional spectrometers--bulky and expensive. Also the complex interferences in nanostructures will offer diverse spectral features suitable for compressive sensing.

9555-30, Session 7

Localised surface plasmon fiber device coated with carbon nanotubes for the specific detection of CO2

Thomas Allsop, Raz Arif, Aston Univ. (United Kingdom); Ron Neal, Plymouth Univ. (United Kingdom); Kyriacos Kalli, Cyprus Univ. of Technology (Cyprus); Vojta Kundrat, Aleksey G. Rozhin, Aston Univ. (United Kingdom); Philip F. Culverhouse, Plymouth Univ. (United Kingdom); David J. Webb, Aston Univ. (United Kingdom)

We explored the potential of a carbon nanotube (CNTs) coating working in conjunction with a recently developed localised surface plasmon (LSP) device (based upon a nanostructured thin film/array of nano-wires of platinum) with ultra-high sensitivity to changes in the surrounding indices. The uncoated LSP sensor's transmission resonances exhibited a refractive index sensitivity of dl/dn ~ -6200nm/RIU and dI/dn ~5900dB/RIU, which is the highest reported spectral sensitivity of a fiber optic sensor to bulk index changes within the gas regime. The complete device provides the first demonstration of chemically specific gas sensing capabilities of CNTs utilising their optical characteristics. This is proven by investigating the spectral response of the sensor before and after the adhesion of CNTs to alkane gases along with carbon dioxide. The device shows a distinctive spectral response in the presence of gaseous CO2 over and above what is expected from general changes in the bulk refractive index. This fiber device yielded a limit of detection of 150ppm for CO2 at a pressure of one atmosphere. Additionally the adhered CNTs actually reduce sensitivity of the device to changes in bulk refractive index of the surrounding medium. The polarisation properties of the LSP sensor resonances are also investigated and it is shown that there is a reduction in the overall azimuthal polarisation after the CNTs are applied. These optical devices offer a way of exploiting optically the chemical selectivity of carbon nanotubes, thus providing the potential for real-world applications in gas sensing in many inflammable and explosive environments.

9555-31, Session 7

A novel sensing and tracing technology based on the hollow-core plastic optical fiber and cone-shape optical coupler in a sun-lighting system

Lingyu Zhang, Deming Liu, Xiaolei Li, Huazhong Univ. of Science and Technology (China)

A novel sensing and tracing technology used for the sun-lighting system is reported in this paper. The system is composed of an azimuth angle sensor, an optical fiber, a sunlight coupling unit, and a sunlight tracing control unit. A hollow-core plastic fiber is designed and fabricated and used to receive and transmit the sunlight. A cone-shape optical coupler is designed and used to trap in more sunlight. Compare with the traditional the traditional sensing and tracing technology, both of the receive angle of the optical fiber and the coupling efficiency of the sunlight to the optical fiber are substantially increased, and therefore the requirement for the sensing and tracing control is reduced. Of course the cost of the optical fiber sun-lighting system is also reduce. This new sensing and tracing technology has been used in an optical fiber sun-lighting system, the sunlight could be transmitted a length of 50m to 100m. The application of this optical fiber sun-lighting in an underground garage would be introduced.

9555-32, Session 8

Colloidal semiconductor nanocrystals for biosensing and optoelectronic applications *(Invited Paper)*

Richard D. Schaller, Argonne National Lab. (United States) and Northwestern Univ. (United States)

Colloidally synthesized, quantum-confined semiconductor nanocrystals offer size-tunable energy gaps, large photoluminescence quantum efficiencies at room temperature, scalable synthesis, and low cost solution processing. Owing to these characteristics, significant interest exists in the development of these materials for use in optoelectronic and sensing applications. Despite high room temperature photoluminescence quantum yields of nanocrystals that in some cases can approach unity, many devices such as displays, lighting, and optical amplifiers experience elevated temperatures during operation. For three semiconductor compositions (cadmium selenide, indium phosphide, and silicon), we utilize static and time-resolved optical characterizations to improve understanding of carrier dynamics under operational conditions. Specifically, we measure quantum yield vs elevated temperature, reveal reversible as well as irreversible exciton quenching pathways, and investigate the role of surface termination on exciton integrity with temperature. This work points to strategies to improve upon the performance of these materials in high temperature applications. We have also made use of these materials in biological sensing applications where we exploit the large absorption cross-sections and high optical stability of some nanocrystals compositions. Using these materials, we report a selective, stable, fast and sensitive all-optical pathogen detection assay.

9555-33, Session 8

Development of optical nanosensor for intracellular pH measurement and imaging

Aleksandar Secenji, Barbara Horváth, Univ. of Pécs (Hungary)

The living cells are dynamic continuously changing systems. To fully understand their working mechanisms, there is a need for real time monitoring of most important parameters. Real time measurement of pH can provide detailed information of H+ transport, H+ consuming and producing reactions, and buffering. There are several techniques for intracellular pH monitoring like NMR imaging or confocal scanning microscopy. These techniques are related to expensive equipment, and in some cases to time-consuming procedures.

A simple fluorescent microscope equipped with RGB camera and use of pH sensitive fluorescent dye is an alternative for real time pH imaging. Unfortunately the free dyes interact with cell components and they are toxic in most of the cases. In the recent times nanoparticle based optical nanosensors are used due to their many advantages instead of dyes.

The main aim of our work is to develop an optical nanosensor, which is suitable for intracellular pH imaging with RGB camera. For this reason a core-shell type of nanosensor have been synthesized. The core of the nanoparticle contains a reference dye, octaethylporphyrin (OEP) (?exc= 400 nm, ?em=620 nm) entrapped in modified Stöber silica, made of phenyltriethoxysilane. The shell synthesis was made with pH sensitive N-allyl-4-isopropylpiperazine-1,8-naphtalamide (AiPPN) (?exc= 400 nm, ?em=527 nm). OEP emission is detected with the red channel of RGB camera and the AiPPN with green channel. The surface modification was performed with aminopropyltriethoxysilane and aminobuthyl[3-(triethoxysilyl)propyl]urea to provide a positively charged particles. The particles had a narrow size distribution, main diameter was 140 nm.

In the future we will test our optical pH sensor in live cells.

9555-34, Session 8

Fresnel-zones-patterned nanoparticles as fluorophore in biological sensing and imaging

Lujiang Qian, Yu Zhou, Qingfeng Zhang, Rui Wang, Yifan Chen, South Univ. of Science and Technology of China (China)

This paper proposes a new approach of implementing Fresnel-zones-patterned nanoparticles (FZPN) as the fluorophore to enhance the fluorescence intensity in biological sensing and imaging applications. The FZPN used to label a biological object-of-interest (e.g., tissue, cell) can re-emit light upon light excitation. Biocompatible nanoparticles bonded to the object-of-interest are arranged according to the amplitude transmittance function of a Fresnel zone plate (ZP). Such structures are expected to increase significantly the penetration depth of fluorescence microscopy.

Firstly, given the wavelength of fluorescence and the desired focal length of a virtual ZP where the nanoparticles are to be placed, the circular diffraction grating with radially varying line period on the ZP can be calculated.

Subsequently, a number of nanoparticles are positioned at locations where the amplitude transmittance of the virtual ZP is equal to 1 (i.e., transparent). On the other hand, the locations where the amplitude transmittance is equal to 0 (i.e., opaque) remain empty. Each nanoparticle can be treated as a point source as its size is much smaller than the wavelength of the impinging light. As a result, the backscatter radiation pattern of a nanoparticle in the far field is similar to the pattern of a dipole. Furthermore, the mean free path of photon in biological tissues is around 100 μm, which is comparable to the size of the virtual ZP. Thus, it can be assumed that the backscatter lighwaves of all nanoparticles are correlated. When a coherent light impinges on the FZPN, the re-emitted lightwaves will interfere constructively and form a bright spot at the desired focus of the virtual ZP. This phenomenon is due to the useful analogy between the FZPN and the classical ZP using diffraction to focus light, both of which follow the Huygens-Fresnel principle. By focusing microscope objective lens on the bright spot, one could sense and image the object-of-interest with a high sensitivity. In the full-length paper, the influence of the ZP size on the scattering field will be analyzed. Furthermore, the effect of the variation of the opacity (e.g., binary or sinusoidal ZP) will be discussed.

9555-35, Session 9

With electroluminescence microcopy towards more reliable AlGaN/GaN transistors *(Invited Paper)*

Martina Baeumler, Michael Dammann, Matthias Wespel, Helmer Konstanzer, Vladimir M. Polyakov, Stefan Müller, Stephan Maroldt, Wolfgang Bronner, Peter Brückner, Fouad Benkhelifa, Patrick Waltereit, Rüdiger Quay, Michael Mikulla, Joachim Wagner, Oliver Ambacher, Fraunhofer-Institut für Angewandte Festkörperphysik (Germany)

Long-term stability and reliability of AlGaN/GaN high electron mobility transistors (HEMT) devices can be validated by various stress tests which allow studying the physical mechanisms responsible for degradation. Electroluminescence microscopy (ELM) allows to monitor microscopic changes in the device related to the degradation process. As the electroluminescence (EL) intensity is related to the kinetic energy and density of the channel electrons accelerated in the electric field, both local current and electric field changes can result in an increase or decrease of the EL intensity. Although the spatial resolution is limited to a few microns, ELM benefits from the fact that submicron imperfections at the Schottky interface of the gate electrode result in strong local current variations. To distinguish between current and field effects, additional techniques as infrared thermography have been applied. The electric field distribution in source drain direction Fx peaks at the drain side edge of the gate foot and the field plates. Fx is strongly dependent on the gate design and

the passivation /semiconductor interface trap density. The latter can be extracted by comparing the EL intensity profiles in source drain direction, recorded at different drain source voltages, to simulated electric field profiles. The results will be compared to CV measurements. ELM has been used to selectively identify suitable positions for further failure analysis of focused ion beam prepared cross sections by scanning and transmission electron microscopy. Process induced imperfections as well as damage at the Schottky interface after stress have been localized.

9555-36, Session 9

Micro-nanofluidic biochip and detector for fast clinical diagnostic at aM nucleic acid concentration

Guoliang Huang, Tsinghua Univ. (China); Qin Huang, National Engineering Research Ctr. for Beijing Biochip Technology (China)

Molecular diagnostics is one of the most important tools currently in use for clinical pathogen detection due to its high sensitivity and specificity. In this paper, a sensitive DNA isothermal amplification method for the detection of DNA at aM (10-18 M) concentrations for fast clinical diagnostic was developed using a PC micro-nanofluidic chip. One important aspect of the microfluidic chip with a surface inert to bio-molecules was the surface contact angle increasing from 71.3° on original surface to 103° on the inert processed surface. A portable confocal optical fluorescence detector was specifically developed for the micro-nanofluidic chip that was capable of highly sensitive real-time detection of amplified products for sequence-specific molecular identification near the optical diffraction limit with low background. The isothermal nucleic acid amplification in the micro-nanofluidic chip could be performed at a minimum DNA template concentration of 1.3 aM, and a detection limit of less than 5 copies of genomic DNA was obtained. We used the whole system and method for the molecular diagnostics of four clinical pathogens with nucleic acid extracted from stool samples, and the result showed that the response time was clearly reduced to 45 minutes for multi-target parallel detection. This novel micro-nanoliter fluidic detection system and method could be used to develop a Micro Total Analysis System as a clinically relevant pathogen molecular diagnostic method via the amplification of targets, and with potential applications in nanobiotechnology, nanomedicine, and clinical molecular diagnostics.

9555-37, Session 9

Polarization-based optical fiber sensor of steel corrosion

Wenbin Hu, Cheng Zhu, Xing Zheng, Min Gao, Donglai Guo, Wuhan Univ. of Technology (China); Wei Chen, School of Materials Science and Engineering, Wuhan Univ. of Technology (China)

A polarizer formed by a metal-coated D-shape optical fiber, has been demonstrated since 1980. By employing this micro-structure, a high extinction ratio of odd and even fundamental mode can be achieved. A novel sensor form by an iron-coated optical fiber polarizer is presented for corrosion real-time monitoring.

The sensor is fabricated by sputtering an iron film with a thickness of 10 - 50 nm on a side-polished single mode fiber. The birefringence characteristic of the newly-formed metal film is varying during the corrosion of the Fe(C) film, and is eliminated as the occurrence of the film spalling at a severe corrosion stage. Two corrosion–dependent optical characteristics (the extinction ratio and optical power loss) contribute to probe the corrosion status. If installed in steel structures, the status of iron-film corrosion indicates the status of steel corrosion.

An experiment is conducted by immersing the sensors in an accelerated corrosive environment with a NaCl solution (3.5 wt%). The experimental results show that the sensors can perform as corrosion indicators of the initial corrosion occurred on the coated film. The extinction ratio varies significantly while the well-crystallize iron is corroded. The optical power loss depends on the spalling of the coated film. By establishing the relation between the corrosion–dependent optical characteristics and the corrosive status, the initial corrosion can be traced and evaluated.

9555-38, Session 9

An optical fiber lateral stress sensor based on a Sagnac interferometer structure

Shun Wang, Ping Lu, Li Liu, Hao Liao, Jiangshan Zhang, Deming Liu, Xinyue Jiang, Huazhong Univ. of Science and Technology (China)

In this article, we propose and demonstrate an optical fiber lateral stress sensor based on a Sagnac interferometer (SI). The SI structure consists of an optical fiber coupler with splitting ratio about 50:50. By inserting a section of polarization-maintaining photonic crystal fiber (PM-PCF) in the sensing loop of the SI structure, a inline interference between the two orthogonal polarization modes (Mx and My) of the PM-PCF is realized. Theoretical study shows that the reflection spectrum of the SI is depended on not only the refractive index difference of the two orthogonal polarization modes (Mx and My) but also the length of the PM-PCF (L). The chosen PM-PCF, whose cross section contains two big air holes side by side which are surrounded by many small air holes. Due to the large asymmetry of the two perpendicular axes x and y, the refractive index difference of the two orthogonal polarization modes, Mx and My, will be very large. Thus resulting in great changes in the wavelength drift induced by the lateral stress applied on the fiber side which changes the refractive index difference of the two orthogonal polarization modes, Mx and My. By suitably selecting the length of PM-PCF and keeping a good state of polarization in the SI loop, a highly sensitive optical fiber lateral stress sensor can be achieved. Experimental results show that the sensor achieves the highest sensitivity of lateral stress strain 1.28 nm/kPa, which demonstrating the ability for lateral stress measurement with high accuracy.

9555-39, Session 9

Spectropolarimetry screening of cytological smears from cervical on the presence of HPV

Sergey B. Yermolenko, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine); Alexander P. Peresunko, Julia G. Karpenko, Bukovinian State Medical Univ. (Ukraine)

Diagnosis of cervical cancer is an actual issue in oncology and gynecology that needs new, innovative approaches. The main concept of the etipathogenesis of cervical cancer is recognized as viral hypothesis. The human papilloma virus (HPV) occupies a central place in it which has the greatest potential for oncology and is a major factor exogenous factor in cervical carcinogenesis.

Pathogenetic cytological feature of the infection of cervical epithelium with human papilloma virus is the presence of koylotsity or “air” cells (balloon-cells) with a halo around the nucleus. These cells are intermediate or surface layer of keratinized squamous epithelium with characteristic large transparent, clearly delineated perinuclear area. So, koylotsitoz can be considered as a marker of human papilloma virus infection.

Assistance in objectification and improving of the accuracy of diagnosis of cervical pathology can provide non-contact optical methods, including a spectro- polarimetry one.

In the method of spectropolarimetry screening of cytological smears of the cervix for the presence of human papillomavirus (HPV) is offered the following. Native cytological smears of the cervix are irradiated in a wide spectral range and examined changes in polarization parameters and modeling anisotropic structure of cervix values of linear dichroism and its spectral dependence in the spectral range of ? = 330 - 750 nm, with a

maximum value at koylotsity reaction in cytological smears in area of ? = 395-415 nm.

9555-46, Session 9

Interaction of two nano particle plasmons for sensor application

Naresh C. Das, U.S. Army Research Lab. (United States)

By combining plasmon wave of two different nano particles, from aluminum (Al) and gold (Au) nano-particles, we observed plasmon resonance peak at two different wavelengths. We used electron beam lithography along with angle metal evaporation techniques to deposit metal particle plasmon layer with nanometer-scale separation. The coupled plasmon layer has two peaks at 525 and 650 nm, which are different from the constituent metal plasmon layers (Al and Au, respectively).

The area of creating artificial molecules by combining more than one nanoparticle (NP) has received significant interest recently. Similar to the way atoms join together in different combination to form all the substances in the universe, we too can make groups of new materials by combining artificial atoms or NPs1. The strong interaction of plasmon waves from different NPs can render many applications possible, including sensors2, and enhanced electro catalytic reactions3. We used an electron beam lithography process along with angle evaporation techniques to achieve nanometer-scale metallic particles with very close proximity. Gold (Au) and aluminum (Al) metal particles were chosen for the plasmonic coupling experiment because of their distinguished plasmonic behavior with peak wavelengths separated by few 100 nm. We used a variable angle ellipsometer model M-200 from J. Wolman and Company to measure change in phase difference, ?, due to plasmonic NPs. The peak resonance wavelength for different plasmonic material was determined.

Two metallic NPs were deposited using different angles of evaporation of substrate with respect to metal crucible. We observed two peaks: one narrow plasmon peak at 525 nm showing a contribution from the Al NPs and another broad plasmon peak at 650 nm due to the Au NPs.

We have shown two-color plasmon absorption peaks due to Al and Au NPs with a nanometer-scale separation between them. The position and peak height of the coupled plasmon curves are different from the individual peaks of Al and Au NPs, respectively.

Technical requirements, manufacturing processes, and cost efficiency for transparent electrodes based on silver nanowires and carbon nanotubes

Thomas Ackermann, Univ. Stuttgart (Germany) and Fraunhofer-Institut für Produktionstechnik und Automatisierung (Germany); Serhat Sahakalkan, Ivica Kolaric, Fraunhofer-Institut für Produktionstechnik und Automatisierung (Germany); Engelbert Westkaemper, Univ. Stuttgart (Germany); Siegmar Roth, Sineurop Nanotech GmbH (Germany)

As product life cycles of displays become shorter the electronic industry is seeking for the usage of alternative materials to conventional indium tin oxide (ITO) as a material for transparent electrodes. Several materials such as nano carbon or silver nanowires have been discussed in literature. However a commercial replacement of ITO has not set on yet since each of the alternative materials perform well in a certain property but underperforms in another compared to ITO. We will present our recent results on transparent conductive films made of co-percolating silver nanowires and carbon nanotubes. This combination leads to superior optoelectrical performance of the ultra-transparent electrodes. We will outline the huge potential of electrical co-percolation of rodlike conductors based on theoretical and experimental data.

Furthermore we will report on scalable manufacturing processes of these films on commercial smart phone cover glasses and flexible foils for roll-to-roll manufacturing. The liquid film coating technique is analyzed with regard to technical suitability and cost efficiency. We were able to produce transparent conductive films with material costs less than three US Dollars per square meter. The ultra-transparent electrodes exhibit optical transmission of 98 % with sheet resistance of 60 Ohm/sq. The optical haze, which is usually a crucial drawback of silver nanowire films, is within the industrial tolerance of today‘s quality standards.

Transparent conductive films are an important research topic. Our contribution will discuss fundamental principles such as electrical percolation theory as well the industrial feasibility of ITO replacement.

9556-3, Session 1

Fast water vapor transmission rate measurement system by graphene-based device

Yung-Hsiang Hsieh, Cheng-Chung Lee, Chien-Cheng Kuo, National Central Univ. (Taiwan)

Flexible organic light emitting diode display is candidate for next generation display device but the water vapor and oxygen is easy to damage the organic element. Therefore, the organic element need barrier film to protect it. Water vapor transmission rate (WVTR, unit: g/m2/day)is used to evaluate the quality for encapsulation of organic element, which is estimated for encapsulating organic element is 10-6 g/m2/day at least in the flexible organic light emitting diode . There are two main ways to measure the WVTR for encapsulation of organic element but they had some disadvantage like that measure for long time or non-reusable. In recent years, graphene is found to be a good gas sensor. Graphene has fast response time and sensitive characteristics. The charge transfer between the molecules and the graphene surface when the molecules absorb on graphene in seconds. In this study, we made a fast WVTR measurement system by graphene-based device. The graphene-based device is prepared by transferred the graphene which is grown by chemical vapor deposition (CVD) on glass subtrate first and then deposited the metal electrode with mask. The source voltage of graphene-based device kept 1V. Calculating the change of device resistance due to charge transfer between the molecules and the graphene surface that could be conversion to how many water molecules absorb on graphene. Using physically plausible model to calculate the adsorption/desorption of the molecules on the graphene surface.

9556-4, Session 1

Invoking the frequency dependence in square modulated light intensity techniques for the measurement of electron time constants in dye-sensitized solar cells

Hamid M. Ghaithan, Saif M. Qaid, King Saud Univ. (Saudi Arabia); Mahmoud Hezam, King Saud Univ. (Saudi Arabia) and Ecole Polytechnique Fédérale de Lausanne (Switzerland); Muhemmad B. Siddique, Univ. of Management and Technology (Pakistan) and Univ. of Management and Technology (Pakistan); Idriss M. Bedja, Abdullah S. Aldwayyana, King Saud Univ. (Saudi Arabia)

Dye-sensitized solar cells (DSSCs) have been considered as one of the most promising new generation solar cells. Enormous research efforts have been invested to improve the efficiency of solar energy conversion which is determined by the light harvesting efficiency, electron injection efficiency and undesirable electron lifetime. A simple, cheap and trustable laser-induced photovoltage and photocurrent decay (LIPVCD) technique is adopted in this work in order to determine the electron lifetime (?e) and electron transport (?tr) in DSSCs. In LIPVCD technique, DSSC is illuminated by a small squared intensity-modulated laser beam. Time-based response of the DSSC is recorded using a transient digitized oscilloscope for further analysis. Sensitization dye used studied DSSCs has an absorption wavelength peak at 532 nm which is obtainable using a proper laser diode. Present LIPVCD technique, using single wavelength, is tested with standard solar cells to give comparable results with other standard techniques (i.e. IMVS, IMPS and OCVD).

Measurements are performed at open-circuit and short-circuit for a variety of DSSCs, so that the photovoltage and photocurrent decay data are acquired and interpreted in the time domain. Studied DSSCs are fabricated with various electrodes include TiO2 nanoparticles and ZnO nanowire based DSSC. It has found that ?tr is much faster than ?e for all tested cells.

9556-5, Session 1

Optical and structural properties of co-sputtered Cu-Si-O and Cu-Ge-O thin films

Lirong Sun, Air Force Research Lab. (United States) and General Dynamics Information Technology (United States); Neil R. Murphy, John G. Jones, Air Force Research Lab. (United States); John T. Grant, Air Force Research Lab. (United States) and Univ. of Dayton Research Institute (United States)

The co-sputtered Cu-Si-O and Cu-Ge-O thin films were prepared using reactive DC, pulse DC and modulated pulse power magnetron sputtering (MPPMS) on two separate Cu and Si or Cu and Ge targets simultaneously. The powers on each target and Oxygen/Argon flow ratio f(O2) were varied to have different stoichiometies determined by XPS. The film thickness, refractive index n and extinction coefficient k were extracted from in situ ellipsometry and the reactive plasma discharge was monitored by optical

emission spectroscopy in real time during film growth. The grazing incident x-ray diffraction measurements reveal that the films deposited at low f(O2) have the nanocrystalline structure of cuprous Cu2O with diffraction peaks of (111) and (200). The films deposited at high f(O2) (≥ 1) have cupric oxide CuO phase. The optical constant n and k, film density and band gap of the co-sputtered film were investigated and determined by in situ ellipsometry, X-ray reflectivity and UV-Vis-NIR spectroscopy. Their structural, chemical and optical properties are able to be tuned by incorporating Cu2O, CuO and the mixtures of them into Silicon oxide or Germanium oxide matrix with varying target powers and oxygen/Argon ratio for applications in optical coatings and optical filters.

9556-6, Session 2

Ultra-slim coherent backlight unit for mobile holographic display *(Invited Paper)*

Chil-Sung Choi, SAMSUNG Electronics Co., Ltd. (Korea, Republic of); Alexander V. Morozov, Alexander Koshelev, Sergey Dubynin, German Dubinin, SAMSUNG Advanced Institute of Technology (Russian Federation); Sung-Hoon Lee, Jae-Seung Chung, Geeyoung Sung, Jungkwuen An, Hoon Song, Juwon Seo, Hojung Kim, Wontaek Seo, Samsung Advanced Institute of Technology (Korea, Republic of); Andrey Putilin, P.N. Lebedev Physical Institute (Russian Federation); Sergey Kopenkin, Yuriy Borodin, P.N. Lebedev Physical Institute (Russian Federation); Sun Il Kim, Hong-Seok Lee, U-in Chung, Sungwoo Hwang, Samsung Advanced Institute of Technology (Korea, Republic of)

The proposed paper relates to illumination devices for holographic display using coherent radiation from laser source. These backlighting systems are known for providing uniform and effective illumination in visualization devices. Backlight units using lens optics, which is bulky, have been implemented to a holographic display, but very few attempts have been made in minimizing the size of backlight units that can be used in the flat panel holographic display. Thickness is one of the key parameters in modern backlighting systems that need to be minimized to reduce the overall size of the display devices.

We propose slim coherent backlight unit for a mobile holographic display. This backlight unit consists of glass substrate for waveguide and two surface gratings produced by two-beam interference. Two surface gratings are used to solve chromatism, whereas the input grating has chromatic aberrations. Red, green, and blue components propagate in waveguide separately with different angles, which can be compensated by only one output grating for each channel.

The area of backlight illumination is 150 by 85mm (5.5 inch), and the thickness is 0.7mm which is thin compared to other conventional coherent backlight units. This backlight unit exhibits a total efficiency of 0.1%, preserving the collimation and a uniformity of 80% over the whole area. Although the efficiency of backlight unit is very low, brightness of backlight is sufficient when viewing window concept is applied.

9556-7, Session 2

Scalable nanostructuring on polymer by a SiC stamp: optical and wetting effects

Aikaterini Argyraki, Weifang Lu, Paul M. Petersen, Haiyan Ou, DTU Fotonik (Denmark)

A method for fabricating scalable antireflective nanostructures on polymer surfaces (polycarbonate) is demonstrated. The transition from small scale fabrication of nanostructures to a scalable replication technique can be quite challenging. Here, an area per print corresponding to a 2-inch-wafer, is presented. The initial nanopatterning is performed on SiC in a 2-step process. Depending on the nanostructures the transmission of the SiC surface can be increased or suppressed (average height of nanostructures ~300nm and ~600nm, respectively) while the reflectance is decreased, when compared to a bare surface. The reflectance of SiC can be suppressed down to 0.5% when the ~600nm nanostructures are applied on the surface (bare surface reflectance 25%). It is observed that the texture of the green SiC colour is changed when the different nanostructures are apparent.

The ~600nm SiC nanostructures are replicated on polymer through a process flow that involves hot embossing and galvanization. The resulted polymer structures have similar average height and exhibit more rounded edges than the initial SiC nanostructures. The polymer surface becomes antireflective and hydrophobic after nanostructuring. The contact angle changes from 68 (bare) to 123 (nanostructured) degrees. The optical effect on the polymer surface can be maximized by applying a thin Al layer coating on the nanostructures (bare polymer reflectance 11%, nanostructured polymer reflectance 5%, Al coated nanostructured polymer reflectance 3%).

The optical measurements were performed with an integrating sphere (8/8deg incident angle) and a spectrometer (QE 65000, Ocean Optics). The nanostructures applied were characterized with scanning electron microscopy (SEM, Zeiss Supra VP40).

9556-8, Session 2

Re-usable metal-metal stamping for three-dimensional active metamaterial fabrication

Robert L. Brown, Alan Selewa, Sung Jun Jang, Alireza Bonakdar, Mohsen Rezaei, Hooman Mohseni, Northwestern Univ. (United States)

Metamaterials are man-made materials composed of sub-wavelength components that display properties not found in nature such as negative refraction, superlensing, cloaking, polarization control, and wavelength filtering. There is much interest in 3D-metamaterials, including stacks of 2D metamaterials like metasurfaces and Frequency Selective Surfaces, which can increase the optical path and interaction of light and metamaterial significantly. Recent progress in metamaterial stacks involves methods that either rely on time-consuming and expensive techniques or fabrication that has little process flexibility. Furthermore, the benefits of having multiple stacks can be negated by the increase in interaction length with lossy metal components. We propose a method of additive metal-metal welding using a conformal stamp that will allow the transfer of multiple stacks of metal, semiconductors, and dielectrics to fabricate stacks of 3D optically active metamaterials. This method offers three advantages over standard methods and materials: 1) The ability to re-use stamps eliminates the need for optical or electron-beam patterning of each layer. 2) Because the stamp is conformal, layers do not need to be perfectly flat. 3) This process relies on metal-metal fusion and can transfer materials already connected to the metal along with the metal. With the ability to transfer semiconductors comes the opportunity to interact with these materials optically or electrically. This opens the door for loss compensation by the use of gain media, tunability of a semiconductor load, or the taking advantage of non-linear optical processes.

9556-9, Session 2

Nanofabrication of ultra-low reflectivity black silicon surfaces and devices

Victor E. White, Karl Y. Yee, Kunjithapatham Balasubramanian, Pierre M. Echternach, Richard E. Muller, Matthew R. Dickie, Eric Cady, Daniel J. Ryan, Michael Eastwood, Byron E. Van Gorp, Jet Propulsion Lab. (United States); A. J. Eldorado Riggs, Niel Zimmerman, N. Jeremy Kasdin, Princeton Univ. (United States)

Optical devices with features exhibiting ultra low reflectivity on the

order of 10-7 specular reflectance in the visible spectrum are required for coronagraph instruments and some spectrometers employed in space research. Nanofabrication technologies have been developed to produce such devices with various shapes and feature dimensions to meet these requirements. Infrared reflection is also suppressed significantly with chosen wafers and processes. Particularly, devices with very high (>0.9) and very low reflectivity (<10-7) on adjacent areas have been fabricated and characterized. Significantly increased surface area due to the long needle like nano structures also provides some unique applications in other technology areas. We present some of the approaches, challenges and achieved results in producing and characterizing such devices currently employed in laboratory testbeds and instruments.

9556-10, Session 3

Development of 3D photonic crystals using sol-gel process for high power laser applications

Florence Benoit, Bertrand Bertussi, Eva Dieudonné, Nicolas Mallejac, Karine Vallé, Philippe Belleville, Commissariat à l'Énergie Atomique (France); Clément Sanchez, Collège de France (France); Stefan Enoch, Institut Fresnel (France)

Three-dimensional photonic crystals (PCs) are periodic materials with a modulated refractive index on a length scale close to the light wavelength of interest. This optical property allows the preparation of precise optical components like highly reflective mirrors [1].

Moreover, these structured materials are known to have a high laser-induced damage threshold (LIDT) in the sub-nanosecond range [2] compared to multi-layered dielectric mirrors. This property is obtained because only one high LIDT material (silica) is used. The second material used in the layer stack is replaced by air.

In this work, we propose to develop a bottom-up approach based on sol-gel chemistry to prepare 3D PCs. PCs are obtained using the self-assembly of narrow-sized distribution colloidal silica particles.

We will firstly describe the synthesis of narrow-sized distribution colloidal silica particles prepared with a polydispersity index below 1.05 and the Langmuir-Blodgett technique used to deposit the organized single layer of particles onto hydrophilic substrates exhibiting good uniformity at large scale.

Then we will illustrate first results through various characterisations of PC samples made in different conditions (optical measurements, SEM (Scanning Electron Microscopy)).

In order to understand experimental results, we have used a numerical modelling based on an ideal opal network with and without on purpose defect embedding. Thanks to this study, we present the new routes we have investigated in order to realize PC samples with optimized optical properties.

9556-11, Session 3

Enhancement in light emission efficiency of silicon-rich oxide/SiO2 multilayer structures deposited by hydrogen ion-beam assisted sputtering

Sheng Wen Fu, National Cheng Kung Univ. (Taiwan)

Recently, the silicon-rich oxide (SRO)/SiO2 multilayer (ML) structures have drawn a great attention owing to their potential optoelectronic applications, especially for the visible light emitting devices (LED). In this study, we prepared SRO/SiO2 multilayers by hydrogen ion-beam assisted sputtering (HIBAS) with different hydrogen anode voltage for the LED application. The property of the prepared samples was determined by Fourier transform infra-red (FTIR), X-ray photoelectron spectroscopy (XPS), photoluminescence (PL) and electroluminescence (EL) analysis.

Figure 1 shows the PL spectrum measurement of SRO/SiO2 films corresponding to different HIBAS energy by 325 nm and 532 nm excitation wavelength. In the range from 450 nm to 650 nm, it is a blue shift from 535 to 550 nm and the PL peaks intensity decrease corresponding to the HIBAS energy from 0 V to 116 V. In contrast, in the range from 650 nm to 1000 nm, the PL intensity increase significantly when HIBAS energy 70V and 116V treated SRO/SiO2 films compared that by 0 V.

The references showed that the PL band at the range from 450 nm to 650 nm and from 650 nm to 1000 nm have been associated with defect-related effects at the Si nanoclusters/SiO2 matrix interface and quantum confinement effects, respectively [1,2,3]. The 520-550 nm PL band has been commonly attributed to the E' center [O3?Si?] (510-550 nm) as a result of point defect [4]. Therefore, HIBAS could enhance the PL intensity owing to improvement of the Si nanocluster appearence. Furthermore, a red shift of PL in the 780-880 nm with samples treated by 70 V and 116 V is observed, which demonstrate the HIBAS gives more energy to synthesize and increase the nucleation of Si nanoclusters size.

As shown in Figure 2(a), the EL spectra of the devices with three HIBAS energy were measured at the same injection current of 1 A. The peak EL intensity of the device treated with HIBAS 70 V and 116 V is about 3 and 5 times larger than the that by HIBAS 0 V, respectively. It is obvious that the improvement in the EL can be acquired by HIBAS. In addition, the blue shift of the EL peak from 552 nm to 512 nm is apparent with increasing HIBAS energy, which is in good agreement with the PL result. Figure 2(b) shows the integrated EL intensity as function of the injection current by HIBAS devices. Firstly, before the maximum of the EL in all samples, there is a linear relation between the integrated EL intensity and the injection current, which indicated that the light emission is resulted from the recombination of electrons and holes in the SRO/SiO2 films.

One can see that there is a linear relationship between the integrated EL intensity and the electrical input current, implying that the EL is originated from the recombination of the holes and electrons injected from the ITO gate and the Al electrode, respectively. Secondly, the external quantum efficiency (EQE) means the number of photons emitted externally divided number of carriers passing junction, therefore, the slope in figure 2(b) is directly proportional to EQE. The slope of HIBAS of 0 V : 70 V : 116 V is 1 : 3.6 : 7.1, which mean that HIBAS 116 V treatment drastically improve the EQE over 7 times than HIBAS 0 V. Furthermore, there are the maximum of EL intensity on all over the devices and the injection current could be adjust over 2.4 A without EL intensity decay for HIBAS 116 V device.

In conclusion, we approve the HIBAS effectively improve the SRO/SiO2 based LED, where the intensity of EL was 15 times higher than the conventional devices at the same operated power.

9556-12, Session 3

Auger recombination in nanoscale III-Nitride material system

Chee-Keong Tan, Nelson Tansu, Lehigh Univ. (United States)

The development in III-Nitride light emitting devices have been impeded by the efficiency droop issue in which the internal quantum efficiency of the devices reduces when operating at high current density. Recent research on the efficiency droop increasingly identified current injection efficiency quenching and Auger recombination as the important mechanisms in leading to the efficiency droop issue. Recent studies affirmed the important role of Auger recombination process in the InGaN material system, even though the reported theoretical and experimental Auger coefficient values remain in disparity. Most studies in investigating the Auger recombination processes have been focused in the bulk nitride system and the literature of the Auger recombination processes in low-dimensional III-Nitride material system such as InGaN quantum well (QW) is still highly limited. Describing the Auger recombination processes in the nitride-based QW system is thus critical in exploring the underlying fundamental issues in the material

system for future prospective device engineering.

In this work we employed a numerical method to analyze the Auger recombination process in the III-Nitride QW system. The Auger recombination coefficient values for the low-dimensional III-Nitride material systems are investigated for InGaN QW. Specifically, the Auger recombination rates are analyzed as a function of InGaN active layer thickness by incorporating various parameters extracted from experiments. Our finding implies more dominant Auger recombination processes in the InGaN QW system when the active layer thickness reduces. The comparison of Auger recombination rates for InGaN QW material systems with various QW thicknesses will be discussed in details.

9556-13, Session 3

Development, electrical, and optical characterization of nanoscale FDSOI MOSFET devices based on quantum well structure for optical communication between chips and internal blocks

Avi Karsenty, Jerusalem College of Technology (Israel); Avraham Chelly, Bar-Ilan Univ. (Israel); Roi Zolberg, Roi Sabo, Jerusalem College of Technology (Israel)

Highlights

? Scientific background: The long term ongoing scaling of CMOS technology is moving the clock speed of future generations ULSI to the ten GHz frequencies and above. In such frequencies, the signal propagation delay on chip and on the circuit board, as well as signal cross talk, impose severe limitations on system design and performance. The direct solution to this problem is to move to optical signal transmission in the critical paths. Unfortunately the indirect energy band structure of silicon prevents the construction of simple and efficient light emitting devices as in the III-V materials such as GaAs. In recent years there is an ongoing wide research effort to find processes and mechanisms of light emission in silicon in spite of the basic physical limitations. The most promising directions are based on quantum effects in nanoscale silicon structures.

? The need/market (if applicable): The merging of the microelectronics with the communication in general and with optical communication in particular, pushes vigorously the efforts to realize on the same silicon chips both electronic and electro-optic functions. This is further motivated by the limitations of the metal wiring on chip and on the PC board, to transfer the electronic signals in the 10GHz range and above. The indirect band structure of silicon is a basic obstacle to the realization of light emitting devices in this material.

? Existing methods/techniques: The efforts for the development of light emitting devices in silicon concentrated in the last decades on quantum structures which indeed exhibit some photoluminescence in the visible range with efficiencies approaching that of Gallium Arsenide. However there is currently no practical light emitting silicon device either because of lack of efficiency, reproducibility and reliability. In particular most of these devices are not compatible with CMOS technology.

? Problems with existing solutions: As the QW MOSFET processing is compatible with standard CMOS technology, and SOI CMOS on SOI wafers is a commercial process, the expected light emission at preferred wavelengths in correlation with the silicon thickness in the transistor, may lead to the development of modified SOI CMOS technology that will include both standard CMOS transistors for the performance of the electronic functions, and Quantum Well Transistor devices for optical communication.

9556-14, Session 3

PbSe/PbSrSe MQW characteristic temperature relationship with laser cavity length

Majed Khodr, American Univ. of Ras Al Khaimah (United Arab Emirates)

A potential materials system that may play a key role in IR spectroscopy applications is PbSe/Pb 0.934 Sr0.066 Se quantum well structure. In this work, the characteristic temperature (T0) relationship with laser cavity length was studied for this material system at three temperature ranges 77< T<150 K, 150< T<300 K, and 77< T<300 K. It was noticed that T0 is high for short cavity lengths then decreases to an almost constant value after some critical length. The data were best fitted to a second degree polynomials which can be used to determine these critical values. Also, we analyzed the effects of quantum efficiency on the characteristic temperature values. Inclusion of theoretical values for the quantum efficiency due to Auger recombination and leakage current reduces the characteristic temperature T0 in these ranges. It was found that inclusion of the quantum efficiency decreases the characteristic temperature by 60% for a wide range of cavity lengths.

9556-16, Session 4

All-polymer based fabrication process for an all-polymer flexible and parallel optical interconnect

Jilin Yang, Tao Ge, Chris Summitt, Sunglin Wang, Yuzuru Takashima, Thomas D. Milster, College of Optical Sciences, The Univ. of Arizona (United States)

We demonstrate a new all-polymer based fabrication process for an all-polymer flexible and parallel optical interconnect cable having a vertical light coupler, which can not only cut down the cost by eliminating metallization process for alignment but also facilitate both in production and application. Throughout the process we used polyimide as the substrate, coated Epocladd as claddings, then Poly-10 and WPR 5100 were used to fabricate waveguides and 45 degree mirror coupler, respectively. As a key process tool, instead of conventional mask aligner lithography, we applied maskless lithography technology to print both of the waveguides and mirror coupler thereby eliminating the time and cost spent on the production of masks. In addition, precisely aligned mirror coupler to waveguides are achieved by using polymer-based, non-metallic, and transparent alignment marks. Such alignment marks are easy to be detected by camera, when a layer of high reflective material, generally Cr metal, is patterned. However transparent polymer material is used in our process, as alignment marks made of it which are actually buried phase structures would be hardly to be observed by conventional camera. Hence to increase the contrast of the alignment marks, we proposed a feature specific alignment system for which the shape and depth of the alignment marks are optimized for phase-based imaging, such as phase contrast and Schlieren imaging. Our results showed a contrast enhancement of alignment marks image compared to that of a conventional imaging system. At last, through this proposal we fabricated a flexible optical interconnect for testing.

9556-17, Session 4

Tolerance analysis of the pulse signal of a noval lateral deformable optical NEMS grating transducer

Chen Wang, Jian Bai, Zhejiang Univ. (China)

In this paper we discuss a tolerance analysis of the pulse signal of a novel opto-mechanical zeroth-order grating transducer in terms of fabrication, illumination as well as alignment. This device gives out rapid variation of

reflective intensity with the displacement of the nanostructured grating elements and the original sinusoidal signal of the device develops into a new signal form, i.e. pulse signal with the decrease of the air gap between two layers of gratings. As the slop of the pulse signal, namely 2.481%/nm is 8 times higher than that of the original signal form, namely 0.3%/nm, the sensitivity of the structure is improved 8 times higher. Since the special function of the device is originated from its extreme sensitivity to variation of its parameters and the size of the structure is in sub-wavelength dimension, the parameter setting of the device is crucial to its performance and also imposes a high demand on the state-of-art processing technology. Thus, in this paper a tolerance analysis of the device in terms of fabrication, illumination, alignment is discussed in detail to get a better understanding of the tolerance of the pulse signal and a guidance of successful realization of an actual device.

9556-18, Session 4

Design of SiOx slab optical waveguides

Eder Lizarraga, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico); Alicia Oliver, Univ. Nacional Autónoma de México (Mexico); Rafael Salas, Univ. de Technologie Troyes (France); Heriberto Márquez, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico); Veronica Vazquez, CIO (Mexico)

Integrated optics is a growing field looking for materials for building passive and active components preferably based in silicon to be compatible with microelectronic industry. SiOx is a suitable candidate for the development of both kind of components due to the potential of precipitation of silicon nanoparticles, which can lead to active components and being a platform of hybrid photonic-plasmonic devices. High refractive contrast between the substrate (SiO2) and the core (SiOx) may be achieved, leading to strong confinement in the core, allowing submicron sized optical waveguides. The advantages of this submicron waveguides is the enhancement of nonlinear effects waveguide and the possibility of making a denser integrated circuit. A modal analysis of the light in the slab waveguide will allow us to select the appropriated guide physical structure. In this work, an analysis of dispersion relation curves b-V of SiOx slab optical waveguides is presented. Here is considered that SiOx refractive index can range between 1.457-1.9, and core thickness between 100 nm- 1000 nm. Starting from the normalized dispersion relation and the distribution of the electric field in the waveguide, the cutoff wavelength or thickness, effective refractive index, effective guide thickness and confinement factor of a selected mode are calculated.

9556-19, Session 4

Design and fabrication of sinusoidal spectral filters for multispectral imaging

Chuan Ni, Jie Jia, Keigo Hirakawa, Andrew M. Sarangan, Univ. of Dayton (United States)

Multispectral imaging beyond the minimal metametric RGB colors still remains a challenge, especially in portable inexpensive systems. We report a novel discrimination technique which utilizes an array of multichroic filters that have a sinusoidal transmission spectra in the frequency domain, known as the Spectra Filter Array (SFA). These spectrally periodic filters are not only convenient for Fourier analysis, but are also highly desirable for preserving the signal integrity. Since the SFA is posed as an optimal sampling of hyperspectral images, it allows for the reconstruction of the full spectrum from subsequent demosaicking algorithms.

Unlike conventional Color Filter Arrays (CFA) which utilizes absorption dyes embedded in a polymeric material, the sinusoidal multichroic filters require an all-dielectric interference filter design. However, the goal of most dielectric filter designs is to achieve sharp transitions with high-contrast. A smoothly varying sinusoidal transition is more difficult with conventional approaches. However, this can be achieved by trading off the contrast. Following the principles of a simple Fabry-Perot cavity, we have designed and built interference filters from 0.5 sinusoidal periods to 2.5 sinusoidal periods from 450nm to 900nm spectral range. Also, in order to maintain a uniform period across the entire spectrum, the material must have a very low dispersion. In this design, we have used ZnS as the cavity material. The six filters have been used in a multispectral imaging test bed.

9556-20, Session 4

Detection of coating fluorophores' densities in improved Q-factor cavities

Nader Shehata, Ishac L. N. Kandas, Virginia Polytechnic Institute and State Univ. (United States) and Alexandria Univ. (Egypt); Chalongrat Daengngam, Prince of Songkla Univ. (Thailand)

This work investigates the relationship between spherical silica cavity Q-factors and the density of coated second order nonlinearities optical structures such as prosion brown (PB) and PCBS. In particular, we fabricate multiple functional cavity with different ionic self-assembled multilayer (ISAM) film thickness in nanometers range (about 1 nm for each one bilayer) and PB/ PCBM densities. The Q factors of these cavities are mainly limited by optical absorption in the case of the ISAM film, and a combination of optical absorption and scattering of the coated fluorophores. The nonlinear optical materials reduce Q-factor to the range of 106-107, which is in the range of producing second harmonic signal. That could help in evaluating the effective density of fluorophores of both coating materials. This work is helpful in different applications including optical communication infrastructure.

9556-21, Session 4

Applications of silicon microspheres as microphotonic filters

Muhammad Zakwan, Ulas S. Gökay, Ali Serpengüzel, Koç Univ. (Turkey)

Elastic light scattering is performed in silicon microspheres at near-infrared telecommunication wavelengths. Lorentzian and Fano lineshape whispering gallery mode resonances are experimentally observed and numerically simulated. The quality factors of the resonances are on the order of 100,000. Possible applications of silicon microspheres include Lorentzian and Fano filters for optical channel dropping and modulation for wavelength division multiplexing.

9556-22, Session 5

Nanofabrication at 1nm resolution by quantum optical lithography

Eugen Pavel, Storex Technologies Inc. (Romania)

A major problem in the optical lithography was the diffraction limit. Here, we report and demonstrate a lithography method, Quantum Optical Lithography [1,2], able to attain 1 nm resolution by optical means using new materials (fluorescent photosensitive glass-ceramics and QMC-5 resist). The performance is several times better than that described for any optical or Electron Beam Lithography (EBL) methods. In Fig. 1 we present TEM images of 1 nm lines recorded at 9.6 m/s.

9556-24, Session 5

Plasmonic structures fabricated via nanomasking sub-10 nm lithography technique

Stephen J. Bauman, Desalegn Debu, Joseph B. Herzog, Univ. of Arkansas (United States)

Fabrication of nanostructures below the resolution limit of typical lithography techniques helps push the boundaries of plasmonics and nano-optics research. Smaller nanoscale (<10 nm) metallic structures and gaps allow for plasmonic enhancement of incident light which is beneficial in various applications such as biosensing, photovoltaic absorption enhancement, surface enhanced spectroscopies, and photocatalysis. However, this high structural resolution can be difficult to obtain with typical techniques. A new nanomasking technique has been developed which allows for fabrication of nanostructures and nanogaps down to sizes less than 10 nm by using a two-step electron beam lithography (EBL) and deposition method with the potential for mass production scalability. This technique improves upon existing alternatives for creation of truly nanoscale features. It provides control over geometrical variation, two-dimensional fabrication, and the ability to simultaneously create many plasmonic hotspots over a large area. This work has fabricated such structures with sub-20 nm metal features and sub-10 nm gaps. Structures can potentially be tuned to specific wavelengths by controlling structure and gap widths. Further work will involve determination of line edge and line width roughness, comparisons of different metals, varying structure heights, and continued scaling up of the technique to determine its feasibility for mass producible plasmonic enhancement and nano-optics applications. Additional future work includes theoretical models in conjunction with experimental optical characterization results.

9556-25, Session 5

Optomechanical nanoantenna

Alireza Bonakdar, Sung Jun Jang, Robert L. Brown, Iman Hassani Nia, Mohsen Rezaei, Hooman Mohseni, Northwestern Univ. (United States)

Optical nonlinearity is a necessary condition for optoelectronic signal processing devices such as modulators, wavelength mixers, and non-magnetic isolators. Unfortunately, nature does not provide us with materials that have large optical nonlinearity, setting limitations on the device performance and power consumption. In addition, implantation of nonlinear materials is a difficult task, since they are not necessarily compatible with the standard III-V semiconductor technology. Previously, we introduced the concept of optomechanical nanoantenna as a promising nanophotonic building blocks to exhibit giant nonlinear response. Here, we designed, fabricated and characterized an optomechanical nanoantenna (OMNA), which shows dramatic change in scattering properties by minuscule changes in geometry. The OMNA is highly compact compared with other types of the developed optomechanical devices due to the plasmonic effect that squeezes optical field many orders of magnitude bellow the diffraction limit setting a sub-wavelength resonance length of the antenna.

We fabricated the OMNA using electron beam lithography and suspended its reconfigurable parts via isotropic RIE etching of a sacrificial layer. In order to explore the nonlinearity response of OMNA, we used pump-probe scheme. Pump laser is responsible to generate optical force at the gap of the antenna and subsequently induces deformation on the antenna. The modification on the antenna's response to the probe due to mechanical deformation can be detected as the amount of the change in the captured reflection and transmission signals. This work brings new opportunities toward material-less nonlinear optics.

9556-26, Session 5

Optimizing a subwavelength grating lens for large incidence angles

Lukas Elsinger, Technische Univ. Graz (Austria) and ams AG (Austria); Peter Hadley, Technische Univ. Graz (Austria); Rainer Minixhofer, Anderson P. Singulani, ams AG (Austria)

Flat transmissive lens designs for infrared sensor applications based on subwavelength gratings were analyzed using a finite difference time domain program (Lumerical). The lens structure consisted of periodically arranged silicon pillars placed on a sapphire substrate. Broadband transmission in a >1.5 μm wavelength band around the design wavelength of ? = 4 μm was observed. For the initial design the pillar height was 2.5 μm, the pitch was 1.8 μm and the filling factor varied between 30% and 70%, resulting in a change of the transmitted phase over 2π, while the transmitted power remained >90%. The Huygens-Fresnel principle was then used to find the correct filling factor at each position for a focusing lens. Other authors have reported severe corruption of the focal spot quality for incidence angles >10° with similar lens designs. While for other usage this might be satisfactory, for sensor applications the lens also has to work at large incidence angles. A parametric sweep of the initial design with varying incidence angle showed a drop in the transmittance appearing at a filling factor of 55-60%, which caused defocusing. The effect of the transmission drop was accompanied by a phase discontinuity. This was investigated numerically and a phenomenological explanation is presented. The subwavelength structure was then optimized to work for a lens design with large incidence angles. A finite element method package (Comsol) was used to characterize the quality of the focal spot at different incidence angles.

9556-27, Session 5

Research on input shaping algorithm for rapid positioning of ultra-precision dual-stage

Fazhi Song, Yan Wang, Xinglin Chen, Ping He, Harbin Institute of Technology (China)

As a high-precision servo motion platform, the dual-stage lithographic system uses lots of long-stroke air-bearing linear motors to achieve rapid positioning. Residual vibration, resulting from direct drive, almost zero damping, parallel decoupling structure and high velocity, leads to too long settling time and is one of the key factors in slowing the speed of positioning. To suppress the residual vibration and realize the high positioning precision in shorter settling time, this paper designs proportional integral derivative (PID) controller with input shaping algorithm for the air-bearing linear motor. The simulation of the system is performed by MATLAB/Simulation. The experimental results indicate that the input shaping algorithm proposed in this paper brings about significant reduction in the positioning time of the linear motor.

9556-28, Session 6

Nanomanufacturing concerns about measurements made in the SEM: Part IV: charging and its mitigation *(Invited Paper)*

Michael T. Postek, András E. Vladár, National Institute of Standards and Technology (United States)

This is the fourth of a series of tutorial papers discussing various causes of measurement uncertainty in scanned particle beam instruments, and some of the solutions researched and developed at NIST and other research institutions. Scanned particle beam instruments especially the scanning electron microscope (SEM) have gone through tremendous evolution to become indispensable tools for many and diverse scientific

and industrial applications. These improvements have significantly enhanced their performance and made them far easier to operate. But, ease of operation has also fostered operator complacency. In addition, the perceived user-friendliness has reduced the need for extensive operator training. Unfortunately, this has led to the concept that the SEM is just another expensive digital camera or another peripheral device connected to a computer and that all of the issues related to obtaining quality data have been solved. Hence, a person using these instruments may be lulled into thinking that all of the potential pitfalls have been fully eliminated and they believe everything they see on the micrograph is always correct. But, as described in this and the earlier presentations, this may not be the case. Care must always be taken when quantitative data are being recorded. The first paper in this series discussed some of the issues related to signal generation in the SEM, including instrument calibration, electron beam-sample interactions and the need for physics-based modeling to understand the actual image formation mechanisms to properly interpret SEM images. The second paper, discussed another major issue confronting the microscopist: specimen contamination and methods of contamination elimination. The third paper discussed mechanical vibration and stage drift and some useful solutions and this fourth contribution discusses some of the issues related to specimen "charging" and some possible solutions for its mitigation.

9556-29, Session 6

Helium ion microscopy of electrospun nano-composites *(Invited Paper)*

Eva M. Campo, Bangor Univ. (United Kingdom); Chuong T. Huynh, Carl Zeiss Microscopy, LLC (United States); Eduardo Larios, Univ. of Texas at San Antonio (United States); Mohan Ananth, Carl Zeiss Microscopy, LLC (United States)

Carbon Nanotubes and polymer nanocomposites have attracted much attention in the last couple of decades. Convenient processing of polymers in microtechnology environments, combined with exceptional properties of CNTs are expected to produce a variety of structural and functional applications. Some examples include high-strength composites, artificial muscles, energy storage and conversion devices, sensors, field emission displays, radiation sources, nanometer sized semiconductor devices, as well as probes and interconnects. However, despite a promising application space, effective processing and manufacturing remains elusive due to the poor understanding of processing effects on interfaces. As a result, understanding of dynamics at the CNT-polymer interface sits at the core of this promising material system. In fact, interfacial dynamics between polymers and nanofillers upon electrospinning is a largely unexplored field of research, and in this work we propose an exploration through innovative microscopy techniques.

Indeed, the advent of Helium Ion Microscopy (He-IM) could impose an inflexion point towards the understanding of the extremely dynamical character of electrospinning. Absence of surface treatments prior to irradiation unveils previously unreported conformation arrangements between CNTs and hosting polymer blend, possibly pointing at complex dynamical processes upon fiber collection during electrospinning. These results further highlight the value of He-IM in the study of soft matter and nanocomposites.

9556-30, Session 6

Controlling orientation of carbon nanotubes by using direct laser writing

Shota Ushiba, Osaka Univ. (Japan); Satoru Shoji, The Univ. of Electro-Communications (Japan); Kyoko Masui, Osaka Univ. (Japan); Junichiro Kono, Rice Univ. (United States); Satoshi Kawata, Osaka Univ. (Japan)

Single wall carbon nanotubes (SWNTs), which consist of a rolled-up single layer graphene with a 1 nm diameter cylindrical shape, exhibit remarkable mechanical, electrical, thermal, and optical properties. The intrinsic characteristics make them ideal candidates as advanced filler materials in composites, leading to a wide range of applications such as MEMS and photomechanical actuators. In our previous research, we demonstrated 3D micro fabrication of SWCNT/polymer composite by using direct laser writing based on two photon polymerization (TPP). Our method allows one to fabricate arbitrary 3D micro structures, and SWCNTs are uniformly distributed throughout the whole structures. Here, we present a technique to orient SWCNTs in a desired direction. Polarized micro Raman spectroscopy is used to elucidate the orientation direction of SWCNTs in structures with high spatial resolution. The G-band peak intensity significantly varies in intensity as a function of angles between the polarization of incident light and nanowire axis. The G-band intensity becomes largest when the polarization of the laser beam is parallel to the nanowire axis, while it becomes smallest when the polarization is perpendicular. This result clearly indicates that the SWCNTs are uniaxially aligned inside the wire. We also demonstrate controlling orientation of CNTs in 3D structures by changing laser scanning direction. The alignment would further improve properties of the composite such as mechanical and electrical properties.

9556-31, Session 6

Self-assembly based nanometre scale patterning for nanowire growth

Abhishek Chandramohan, Durham Univ. (United Kingdom); Rong Sun, Lund Univ. (Sweden); Natalia Kaliteevskaya, Durham Univ. (United Kingdom); Jonas Johansson, Kimberly A. Dick, Lund Univ. (Sweden); Budhika Mendis, Michael C. Petty, Andrew J. Gallant, Dagou A. Zeze, Durham Univ. (United Kingdom)

Periodic nanostructure arrays have been ubiquitously exploited lately due to their properties and prospective applications in production of templates for self-induced and gold (Au)-catalysed nanowires (NWs) as this approach is relatively cheap, time-efficient and do not require electron beam lithography. The technique consists creating nanoholes in SiO2 to expose the silicon Si (111) beneath where self-induced NWs can nucleate, while nanodots deposited onto the Si (111) surface serve as catalyst seeds.

For Au-catalysed NWs, a monolayer of self-assembled polystyrene nanospheres (PNS 300nm) was created on a 2 inch Si wafer by spin coating and later etched for a short time before a very thin Au-catalyst layer was deposited. In turn, for self-induced, PNS monolayer was created onto a SiO2-Si substrate. A longer etch was required to reduce PNS diameter significantly to leave relatively larger spacing where chromium is blanket deposited. PNS were lifted off by sonicating the samples in toluene produce the periodic arrays of nanodots and nanoholes, respectively. The underlying SiO2 was etched further through the nanoholes to uncover the Si below. 200 nm holes and 30-70 nm dots were demonstrated through the bespoke methods. The patterned substrates served as master templates, subsequently copied using polydimethylsiloxane (PDMS) to produce a flexible stamp for nanoimprint lithography. A bi-layer resist lift off process was developed to print the replicated nanodots or nanoholes on large-area substrates onto which III-V NWs were subsequently grown.

9556-32, Session 7

Janus tectons: a versatile platform for self-assembling chromophores on sp2-carbon based substrates *(Invited Paper)*

Ping Du, David Kreher, Fabrice Mathevet, Univ. Pierre et Marie Curie (France); Fabrice Charra, Commissariat à l'Énergie Atomique (France); André-Jean Attias, Univ. Pierre et Marie Curie (France)

In view of the demanding forthcoming applications in nanotechnology, it is

of prime interest to create functions out-off the plane and fully exploit the room above the substrate. Accessing the third dimension is so a mandatory step for nanooptics/electronics. Previously we introduced the Janus-like 3D tecton concept. It consists of a dual-functionalized unit presenting two faces linked by a rigid spacer: one face (A) is designed for steering 2D self-assembly, the other one (B) is a functional molecule. The objective is to take advantage of the in-plane self assembling of building blocks lying on face A to control the positioning of out-off plane active unit B, linked to the base by a rigid pillar. Here we present a series of Janus tectons incorporating chromophores ranging from fluorescent dyes to photoswitchable molecules. We will present the optical properties in solution as well as the properties of the self-assembled functional monolayers on flat sp2-carbon based susbstrates like HOPG and graphene.

9556-33, Session 7

Linear and nonlinear optical processing of polymer matrix nanocomposites

Travis J. DeJournett, Karen Han, Lauren R. Olasov, Fan W. Zeng, Brennan Lee, James B. Spicer, Johns Hopkins Univ. (United States)

This work focuses on the scalable synthesis and processing of nanostructures in polymer matrix nanocomposites (PMNCs) for applications that require photochemical functionality of these nanostructures. An in situ vapor deposition process using various metal and metal oxide precursors has been used to create a range of nanocomposites that display photochromic and photocatalytic behaviors. Under specific processing conditions, these composites consist of discrete nanoparticles distributed uniformly throughout the bulk of an optically transparent polymer matrix. Incorporating other chemical species as supplementary deposition agents in the synthesis process can modify these particles and produce complicated nanostructures with enhanced properties. In particular, work has been carried out to structure nanoparticles using laser irradiation. Starting with metallic or metal oxide nanoparticles in the polymer matrix, localized chemical vapor deposition in the near-particle environment has been carried out using laser irradiation to decompose chemical precursors leading to the formation of secondary structures surrounding the seed nanoparticles. Control of the spatial and temporal characteristics of the excitation source allows for synthesis of nanocomposites with a high degree of control over the location, composition and size of nanoparticles in the matrix and presents the opportunity to produce patterned materials with spatially varying properties.

9556-34, Session 7

High contact angle hysteresis of nanopillared quartz surfaces

Ming-Tsung Hung, Shing-Lung Chen, Shang Yang, National Central Univ. (Taiwan)

Introducing micro/nanostructure on the surfaces is an effective way to achieve superhydrophobicity. However, it usually exhibits very low contact angle hysteresis. In this study, we present a nanopillared quartz surface with large contact angle and high hysteresis. Quartz is a very unique material with great optical, electrical, thermal, and mechanical properties, but with very low manufacturability. The nanopillar structures are fabricated by a cost-effective wet etching of ammonium bifluoride solution. A nanometer-thick platinum layer is deposited on the substrate and annealed to form nanoparticles prior the etching as an etching mask. Different pillar lengths and densities are fabricated by controlling the etching conditions with different etching masks. In the contact angle measurements, the surfaces turn into hydrophobic on the nanostructured samples and with high hysteresis. Compared with the theoretical models, it suggests that the droplet penetrates into the structures and partially contacts the bottoms surface. The ratio of the bottom contacting area decreases with the increase of the structure density and the increase of the structure height. The hysteresis is roughly proportion to the penetrating contact area, where the movement of the droplet is impeded. The situation becomes severe when the droplets have larger portion touching the bottom surface.

9556-35, Session 7

Nanoscale patterning of poly (L-lactic acid) (PLLA) films with nano-imprinting methods

Akshit Peer, Iowa State Univ. (United States) and Ames Lab. (United States); Rabin Dhakal, Iowa State Univ. (United States); Rana Biswas, Iowa State Univ. (United States) and Ames Lab. (United States); Jaeyoun Kim, Iowa State Univ. (United States)

Many diverse biological applications can benefit from nanoscale texturing of materials for bio-medical functions. Texturing of bio-materials can increase the available surface area so that they can be coated with larger doses of therapeutic agents. We demonstrate nanotexturing of poly (L-lactic acid) (PLLA) – a material used for drug-eluting coronary stents and cell growth template.

We develop a rapid technique for texturing PLLA films based on nanoimprinting. A master pattern consisting of a periodic array of holes or nanocones with sub-micron pitch was developed on a master substrate by lithography. The inverse of this pattern was transferred to a polydimethylsiloxane (PDMS) mold by nanoimprinting.

We investigated the transfer of the PDMS pattern onto PLLA films by drop-casting the PLLA solution on the mold, and imprinting PLLA films with the PDMS mold, under elevated pressure and temperature. PLLA was dissolved in chloroform and the solution was either drop casted directly on the PDMS mold or was spin coated on the glass substrate to be stamped later by the PDMS mold. We successfully achieved nanoarrays of holes with pitch ~700 nm, and hole diameter ~500 nm, with triangular lattice periodicity and varying depths on PLLA films. SEM images demonstrate that drop-casting achieves the most reliable transfer of patterns onto the PLLA, whereas nanoimprinting the PLLA films results in shallower and less resolved features. We compare the nanopatterns on PLLA to those on a polystyrene film. We will describe the optical reflectance from these films and compare the results with simulations.

Nanomanufacturing-related programs at NSF *(Invited Paper)*

Khershed P. Cooper, National Science Foundation (United States)

The National Science Foundation is meeting the challenge of nanoscience and technology implementation through several nanomanufacturing-related research programs. The goal of the core Nanomanufacturing (NM) and the inter-disciplinary Scalable Nanomanufacturing (SNM) programs is to meet the barriers to manufacturability at the nano-scale by developing the fundamental principles for the manufacture of nano-scale materials, structures, devices, and engineered systems. These programs address issues such as scalability, reliability, quality, performance, yield, metrics, and cost among others. The programs seek nano-scale manufacturing ideas that are transformative, that will be widely applicable and that will have far-reaching technological and societal impacts. It is envisioned that these basic research programs will provide the knowledge base for larger programs such as the manufacturing Nano Science and Engineering Centers (NSECs), the Nanosystems Engineering Research Centers (ERCs), the STTR/SBIR program and the current and future nano-related National Network for Manufacturing Innovation (NNMI) Institutes. In this talk these different programs will be briefly described. The presentation will include discussions on novel approaches to nanomanufacturing and process integration and their implications for measurement and control protocols. Nanomanufacturing concepts and ideas will be illustrated by examples of projects from the NM and SNM programs.

9556-37, Session 8

Challenges and needs for automating nano image processing for material characterization *(Invited Paper)*

Yu Ding, Satish T. S. Bukkapatnam, Texas A&M Univ. (United States)

Working with various nanomanufacturing processes, the authors realize that measurements revealing the structure and function of nano subjects are most likely in an image format. Consequently, image processing techniques are inevitably needed to extract critical information pertinent to a subject's formation as well as interaction with the host materials. These nano images are of large data size and contain complicated features. The current nano image processing methods are slow, expensive and labor intensive. There is a strong need to develop fast and reliable methods and procedures, enabling process control compatible automated processing of nano images.

The international standard on nanotechnology leaves it for the users to identify an appropriate data analysis algorithm or to seek a third party software solution. When an incapable image processing tool is used, this approach leaves a gap in the whole loop of nano metrology on imaging data. The high resolution enabled by the physical instruments may not be preserved.

The authors believe that nano images have their uniqueness. Features valid, and techniques favored, in the general image processing or bio-imaging field may no longer be effective in nano imaging. Specialized image processing techniques are needed to address the challenges. Towards that goal, the authors will discuss the recent developments of image processing methods, specifically tailored for nano image data, as well as the near- and medium-term needs in the area of nano metrology and imaging. The authors will also share their perspectives on how some of the research challenges may be addressed.

9556-38, Session 8

Scatterometry reference standards to improve tool matching and traceability in lithographical nanomanufacturing

Emil Agocs, Bernd Bodermann, Physikalisch-Technische Bundesanstalt (Germany); Sven Burger, JCMwave GmbH (Germany); Gaoliang Dai, Johannes Endres, Hermann Gross, Physikalisch-Technische Bundesanstalt (Germany); Poul-Erik Hansen, Danish Fundamental Metrology Institut (Denmark); Sebastian Heidenreich, Michael Krumrey, Physikalisch-Technische Bundesanstalt (Germany); Bernd Loechel, Juergen Probst, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany); Frank Scholze, Victor Soltwisch, Matthias Wurm, Physikalisch-Technische Bundesanstalt (Germany)

Scatterometry is an important and high sensitivity metrology technique to support the lithographic nanomanufacturing process in semiconductor industry. However, today it is usually not applied for absolute measurements of critical dimensions (CD) and quality control due to the lack of traceability. The reasons for this have been some possible sources of systematic measurement deviations caused by a number of approximations and assumptions commonly applied in measurements and data analysis as well as the lack of reliable standard samples. To establish scatterometry as traceable and absolute method for dimensional measurements we have investigated the influences of some of these approximations and we have developed, characterised and calibrated scatterometry standard samples suitable for tool validation [1].

We investigated both experimentally and by numerical simulations the influences of different tool or sample specific approximations and discuss and quantify their influences on the measurement uncertainty budget.

Two different standard samples, based either on Si or on Si3N4, have been developed. The etched gratings have periods down to 50 nm and contain areas for AFM measurements for comparison. We have characterised these samples using AFM, optical, EUV as well as X-Ray scatterometry and spectroscopic ellipsometry. For the calibration a combined analysis of DUV and EUV scatterometry, spectroscopic ellipsometry and GISAXS measurement data supported by AFM results will be applied using Bayes algorithms.

We report on the status of these developments and discuss the final design and aimed specifications of these standard samples and of possible future extensions.

Quantitative tool characterization of 193 nm scatterfield microscope

Martin Y. Sohn, Bryan M. Barnes, Hui Zhou, Richard M. Silver, National Institute of Standards and Technology (United States)

Evaluation of uncertainties is a critical element in quantitative nano-scale measurements using optical microscopy techniques. Instrument characterization underlies the quantitative evaluation of measurements of deep sub-wavelength features. The scatterfield microscopy technique, which articulates the illumination at the sample plane, is an efficient method for angle- and polarization-resolved microscope characterization to enable the uncertainty evaluations. The tool characterization results are used for the Fourier space normalization of electromagnetic simulation to permit comparisons with experimental imaging data. For this purpose the NIST 193 nm scatterfield microscope operating with an ArF Excimer laser was characterized. The illumination and collection optics were scanned angularly, utilizing a small aperture at the conjugate back focal plane of the objective lens so that the optics train was characterized with respect to angularly discrete cones of the illumination beam. Each cone beam can be approximated as a plane wave by using Köhler configuration, simplifying the analysis of the scattered light induced by the discrete illumination beam at the sample plane. Under this approximation, the illumination and entire tool function sets were measured at sample and imaging CCD planes, respectively, producing the collection tool function set numerically. We report tool imperfection effects upon these tool functions, specifically, comparing to the optical simulations of the designed optical paths varied with misalignments and aberrations that lead to changes in the tool functions. Through these comparisons, we investigate the relationship between the microscope tool imperfection factors to the deviations in the illumination as well as in the collected scattered light.

Laser velocimetry for measurement of non-sinusoidal vibration in sub-nanometer scale without lock-in amplifiers

How-Foo Chen, Wei-Lun Chiang, National Yang-Ming Univ. (Taiwan)

Laser velocimetry capable of measuring slow motion or small displacement normal to vibrational surface always find its position in industry and scientific applications, even in life science, such as mechnobiology of cells. However, measurement of small velocity or displacement down to sub-nanometer scale is always a challenge due to the significant amount of low-frequency noise from environment, detectors, and circuits. When such sensitivity is required, utilization of lock-in amplifiers is necessary to filter out the noise and to satisfy the requirement. But the measurement is then also limited to single-point detection. Without lock-in amplifiers, the measurement sensitivity is usually limited to the micron scale at the smallest. Utilizing self-mixing dynamics of a semiconductor laser for velocity measurement usually has the sensitivity limited to about

centimeter per second and also to a single-point measurement because one laser can be used only for one detection point. Different from those technologies, we have developed a laser Doppler velocimetry in a Mach-Zehnder configuration. A heterodyne scheme combined with a down-conversion scheme, digital filtering, and Hilbert transform is used to gain the measurement sensitivity down to sub-nanometer scale without the usage of a lock-in amplifier. Environment perturbation in tens of nanometer scale can be removed by empirical mode decomposition (EMD). The setup can detect sub-nanoscale displacement and velocity of a surface with non-sinusoidal vibration frequency down to sub-Hertz. Lack of lock-in amplifiers promises this Doppler velocimetry technology not limited to single-point measurement of a surface vibrating down to sub-nanometer scale.

Self-assembly of composite materials based on carbon nanotubes

Dmitrii Zhukalin, Andrei V. Tuchin, Larisa A. Bityutskaya, Voronezh State Univ. (Russian Federation)

One of the urgent problems of condensed matter physics is the study of interrelation between the formation process and the properties of self-organized structures. The main goal of this work is to study nonlinear dynamic processes during the aggregation of short carbon nanotubes in a drying drop. The autowave process is characteristic of dynamically ordered structures and can be seen in physical, chemical, biological and medical systems. Recently, a drying drop has been used as a reactor with distributed active medium, allowing to observe nanoprocesses in a contained environment. Taking into account the dynamic conditions of the drying drop, including the capillary flows, temperature gradient and gradually increasing concentration of the components - “The Droplet reactor” is of great interest in studying the self-assembly and self-organization of nanoparticles.

The colloidal suspension containing short carbon nanotubes in distilled water was used as the active medium. The dynamics of the thermophysical properties of aggregation process, as well as morphology was investigated in situ. The phenomenon of formation of the thermal autowave spatio-temporal structures was observed. According to its distinctive features (disequilibrium, nonlinearity, spontaneity, openness), the autowave process of aggregation of nanotubes can be seen as a dissipative structure with the increasing amplitude of temperature fluctuations. As a result of this aggregation, fractal structures are formed.

It can therefore be concluded that autowave processes represent unique thermodynamic characteristics of self-organization. Thus, autowave processes can be used for diagnostic and identification purposes during the synthesis of various functional materials.

Non-circular nanohole array as selective emitter for thermophotovoltaic system

Jin Hwan Kim, Moo Whan Shin, Yonsei Univ. (Korea, Republic of)

We fabricated two-dimensional tantalum (Ta) photonic crystal with non-circular nanohole array as a selective emitter for the thermophotovoltaic system. We optimized geometric parameters (pitch, diameter, and depth) for each of patterns of rectangular, hexagonal, and circular nanohole array by using finite difference time domain (FDTD) techniques. The cutoff wavelength of the selective emitter was designed to coincide with the bandgap energy of a promising low-bandgap (0.55 eV, 2.25 ?m) photovoltaic material, InGaAsSb. The three types of nanohole arrays were thoroughly investigated in the aspect of spectral selectivity, and fabricability (minimum feature size, and aspect ratio). Spectral selectivity was defined as the ratio of summation of emissivity for the useful wavelength range from 1 to 2.25 ?m to that from 1 to 4 ?m, and the optimized spectral selectivity was over 0.9. The non-circular nanohole arrays showed similar spectral selectivity compared to typical circular nanohole array even with relatively large feature size and low aspect ratio. We tried to transfer the optimized non-circular pattern onto polycrystalline Ta substrates via typical photolithography process. The fluorine based deep reactive ion etching was developed for the Ta emitter to exhibit clear vertexes of polygonal shape and relatively high aspect ratio. Emissivity of the emitters was measured by using the UV-Vis-NIR spectrophotometer, and the measurement verified the simulated results.

Design and fabrication of multilayer dielectric gratings for spectral beam combining

Hyun-Ju Cho, Daeduk College (Korea, Republic of); Yong-Soo Lee, Hyun-Tae Kim, Doosan DST Co., Ltd. (Korea, Republic of)

Metal gratings are mostly used on low energy optics, buy it has low diffraction efficiency and laser damage threshold. Spectral beam combining is a method to make high power laser beam using diffraction gratings. Multilayer dielectric (MLD) high reflectance mirror is designed for high efficiency gratings using HfO2 and SiO2 for high laser damage threshold. On the top of the mirror, polarization dependent SiO2 grating structure is simulated by finite domain time division (FDTD) method at 1060nm for spectral beam combining. To estimate the far field diffraction characteristics, we first calculate near field electromagnetic wave properties at the substrate region and these are transformed to angular diffraction characteristics at about 1 meter apart from the grating. Multilayer dielectric mirrors is deposited by electron beam evaporation method at the substrate temperature 250? and the reflectance of the deposited mirror was measured by spectrophotometer. Four types of high efficiency MLD gratings are selected and these are fabricated by lithography and reactive ion etching method. To fabricate the designed submicron structure, 4X stepper is used for pattern formation on the photo resistor. We use fused silica as a substrate and additional dummy silicon wafer substrates are used for grating structure confirmation using scanning electron microscope. The diffraction efficiencies are measured by the angle resolved power measurements method and these are compared with simulated results.

Advanced length scaling method of optical nanoantennas

Seunguk Kim, Jeonghee Shin, Jae-Eun Jang, Byoungok Jun, Daegu Gyeongbuk Institute of Science & Technology (Korea, Republic of)

Due to the tiny size of optical nanoantennas, some typical radio frequency (RF) antenna theory, especially length scaling regime, are unsuitable for optical region. Various approaches to obtain meaningful scaling method have been recently studied and estimated. However, suggested models so far still have some mismatches from the real values of optical nanoantennas in visible light and near infrared (NIR) regions. Even if simplified dielectric constant of metals is available near the ultraviolet (UV) range, it shows appreciable difference with the real dielectric constant of metals in visible to NIR regions, so that it induces severe deviation for the dimensional factors of optical nanoantennas such like a length and a width. Here, to improve the accuracy of scaling regime, we used waveguide theory and tried to find a well-defined dielectric constant of metals based on Lorentz-Drude model. Also, metallic monopole nanoantennas which have various dimensional conditions were formed on the dielectric (SiO2) layer to confirm whether our simulation is well-matched with real values. As a result, the characteristics of fabricated optical nanoantennas are well matched with simulated values in visible light and NIR regions. The deviation of geometric parameters, especially lengths, between simulated and experimental values is less than 5 nm.

Design of optical channel waveguides in SiO2 by ion implantation

Helena De los Reyes, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico); Gloria V. Vázquez, Ctr. de Investigaciones en Óptica, A.C. (Mexico); David M. Salazar, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico); Alicia Oliver, Univ. Nacional Autónoma de México (Mexico); Heriberto Márquez, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico)

Design of optical channel waveguides straight, curved, and S-bends based on silver ion implantation in substrate of SiO2 is presented. Step index profiles have been reached using a sequential multiple ion implantation process with energies of implantation from 4.3 to 9 MeV and fluences of 1014 to 1015 ions/cm2 and are used for three-dimensional (3-D) beam propagation method calculations. (BPM). An analysis of modal optical confinement was done by means of effective index method (EIM) for selecting the right dimensions of channel waveguides. Here is considered core index range between 1.4623-1.4662 which is related with fluence. Depth and width for the waveguides were chosen to provide single mode operation. Bending losses are determined as function of bending radius, refractive index change (Δn), and wavelength. The results are presented taken in consideration bending and transition losses.

Influence of wetting states on optical characteristics of Si nanopatterns

Minji Gwon, Sujung Kim, Ewha Womans Univ. (Korea, Republic of); Jiaqi Li, IMEC (Belgium) and KU Leuven (Belgium); Xiumei Xu, IMEC (Belgium); Eunsongyi Lee, Ewha Womans Univ. (Korea, Republic of) and The Univ. of Manchester (United Kingdom); Dong-Wook Kim, Ewha Womans Univ. (Korea, Republic of); Chang Chen, IMEC (Belgium) and KU Leuven (Belgium)

Nowadays, state-of-the-art nanofabrication techniques allow us to produce sub-100 nm-scaled devices in the mass production level. Such development of nanotechnology requires reliable wet cleaning of nano-patterned Si wafers. Establishment of desirable cleaning processes definitely requests characterization methods to examine wettability in nano-patterned Si wafers. Recently, we proposed that simple optical reflectance measurements could quantitatively determine the instantaneous water imbibition depths and define the actual wetting state on Si nanopillars (NPs) (diameter: 40 nm) [Xu et al., ACS Nano 8, 885 (2014)]. In this work, we carried out simulation studies of optical characteristics of Si nanopillar (NP) arrays (diameter: 40~130 nm and height: 420 nm) using finite differential time domain (FDTD) method. Reflectance spectra of wetting and non-wetting NPs showed clear difference. The spectra in the long wavelength range were well explained by the interference at the top and bottom of the NPs. As the diameter of NPs increased, resonant guided modes in individual NPs and coupled guided modes appeared in visible range. Wettability of such large-sized NP arrays also did influence the resonant mode excitation. Our results showed that simple optical reflectance measurements were useful to examine surface wettability of nanopatterns.

Nanoindentation for surface modification of nanofilms

Angelika Luchenko, V.E. Lashkaryov Institute of Semiconductor Physics (Ukraine); Mykola M. Melnichenko, National Taras Shevchenko Univ. of Kyiv (Ukraine)

The miniaturization of the dimensions of functional elements and nanostructuring of materials require solving the issues of preparation and control of physical and chemical properties on the micro- and nanolevels under both static and dynamic conditions. Nanoindentation as a set of approaches, methods and specific hardware is practically the only universal tool for probing the mechanical behavior of submicron materials with nanovolumes, ultra-thin surface layers and films. At the same time physical and chemical properties of nano-objects and nanostructures can differ strongly to the macroscopic properties.

Here we show it is practically to use a scanning tunneling microscope for indentation in the continuous micro- and nano-range. A maximum load of 2.64 cN (and 0.4 cN minimum) was applied on a piezo-scanner to achieve the indentation. The relaxation after the surface is structurally modified by contact was investigated. It is shown that within a few hours of modification there is clear evidence of inevitable loss of information about the morphology initially modified area. These images demonstrate the fundamental possibility of conducting research on the observation of diffusion and relaxation processes at the nanoscale with a scanning tunneling microscope. The possibility of modifying the sample surface tunneling current was shown. This may enable preparation of the surface for subsequent applications in which it is necessary to reduce the average elevation on the surface. Nano-objects on the surface of the experimental samples were created by using the developed technique.

Optical properties of LED with patterned 1D photonic crystal

Pavol Hronec, Jaroslava ?kriniarová, Anton Kuzma, Jaroslav Ková? Jr., Slovenska Technicka Univ. (Slovakia); Anna Bencurova, Stefan Hascik, Pavol Nemec, Slovak Academy of Sciences (Slovakia)

In this paper we focus on the application of the one-dimensional photonic crystal (1D PhC) structures on the top of Al0.295Ga0.705As/GaAs multi-quantum well light emitting diode (MQW LED). 1D PhC structures with periods of 500 nm, 600 nm, 700 nm, 800 nm and 900 nm were fabricated by the E-Beam Direct Write (EBDW) Lithography. Effect of 1D PhC period on the light extraction enhancement was studied by experimental method and it was simulated by FDTD simulation method. Simulations were prepared with unpolarized and incoherent light source to simulate appropriate properties of real LEDs and their far fields for different periods of 1D PhC patterned on LEDs.

On the LED heterostructure with patterned 1D PhC, the ohmic contacts were prepared by thermal evaporation of gold based contact metals onto the pattern semiconductor surface: AuBe alloy for p-type upper contact and AuGeNi alloy for n-type bottom contact, respectively. Contacts were shaped by conventional lift-off procedure. Subsequently the samples were alloyed at 450?C for 2 minutes in flowing forming gas. Finally, MESA etching was performed by wet chemical etching for isolation of devices.

LEDs light-current characteristics are measured by using integrating sphere. 1D PhC LED radiation profiles were obtained from Near Surface Light Emission Images (NSLEI). NSLEI measurements were performed by CCD camera and evaluated by image processing. Measurements showed the strongest light extraction enhancement using 600 nm period of PhC. Investigation of PhC LED radiation profiles showed strong light decoupling when light reaches PhC structure.

9556-49, Session PWed

The significance of the number of periods and period size in 2D photonic crystal waveguides

Mirsaeid Sarollahi, Jonathan Mishler, Stephen J. Bauman,

Salvador Barraza-Lopez, Paul Millett, Joseph B. Herzog, Univ. of Arkansas (United States)

This work investigates the significance of the number of periods in two-dimensional photonic crystals in addition to other parameters including period length and material properties. Straight and curved 2D photonic crystal waveguide models have been developed to study various photonic crystal properties and parameters. The number of photonic crystal posts (number of periods), wavelength, diameters of photonic crystal pots, period length of photonic crystals and material properties have been investigated to determine their effect on the losses in the waveguide. The models focus on a hexagonal period and have been designed to study transmission properties of the waveguide. Additionally, a simplified study focuses specifically on the transmission of light through photonic crystal layers. This flexible model will reveal a thorough analysis of photonic crystal properties. Future work plans to investigate multiple incident angles, polarization, and create a similar 3D model.

9556-50, Session PWed

Optical enhancement of photoluminescence with colloidal quantum dots

Gabrielle Abraham, David A. French, Pooja Bajwa, Colin D. Heyes, Joseph B. Herzog, Univ. of Arkansas (United States)

Unique plasmonic structures will be investigated with optical spectroscopy measurements. A new fabrication method has been developed which can create plasmonic structures with features that are below the limit of electron beam lithography. With these smaller dimensions, the plasmonic devices could produce interesting optical properties. This work will focus on measuring these structures with dark-field reflection spectroscopy. Dark-field spectroscopy is a valuable method for capturing and examining low signals of spectra. This is particularly useful when studying the scattering and resonant frequencies of the spectra produced by plasmonic nanodevices. Additional investigations include examining potential plasmonic enhancement in micro photoluminesce spectroscopy with these novel nanostructures. Both computational modeling and spectroscopy experimental results will be presented. This study analyzes how the geometry and environment of the structures; including thickness, size, and adhesion layer effects; alters the spectral intensity of the resultant scattered light.

9556-52, Session PWed

Wearable and stretchable substrates fabricate for display by O2-plasma surface treatment

Sang Chul Lim, Myung Chan An, Dong IC Lee, Se Hyuk Yeom, Chang Taek Seo, Gyu Seok Choi, Gumi Electronics & Information Technology Research Institute (Korea, Republic of)

Bi-layer substrates under uniaxial compression exhibit micron-scale features that can impart mechanical flexibility in functional electronic devices including interconnects, transistors and solar cells. Bi-layer substrates are produced by forming thin rigid oxide membranes on pre-strained elastomeric substrates using oxygen plasma treatment. The wrinkle process comprises stretching of a soft elastic polydimethylsiloxane(PDMS) substrate and subsequent oxygen plasma treatment, resulting in a hard SiO2-like (SiOx-) layer on the surface.

These were treated on one side with oxygen plasma for 5, 10, 15 min to create a nanoscale silica skin, thus presenting identical surface chemistry in all experiments. This paper presents a cost-effective and simple method to form wrinkled stiff SiOx thin films on PDMS substrates at room temperature by oxygen plasma on pre-strained PDMS. The orientation of the generated structures was always perpendicular to the pre-stretched direction and the pitch of the structure could be adjusted ranging from 1.1 ?m to 3 ?m by controlling the strength of the pre-stretched strain and the thickness of the surface metal film. Upon relaxation, highly controlled and regular wrinkling of the silica skin resulted.

Systemic studies have been conducted to understand the dependence of the wavy profile on the PDMS pre-strain, oxygen plasma exposure time, and PDMS modulus. The mechanics analysis has been verified to be quantitatively or qualitatively accurate by experimental comparisons. The wrinkled SiOx/PDMS system is stretchable and provides a wavy mold for stretchable electrodes. The constant electrical resistance during mechanical stretching shows the stretchablity of this system. In this study, the metal thin film/contoured substrate is stretchable and has been demonstrated as stretchable electrical conductors.

Keratin/poly (vinyl alcohol) blended nanofibers with high optical transmittance

Hak Yong Kim, Chonbuk National University (Korea, Republic of)

In conclusion, highly optically transparent composite NFs were fabricated by simple process involving immersion of human hair derived keratin/PVA electrospun composite NFs in water without adding any additive. Thus obtained transparent composite NFs were characterized in detail by applying various techniques. On the basis of experimental results, the composite NFs having enhanced mechanical strength and flexibility could exhibit high optical transparency (about 88%) at a wave length of 600 nm. To the best of our knowledge this type of report has not been published so far and we expect that this type of synthesis technique would be a new paradigm for fabricating different composite NFs reinforced with keratin as a transparent substrate to encourage the use of natural and environmentally friendly materials.

9556-54, Session PWed

Development of EUV scatterometer with high-harmonic-generation EUV source for nano-scale grating

Chia-Liang Yeh, Industrial Technology Research Institute (Taiwan)

We have developed a EUV scatterometer using a focused high-order harmonic generation (HHG) source for nano-scale grating measurement. The coherent light source with multiple discrete wavelengths of 25-35 nm was pumped by a table top Ti:sapphire laser system. A charge-couple-device (CCD) camera directly records the diffraction image of the zero and the first order diffraction information from the grating samples. The grating structure can be reconstructed base on the calculations from the location and the intensity distribution of diffraction pattern.

9556-55, Session PWed

Modeling and adaptive neural network control of the short-stroke wafer stage

Yiguang Wang, Xinglin Chen, Yan Wang, Zhenxian Fu, Sheng Qiang, Harbin Institute of Technology (China)

The short-stroke wafer stage for lithography is a six degrees of freedom (DOF) ultra-precision moving body driven by six voice coil motors (VCM). To improve the exposure quality of wafer scanner, focusing and leveling are required during the exposure. Due to coupling, however, the vertical adjustment of the stage has a great coupling impact on the horizontal motion. To solve this problem, a novel 6-DOF model, based on dynamics and kinetics modeling, is proposed for the short-stroke wafer stage.

Compared with the conventional model, no coupling effect is neglected in this model. Based on this model, a robust adaptive neural network multiple input multiple output (MIMO) controller is proposed for the short-stroke wafer stage. The external disturbances, un-modeled dynamics and model uncertainties involved in the control system are considered as a lumped effect in the proposed method and can be estimated by a radial basis function (RBF) neural network real time online. The stability analysis of the proposed control strategy is conducted based on the lyapunov method. To verify the correctness and effectiveness of the proposed model and control method, a simulation is carried out. The results show that, under considered measurement noise, external disturbances and un-modeled dynamics, the system stability and tracking convergence can be guaranteed and nano-scale tracking accuracy can be achieved.

9556-56, Session PWed

Optical reflectivity as an inspection tool for metallic nanoparticles deposited randomly on a flat substrate

Omar W. Vázquez-Estrada, Ctr. de Ciencias Aplicadas y Desarrollo Tecnológico (Mexico); Gesuri Morales-Luna, Alipio G. Calles, Alejandro Reyes-Coronado, Univ. Nacional Autónoma de México (Mexico); Augusto García-Valenzuela, Ctr. de Ciencias Aplicadas y Desarrollo Tecnológico (Mexico)

Nowadays we have different tools to determine the surface coverage fraction of a monolayer of nanoparticles deposited on the surface of a flat substrate, for example: electron microscope, scanning electron microscope-SEM, atomic force microscope-AFM, among others. These techniques have several limitations such as the analysis of a small area and sometimes the sample can be destroyed or altered by the analysis itself. In this work, we present a multiple scattering model for the reflectance of a monolayer of spherical particles supported onto a flat substrate, which allows us to determine indirectly the surface covered fraction of the monolayer, by measuring the reflection of coherent light scattered by the system. Additionally, this model can be extended to study the reflectance spectra in real time of a forming monolayer, estimating the surface coverage fraction supported in any type of flat substrate (e.g. silica, glass, quartz). The advantages of this technique are that the sample is not damaged during the analysis and it also allows to sense large areas of the sample by simply modifying the width of the laser spot. Currently, we are in the process of determining the best configuration to perform optical reflectivity measurements, in order to estimate the surface coverage fraction of a monolayer of spherical nanoparticles deposited on the surface, either varying the angle of incidence of a laser beam or by using reflectivity spectra at a fixed angle of incidence. Specifically, we are studying the minimum value of the surface coverage that can be quantified using optical reflectivity measurements, assuming different sensitivities and noise scenarios with detectors commonly found in most optical laboratories.

Viability of sizing metallic nanoparticles in suspension from effective refractive index measurements

Gesuri Morales-Luna, Univ Nacional Autónoma de México (Mexico); Roberto Márquez-Islas, Univ. Nacional Autónoma de Mexico (Mexico); Omar W. Vázquez-Estrada, Humberto Contreras-Tello, Univ Nacional Autónoma de México (Mexico); Augusto García-Valenzuela, Univ. Nacional Autónoma de México (Mexico)

Many nanofluids of technological interest consist of suspensions of metallic nanoparticles. Optical determination of the particles' size is of interest since it can be done in situ. In cases when a plasmonic resonance in the extinction spectrum is clearly visible (e.g. with Ag and Au nanoparticles) one can use its location in the spectrum to infer the particles size. In the absence of a clean resonance peak, due for instance to a distribution in particles shape and size, or for metals with higher losses (eg. Cu or Fe), such method cannot be used. A general and accurate measurement of particles' size in absorbing nanofluids from optical measurements is therefore not available today and further research is needed. Recently we developed a novel methodology based on measurements of optical properties of a nanofluid to determine the size and refractive index of nanoparticles in suspension [1]. However, the method is limited to cases where the absorption is much smaller than the scattering cross-sections, which is not satisfied by metallic nanoparticles within the VIS-IR spectrum. In this work we explore variations of the original method also relying on measurements of the extinction coefficient and refractive index of nanofluids to size metallic nano-particles. The viability of the new method, achievable accuracy and precision is investigated theoretically and experimentally. Additionally we explore the possibility of exploiting dependent-scattering effects for characterizing nanoparticles in suspension. Such effects in nanofluids are already strong for relatively small volume fractions of about 2%.

Wafer defect inspection using compoment tree of SEM images

SungHyon Kim, Il-suk Oh, Chonbuk National Univ. (Korea, Republic of)

This paper proposes a novel defect detection method using component tree of SEM images. The component tree contains rich information about the topological structure of images such as stiffness of intensity changes, area and volume of lobes. The information is very effective in detecting suspicious spot for the defects. A quasi-linear algorithm for constructing the component tree and computing those features is available.

This paper modifies the original component tree algorithm to be suitable to the defect detection. One is to exclude the pixels near the ground level in the initial stage of constructing the component tree. The experiment showed that the scheme speeded up whole process about 10 times.

The other idea is to detect significant lobes by using both the volume and area attributes. To find out significant lobes, the original algorithm deletes repeatedly the leaf nodes in decreasing order of volume. It produced a merged pattern of nearby defects. The modified algorithm uses both the volume and area attributes. It repeats the operation of deleting the leaf nodes in decreasing order of volume. The algorithm exempts the leaf node from the deletion whose parent's area is less than a, where a is the predefined area threshold. If no leaf node is found any more, the process finishes. The n nodes with the largest volume are output as suspicious defects.

The experiments performed with actual SEM images and printed electronics images showed promising results. For a 1000*1000 image, the proposed algorithm ran whole process in 1.36 seconds.

Conference 9557: Nanobiosystems: Processing, Characterization, and Applications VIII

SPIE. OPTICS+ PHOTONICS NANOSCIENCE+ ENGINEERING

Monday - Wednesday 10–12 August 2015

DNA-based membranes: development and applications *(Invited Paper)*

François Kajzar, Mihaela Mindroiu, Gratiela Tihan, Ana-Maria Manea, Univ. Politehnica of Bucharest (Romania); Agnieszka Pawlicka, Univ. de São Paulo (Brazil); Ileana Rau, Univ. Politehnica of Bucharest (Romania)

In this paper we will present the results of our research on developing new deoxyribonucleic acid (DNA)-based conducting membranes for application in electrochromic devices. Improvements of performances of DNA-based solid bioelectrolyte in smart windows were achieved by adding plasticizer like glycerol and different amounts of photosensitive chromophores, such as Nile Blue. The results were obtained and analyzed by a variety of experimental tools and techniques such as FT-IR, UV–VIS spectroscopy, fluorescence, electric conductivity, contact angle, charge density measurements, and cyclic voltammetry. The biomembranes with the highest ionic conductivity values were successfully applied in smart windows with glass/ITO/WO3/DNA-based membranes/CeO2–TiO2/ITO/glass configuration which have shown a good change of transmittance under the applied electric field. The obtained results suggest that the DNA-based electrolytes are promising materials to be applied in electrochromic devices

Single molecule spectroscopy of conjugated polymers in solution *(Invited Paper)*

Ifor D. Samuel, Paul A. Dalgarno, Francisco Tenopala Carmona, Univ. of St. Andrews (United Kingdom); Stephanie Fronk, Guillermo C. Bazan, Univ. of California, Santa Barbara (United States); Carlos Penedo, Univ. of St. Andrews (United Kingdom)

Conjugated polymers are an important class of organic semiconductor that can readily be deposited from solution to make thin films for a range of optoelectronic devices including light-emitting diodes, solar cells and transistors. These in turn have been used to make biophotonic devices including a wearable light source for skin cancer treatment and a muscle contraction sensor. As the devices are made from solution, it is important to understand the polymer in solution including the influence of conformational disorder. Single molecule spectroscopy has been a remarkably effective tool in the study of biological molecules in solution, but so far its application to conjugated polymers has been restricted to solid films consisting of dilute blends of conjugated polymers with non-conjugated host polymers. We have developed a process to immobilise poly(3-hexylthiophone) on a surface and will report single-molecule fluorescence measurements of this polymer in solution.

9557-6, Session 2

Novel photonics polymers for 4K/8K real color display system in bio-imaging *(Invited Paper)*

Yasuhiro Koike, Keio Univ. (Japan)

The real-color and high-resolution display has been strongly required especially in medical- and bio-imaging fields. For example, with such an advanced display, very initial stage of cancer cell will be detected, which cannot be observed with a naked eye through conventional microscope. 4K/8K Liquid Crystal displays (LCDs) for these medical and bio-imaging applications have been intensively studied, however the color degradation deviated from real color has been a serious problem. Such a color degradation is mainly caused by the birefringence of several films used in LCD panel. We have proposed the zero-zero birefringent polymer which exhibit no birefringence even by both orientation of polymer chains and adding stress to polymer matrix. With this, the color degradation, especially color-shift caused by changing viewing angle, has been much improved. For transmitting required data signal for 4K/8K display, tremendously large bit rate such as 100 Gbps is needed, which means the paradigm-shift from electrical wire to optical fiber communication around 4K/8K displays. We have developed the world's fastest graded-index plastic optical fiber (GI POF) covering 40 Gbps, which is one of strong candidates for realizing such advanced imaging systems. Details of our photonics polymers towards 4K/8K systems will be described in my presentation.

9557-7, Session 3

Biological matrices for light amplification *(Keynote Presentation)*

Jaroslaw Mysliwiec, Konrad Cyprych, Lech Sznitko, Adam Szukalski, Kacper Parafiniuk, Andrzej Miniewicz, Marek Samoc, Piotr Hanczyc, Antoni C. Mitus, Grzegorz Pawlik, Wroclaw Univ. of Technology (Poland); Francois Kajzar,

Ileana Rau, Univ. Politehnica of Bucharest (Romania)

In recent years there has been a growing interest in biopolymers as functional materials for photonic applications. From the rich world of organic materials, biopolymers are of particular interest as they often exhibit unusual properties that are not easily replicated in conventional organic or inorganic materials. Furthermore, natural biomaterials are renewable resources and are inherently biodegradable. Here we show results of studies carried out on selected biological matrices doped with luminescent dyes for light amplification based on periodical gain or refractive index modulation, or on random but coherent light scattering in amplifying medium. The employed biological self-assembling templates were deoxyribonucleic acid (DNA), collagen, lysozyme type fibrils or starch. Laser action was studied in slab planar waveguides doped with dyes like Rhodamine, stilbene, Nile blue or derivatives of pyrazoline. It has been shown that simple incorporation of highly luminescent dye into a biopolymeric matrix can lead to efficient solid laser materials. Additionally, naturally occurring inhomogeneities of biopolymer layers prepared by a drop casting process can scatter emitted light in such a way that feedback is introduced to the system and coherent and incoherent random lasing can be observed. The mechanisms of diffusive transport of light, its amplification and randomization in biopolymeric matrices were studied theoretically in terms of non-standard diffusion approach, including sub/super diffusion.

9557-8, Session 3

Optical amplification in DNA-surfactant complexes incorporating hemicyanine dyes with long and short alkyl chains *(Invited Paper)*

Yutaka Kawabe, Yuki Suzuki, Chitose Institute of Science and Technology (Japan)

Hemicyanine dyes are promising materials for solid-state tunable dye lasers because of their high activity for light amplification and superior durability under optical pumping when doped in DNA-surfactant complexes [1]. A hemicyanine with a long alkyl chain, 4-[4-(dimethylamino) stylyl]-1-dococylpyridium bromide (DMASDPB or Hemi22) has been usually incorporated in the complex films prepared by various methods, demonstrating amplified spontaneous emission (ASE), laser oscillation and its wavelength tuning. While these achievements seemed to have confirmed the importance of intercalation or groove-binding of the dyes to DNA strand, our recent results for the hemicyanine and other dyes suggested that the influence from surfactant molecules was more essential than that from DNA itself [2].

Considering that dye-DNA interaction mode depended on the size and structure of molecules, another hemicyanine, 4-[4-(dimethylamino)stylyl]-1-methylpyridium iodide (DMASMPI or Hemi1) with methyl substituent instead of C22 of Hemi22, was doped in the complex for comparison. The dye had high solubility in water and gave fluorescence enhancement when dissolved in aqueous solution with DNA, indicating direct interaction between the dye and DNA double strand. DMASMPI also showed ASE under optical pumping with a threshold value nearly identical to that for DMASDPB. Lasing characteristics of the dyes and related topics will be presented.

Disorder and broad-angle iridescence from morpho-inspired structures *(Invited Paper)*

Bokwang Song, Seok Chan Eom, Jung Hoon Shin, KAIST (Korea, Republic of)

The ordered, lamellae-structured ridges on the wing scales of Morpho butterflies give rise to their striking blue iridescence by multilayer interference and grating diffraction. At the same time, the random offsets among the ridges broaden the directional multilayer reflection peaks and the grating diffraction peaks that the color appears the same at various viewing angles, contrary to the very definition of iridescence. While the overall process is well understood, there has been little investigation into confirming the roles of each factor due to the difficulty of controllably reproducing such complex structures. Here, we propose and fabricate Morpho-inspired structures with controlled random offsets. By selective etching of a monolayer of random-sized silica microspheres on a Si wafer, vertical offsets are controlled quantitatively. And directional deposition of 8 pairs SiO2/TiO2 multilayers generates their brilliant blue reflection. We find that while random offsets are necessary, it alone is not sufficient to produce the broad-angle reflection of Morpho butterflies. We identify diffraction as a critical factor for the bright, anisotropic broadening of the reflection peak of Morpho butterflies to a solid angle of 0.23 sr, and suggest random macroscopic surface curvature as a practical alternative, with an isotropic broad reflection peak whose solid angle can reach 0.11 sr at an incident angle of 60o. Furthermore, Morpho-inspired structures applying grating diffraction will be presented to fully reproduce the reflection of Morpho butterflies.

9557-11, Session 4

Nanoparticle-based biomimetic functional materials *(Invited Paper)*

Kuniharu Ijiro, Hokkaido Univ. (Japan)

Self-assembly originated from molecules, is ubiquitous from nature to unnature systems. The formation of double-stranded structure of DNA, virus, molecular crystals, liposomes etc. are all instances of molecular self-assembly. In the biological system, for example, virus is an impressive feat of molecular engineering by assembly of hundreds of proteins through the weak hydrophobic effect. We propose a robust strategy for the size-controllable fabrication of gold nanoparticle vesicles(AuNVs) which are biomimetic nanostructures of virus consisted of gold nanoparticles instead of proteins by using carbohydrate terminated fluorinated surface ligand self-assembly with 5~40nm AuNPs, indicating that carbohydrate can act as stronger molecular glue than oligo(ethylene glycol). Carbohydrate was introduced to tune the hydrophilic effect of the ligand by varying the number of glucose (namely, glucose, maltose, and maltotriose). AuNVs size could be efficiently controlled by varying surface ligands, water content in dioxane, and AuNPs size. We find some similarities between VLPs and AuNVs composed of 30nm gold nanoparticles. Photonic properties of not only AuNVs but also other self-assemblies of nanoparticles were measured. Strong surface-enhanced Raman scattering (SERS) of molecules were detected from the AuNVs and self-assembled gold nanoparticles.

9557-12, Session 4

Gold based hybrid nanosystems as potential agents for diagnostic and therapy *(Invited Paper)*

Frederic Lerouge, Ecole Normale Supérieure de Lyon (France); Julien R. G. Navarro, KTH Royal Institute of Technology (Sweden); Cristina Cepraga, BASF SE (France); Arnaud Favier, Marie Thérèse Charreyre, Denis Chateau, Frederic Chaput, Cyrille Monnereau, Chantal

Andraud, Patrice L. Baldeck, Ecole Normale Supérieure de Lyon (France)

The tremendous developments in the design of gold based nanomaterials opened the way to a lot of applications in nanomedicine. In this context optical nanosystems for imaging and/or therapy present a great interest. Recent works showed that sharp and edgy nanostructures appear to exhibit interesting features since their surface Plasmon band provide a strong field making them suitable for detection and therapy.

A complete study of bio compatible polymer functionalized gold nanostars and bipyramidal-like nanostructures will be presented. The synthesis of the nanoparticles will be described together with their photophysical properties, in suspension or on single objects. The use of multifunctional polymers enables their anchoring on the particles and their functionalization with organic dyes presenting interesting photophysical properties. Dark-field microscopy shows that the biocompatible gold nanoparticles are internalized after incubation with cancer cells. Finally, the study on these hybrid nanostructures is deepened, showing very interesting chromophore-particle interactions.

9557-13, Session 4

Solution-processed low dimensional nanomaterials with self-assembled polymers for flexible photo-electronic devices *(Invited Paper)*

Cheolmin Park, Yonsei Univ. (Korea, Republic of)

Self assembly driven by complicated but systematic hierarchical interactions offers a qualified alternative for fabricating functional micron or nanometer scale pattern structures that have been potentially useful for various organic and nanotechnological devices. Self assembled nanostructures generated from synthetic polymer systems such as controlled polymer blends, semi-crystalline polymers and block copolymers have gained a great attention not only because of the variety of nanostructures they can evolve but also because of the controllability of these structures by external stimuli. In this presentation, various novel photo-electronic materials and devices are introduced based on the solution-processed low dimensional nanomaterials such as networked carbon nanotubes (CNTs), reduced graphene oxides (rGOs) and 2 dimensional transition metal dichalcogenides (TMDs) with self assembled polymers including field effect transistor, electroluminescent device, non-volatile memory and photodetector. For instance, a nanocomposite of networked CNTs and a fluorescent polymer turned out an efficient field induced electroluminescent layer under alternating current (AC) as a potential candidate for next generation displays and lightings. Furthermore, scalable and simple strategies employed for fabricating rGO as well as TMD nanohybrid films allowed for high performance and mechanically flexible non-volatile resistive polymer memory devices and broad band photo-detectors, respectively.

Towards modeling of random lasing in dye doped bio-organicbased systems: ray-tracing ad cellular automaton analysis *(Invited Paper)*

Antoni C. Mitus, Krzysztof Lankowski, Pawe? Stopa, Witold Zaklukiewicz, Grzegorz Pawlik, Jaroslaw Mysliwiec, Wroclaw Univ. of Technology (Poland); François Kajzar, Ileana Rau, Univ. Politehnica of Bucharest (Romania)

One of many photonic applications of biopolymers as functional materials is random lasing resulting from an incorporation of highly luminescent dyes into biopolymeric matrix, which leads to a random but coherent light scattering in amplifying medium. In spite of numerous theoretical and experimental studies the origin of the coherence is still not clear and various scenarios are discussed. In particular, inhomogeneity of biopolymeric layers can hypothetically promote the feedback in the scattering of the emitted light resulting in coherent and incoherent random lasing. In this paper we analyze the light scattering in a model system of scattering centers of various shapes and dimensions using ray-tracing techniques. We analyze the conditions under which diffusive and localized (Anderson-localization-like) trajectories appear. Lasing in model systems is studied using a generalized version of cell-automaton model of Wiersma [1].

9557-17, Session 6

DNA-nucleobases: gate dielectric for flexible GFET-based sensor applications *(Invited Paper)*

Adrienne Williams, Fahima Ouchen, Steve S. N. Kim, Air Force Research Lab. (United States); Said Elhamri, Univ. of Dayton (United States); Eva M. Campo, A. Douglas Winter, Bangor Univ. (United Kingdom); Gregory Kozlowski, Wright State Univ. (United States); Rajesh R. Naik, James G. Grote, Air Force Research Lab. (United States)

In this study, physically vapor deposited (PVD) deoxyribonucleic acid (DNA) nucleobase guanine was physically vapor deposited (PVD) in the fabrication of test platforms in potential application in a bio-based field-effect transistor. Another test platform was fabricated by spin coat of polymethylmethacrylate (PMMA) as a gate dielectric onto PVD guanine as a passivation layer. These test platforms were used for comparison of the dielectric properties of the guanine and PMMA to an already-established gate dielectric material for organic thin film transistors. During this time, there were no observed changes in the graphene's transport properties due to guanine and PMMA layers. It appears that guanine does not affect the charge carrier mobility of the graphene, but PMMA decreases the mobility of graphene as a gate dielectric standalone. Other transport properties of the graphene, such as charge carrier concentration, conductivity type,

and resistivity were studied as well. These test platforms can be used as a potential device in biosensors, environmental, computer processing and graphene-based electronics.

9557-18, Session 6

Harvesting of living cell sheets from conjugated polymer surfaces via phothothermal disassembly of a protein layer *(Invited Paper)*

Eunkyoung Kim, Yonsei Univ. (Korea, Republic of)

Various types of cells, e.g. human mesenchymal stem cells (MSCs) and human dermal fibroblasts, were efficiently and selectively harvested by near-infared (NIR) light using the photothermal effect of a conjugated polymer (CP) nano-thin film. CP-coated substrates were prepared via a simple and fast solution-casting polymerization (SCP) technique. The absorption of CP thin films in NIR region was effectively triggered cell harvesting upon exposure to an NIR source. In the case of MSCs culture system, the proliferation and harvesting of MSCs on the PEDOT surface were controlled quantitatively by controlling the NIR absorption of the CP film through electrochemical doping. This light-induced cell detachment method based on CP films provides the temporal and spatial control of cell harvesting, as well as cell patterning. In the case of fibroblasts culture system, various patterned cell sheets were harvested via the photo-induced local heating of CP films that induced protein disassembly. Such disassembly of proteins allowed a fast detachment of a cell sheet with cell-to-cell interactions. This CP-based substrate can be used for repetitive culture and detachment of cells with no photodegradation and photobreakage in the CP films by NIR exposure.

9557-20, Session 6

Metal pattern formation by using DNA brushes *(Invited Paper)*

Hideyuki Mitomo, Satoshi Nakamura, Shigeaki Suzuki, Yasutaka Matsuo, Kenichi Niikura, Kuniharu Ijiro, Hokkaido Univ. (Japan)

DNA has attracted much attention as templates for the fabrication of nanodevices because of its characteristic double-helix structure and functional molecular recognition. Many kinds of DNA-templated nanomaterials such as nanowires or nanoparticle assembly have been reported. However, in many cases, systematic assembly of nanomaterials up to micrometer scale is required to make usable devices. In this study, we have prepared DNA brushes, those are brush-like structures composed of DNA polymers, through the immobilization of oligonucleotides through the streptavidin-biotin interaction and polymerization of them on glass substrates to develop a fabrication method of large scale metal pattern by using DNA as a template. The length and density of the DNA polymers on the prepared DNA brush were determined by gel electrophoresis and UV absorption measurements. 2D-patterned DNA brush was prepared by patterned denaturation of streptavidin through the UV irradiation. The height and morphology change of the DNA brushes depending on the external environments were observed by atomic force microscopy and fluorescence microscopy. When gold thin film was prepared on 2D-patterned DNA brush through vapor deposition, morphology change of the DNA brush formed 3D metal pattern like a press working of sheet metal. On the other hand, sequence-specific electroless plating on DNA were performed on block-copolymer type DNA brushes to fabricate 3D patterned metal array. These approaches using DNA brushes will work as novel fabrication method for 3D metal pattern.

9557-21, Session 6

Ordered auditory neuron growth on mirco-structured nanocrystalline diamond surface *(Invited Paper)*

Yixiao Cai, Fredrik Edin, Hao Li, Mikael Karlsson, Uppsala Univ. (Sweden)

Recently it has also been shown that nanocrystalline diamond (NCD) can be used for sensitive bio-sensors. Several surface modification methods for NCD has been developed and proteins and DNA has successfully been attached to the NCD surfaces. Previous experiment concerning cell response on NCD surfaces has mainly focused on certain surface chemical modifications, for instance surface termination by using plasma techniques (oxygen, hydrogen, fluorine, ammonia etc). Moreover, these studies have been exploring plain NCD surfaces. In our study we use textured NCD surfaces, consisting of micrometre-sized nail-head-shaped pillars, for neuron growth. The micro structured NCD surface was fabricated by a sequence of micro/nano-fabrication processes including sputtering, photolithography and plasma etching.

The textured NCD surface was created by a sequence of standard micro/nano-fabrication procedure including sputtering, photolithography and Bosch process of etching. A pattern was fabricated on top by utilizing lithography then followed by inductively coupled plasma (ICP) etching. Pillars of silicon with NCD/Al were thus fabricated and finally Al was etched away in a typical aluminium wet etch. The sample was cleaned again to insure a hydrophilic surface. The CVD system was employed for the following oxygen termination. The surfaces was cultured and incubated with neuron cells continuously for 1 week.

Primary findings reveal axonal growth along the NCD pillar pattern, indicating guided growth of auditory neurons. In this study, the axons were studied by scanning microscopy2 and it showed the potential biocompatibility of such micro-fabricated surface. The obtained morphology revealed a promising neuron guide between each pillar spatial pattern.

9557-22, Session PWed

Picogreen dye as an active medium for plastic lasers

Pradeep Chandran, Cochin Univ. of Science & Technology (India); C P G Vallabhan, Cochin University of Science and Technology (India); P. Radhakrishnan, V. P. N. Nampoori, Cochin Univ. of Science & Technology (India)

With the development of DNA Photonics, the double helical molecular structure has not lost its place being in prime focus among researchers and scientists. From being a biological entity, it has now transformed into a promising nanophotonic material. DNA has found its way to the field of Photonics, and has become a promising material in bio-organic light emitting diodes, bio-organic field effect transistors, light emitting transistors, high energy capacitors, bio-sensors, optical waveguides, optical switches, and as a host material for numerous lumophores/chromophores with enormous fluorescence amplification.

Picogreen is a fluorescent dye used as a probe for quantitation of double stranded DNA. In its pristine form the dye exhibits negligible emission characteristics, but is known to fluorescene with more than a thousand fold

enhancement in the presence of DNA. Such strong enhancement interested us to look out for its potential as lasing medium.

We have therefore fabricated modified DNA lipid complex intercalated with Picogreen dye thin film and observed amplified spontaneous emission at 568 nm and 560 nm while exciting at second and third harmonic frequency respectively from 10 Hz Nd:YAG laser. We estimated an ASE threshold at ~ 0.1 – 0.2 mJ with a spectral narrowing from 70 nm to 5 nm. The film of 3 ?m thick could sustain approximately 200 pulses of 1.5mJ, 532 nm laser radiation before the emission could degrade to 50% of the initial intensity. Here, we see that the DNA not only act as a host material but plays an important role in the luminescence of the dye molecules that could lead to the development of DNA lasers.

9557-23, Session PWed

Enhanced brightness from all solution processable biopolymer LED

Pradeep Chandran, International School of Photonics (India); Manoj A. G. Namboothiry, Indian Institute of Science Education and Research (India); C. P. G. Vallabhan, P. Radhakrishnan, V. P. N. Nampoori, International School of Photonics (India)

Since the discovery of light emission from polymers over two decades ago, especially conjugated polymers paved way for simpler technology viz. solution casting method to make light emitting devices. However in the past few years, biopolymers such as Deoxyribonucliec acid (DNA) has gained tremendous interest among researchers trying to develop BioLED. Marine derived DNA from salmon sperm has been exploited as biodegradeable polymeric material for photonic and electronic applications. Many devices such as optical waveguides, bio-organic light emitting devices, bio field effect transistors and bio sensors are at the research table with promising results. What the DNA could offer in LED application is multifold. Through the emerging field of 'DNA Photonics', it could be exploited as a biodegradable polymeric material for photonics and optoelectronics application. Apart from being biodegradable, abundant, inexpensive and renewable resource, they hold a unique optical and electrical properties. Being optically transparent in the visible region, electrically conductive, tunable resistivity from 1015 to 109 ?-cm by varying its molecular weight, suitable refractive index and dielectric constant, all yielding to be a promising material for optical and optoelectronic devices. Additionally, the HOMO (5.6 eV) and LUMO (0.9 eV) levels support hole transportation and also effectively block electrons enabling it to use as an electron blocking layer in LED which has resulted in increased brightness and luminous efficiency.

Motivated by the potential of DNA as an interesting material in the field of light emitting diodes, much research was directed to designing and developing BioLED. Here, we present the effect of thickness of electron blocking DNA layer in polymer LEDs. In this investigations, a blend of F8BT based green emitting polymer and PFO based blue emitting polymer was used as active layer. We also show an 8 fold increase in brightness of polymer LED by introducing PFN as electron injection and DNA:CTMA as electron blocking layer on either side of the polyfluorene active layer. It has been observed that the variation in thickness of DNA layer even at small values is very crucial.

9557-24, Session PWed

Photoresponsive behavior of azobenzene hybrid materials

Valentin Victor Jerca, "Costin D. Nenitescu" Institute of Organic Chemistry (Romania) and Univ. Politehnica of Bucharest (Romania); Florica Adriana Jerca, "Costin D. Nenitescu" Institute of Organic Chemistry (Romania); Ileana Rau, Ana-Maria Manea, Univ. Politehnica of Bucharest (Romania); François Kajzar, Univ. Politehnica of Bucharest (Romania) and Univ. d'Angers (France); Dan Sorin Vasilescu, Univ. Politehnica of Bucharest (Romania); Dumitru Mircea Vuluga, "Costin D. Nenitescu" Institute of Organic Chemistry (Romania)

Despite of the large number of publications devoted to the study of the E-Z-E isomerization phenomena [1, 2], deciphering the relationship between molecular structure and photo-orientation behavior still remains a problem that needs to be tackled. In accordance, when an azo molecule is substituted with various donor-acceptor groups very different photoresponsive behavior is observed [3]. Embedding azo-derivatives into an organic-inorganic matrix we expect very different behavior as compared to previous studies performed on similar organic polymers [4]. In the case of hybrid matrices, the polymer backbone can undergo different motions when the thermal relaxation of the azo derivative occurs, and can modify the kinetic parameters of the Z-to-E isomerization of the azo chromophore. This information is extremely useful in order to gain control over the overall response time of the material.

Herein, we describe the E-Z-E isomerization of four poly(methacrylate-co-methacryloxypropyl trimethoxy-silane) copolymers substituted with different azobenzene moieties in the side-chains (see figure). The E-Z photoisomerization rates and the reaction kinetics of the Z-E thermal relaxation of the copolymers were investigated in solid matrix (thin films) using UV-Vis spectroscopy. In addition, a comparison between the photoresponsive properties of these hybrid materials and similar organic polymers is made.

Conference 9558: Nanostructured Thin Films VIII

Wednesday - Thursday 12–13 August 2015

Part of Proceedings of SPIE Vol. 9558 Nanostructured Thin Films VIII

SPIE. OPTICS+ PHOTONICS NANOSCIENCE+ ENGINEERING

9558-1, Session Key

Optical coatings and metamaterials *(Keynote Presentation)*

H. Angus Macleod, Thin Film Center, Inc. (United States)

Most optical systems consist largely of a series of surfaces that are shaped and finished so as to manipulate the light in desired ways. Although they succeed in determining the direction of the light, they are less successful in assuring the quality. Modifying the quality of the light, most often in terms of its behavior with respect to wavelength and incident angle, is the task of an optical coating and virtually all optical surfaces in all optical systems carry such treatments. The typical coating consists of a number of thin layers exhibiting interference effects that yield a suitable performance. Unfortunately, coating performance is constrained by the normal properties of interference and this limits its capabilities. Coatings could benefit considerably from the use of metamaterials and those exhibiting a negative index of refraction would be of incredible value. Unfortunately such negative index still appears elusive. Negative refraction has been convincingly demonstrated particularly for p-polarization and this is certainly useful in a number of applications but metamaterials have not so far yielded the complete set of properties representing the true negative index that could transform the field of optical coating.

9558-2, Session 1

Inorganic polarization devices with optical function layers fabricated by glancing angle deposition technique *(Invited Paper)*

Akio Takada, Nobuyuki Koike, Eiji Takahashi, Dexerials Corp. (Japan)

Polarization devices such as polarizers and waveplates are indispensable for the polarization management in LCDs. Polymer thin films with several polarization functions have been widely used as these polarization devices. Recent trend of LCD projectors, especially in high-end models, towards higher brightness entails that polarization management under strong radiation from the light source is required in the optical unit. Because polymer devices are composed of organic materials, thermal durability would be limited. Therefore, the polarization devices with high thermal durability, namely the absorptive gird polarizer and form birefringent waveplate, were developed. These devices are composed only of inorganic materials and structured with periodic multilayer nanostructures. Glancing angle deposition (GLAD) technique was employed to fabricate their optical functional layers. The structure of the polarizers is featured with a tri-layer consisting of an absorptive layer and a thin SiO2 layer on sub-wavelength pitch gratings made of aluminum. The absorptive layer was deposited only on the top of the SiO2 layer by taking advantage of GLAD and several materials were investigated to optimize the optical properties. On the other hand, the birefringent layer of the waveplate was composed of Ta2O5+TiO2 and formed by the serial bideposition technique in which the azimuth of the substrate is rapidly switched by 180 degrees with each deposition during GLAD. The retardation value can be precisely controlled by the thickness of the birefringent layer. Optical and thermal characterization results showed that these inorganic polarization devices were suitable for the practical application.

9558-3, Session 1

Wideband antireflection coatings combining interference multilayers and a subwavelength structure prepared by reactive ion etching

Stephane Bruynooghe, Carl Zeiss Jena GmbH (Germany); Marcel Schulze, Friedrich-Schiller-Univ. Jena (Germany); Michel Challier, Michael Helgert, Diana A. Tonova, Michael Sundermann, Thomas Koch, Alexandre Gatto, Carl Zeiss Jena GmbH (Germany); Ernst-Bernhard Kley, Friedrich-Schiller-Univ. Jena (Germany)

Transparent multilayer stacks are commonly used to reduce Fresnel reflections in optical systems. It is well established that the refractive index of the outermost layer of an interference layer stack strongly influences the residual reflectance of wideband AR coatings and that the lower the refractive index of the last layer the better the AR properties. Some limitations for the residual reflectance are evident especially for low-index substrates since materials with very low refractive indices are unavailable in nature. In this work, SiO2 thin films were grown by physical vapour deposition and dry etched using a mask-less technology in a plasma containing a fluorine gas compound. During the plasma etching subwavelength stochastic structures which show low refractive index properties are formed using a so-called self-masking effect. The optical and structural properties of the SiO2 nanostructures are examined by spectroscopic ellipsometry, spectralphotometry and scanning electron microscopy. The dependence of the effective refractive index on the structure depth is determined using an optical model based on the effective medium approximation and the index function is discretized in a finite number of homogeneous layers. Owing to their low refractive index properties, the SiO2 nanostructures are combined as outermost layer with a multilayer system prepared by magnetron sputtering in order to realize an antireflective coating with low residual reflectance designed for the 400-900 nm spectral range on a low-index substrate. The AR properties will be presented together with the simulation of the optical properties and the morphology of the nanostructures.

9558-4, Session 2

Biomimetic anti-wetting materials: from molecules to surface properties *(Invited Paper)*

Frédéric Guittard, T. Darmanin, Univ. de Nice Sophia Antipolis (France)

Superhydrophobicity is characterized by the repellency of water on a surface with an apparent contact angles of water above 150° and various adhesive properties characterized by dynamic contact angle measurements. The potential applications of superhydrophobic materials are extremely wide and include anti-icing coatings, anti-corrosion coatings, anticorrosion coatings, anti-bacteria coatings, textiles, oil/water separation, water purification and desalinization, microfluidic devices, optical devices, batteries, sensors, drug delivery or heterogeneous catalysis. Recent advances in the potential applications of superhydrophobic materials will be carefully described in this presentation and a focus on surfaces built up from electrodeposition of conductive polymers. (see publications and review: www.unice.fr/interface)

9558-5, Session 2

Surface plasmon spectroscopy study of electron exchange between single gold nanorods and metal oxide matrix during hydrogen gas sensing

Michela Cittadini, Univ. degli Studi di Padova (Italy); Sean Collins, Paul Mulvaney, The Univ. of Melbourne (Australia); Alessandro Martucci, Univ. degli Studi di Padova (Italy)

The direct optical monitoring of electron exchange on single plasmonic nanoparticles, involved in chemical reactions with gas molecules, is one of the main challenges in the heterogeneous catalysis and gas sensing fields.

Catalysts are substances that speed up reactions by providing an alternative pathway with lower activation energy than that required for the uncatalysed reaction. A lot of research, both fundamental and applied, has been carried out to investigate how catalysts work and to increase their efficiency.

The present work shows how the use of Dark Field Microscopy (DFM) coupled with surface plasmon spectroscopy, enables the direct observation of the kinetics of H2 gas interaction with single gold nanorods (NR) coupled with Pt nanoparticles (NPs) and/or with metal oxide matrices. The plasmonic particles, gold NRs, act as optical probes, and enable the monitoring of the electron exchange through the measurement of their surface plasmon resonance (SPR) band shift. To improve the redox reaction kinetics, the Au NRs have been coupled with Pt NPs and embedded also into a TiO2 or ZnO low scattering matrix. The Au NRs, the Pt, TiO2 and ZnO NPs have been synthetized by colloid chemistry. Several samples made of bare Au NRs, or Au NRs coupled with only Pt NPs or with Pt and TiO2 NPs or with Pt and TiO2 have been deposited by spin coating on silica substrates.

The longitudinal Au SPR band shift has been monitored by DFM looking at the variation of the scattering spectrum of a single Au NRs in the presence of H2. Time-resolved measurements have been also conducted at fixed wavelength in order to monitor the kinetics of the H2 reaction. With such measurements it was possible to elucidate the importance of the adsorbed oxygen and the TiO2 matrix on the H2 reaction with the Pt NPs.

9558-6, Session 2

Real-time observation of drying kinetics and morphology evolution in organic bulk heterojunctions

Nusret S. Güldal, Tayebeh Ameri, Andres Osvet, Christoph J. Brabec, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany)

In organic photovoltaics field, an optimized bulk heterojunction film consists of an electron-donating conjugated polymer and an electron-accepting fullerene derivative, which is organized in a well phase-separated, yet interconnected network. This sensitive morphology, affecting the light absorption, exciton dissociation and subsequent charge generation-extraction, is determined by the film formation during solution casting under certain processing conditions. Therefore, a number of previous studies focused on characterizing the thin film formation during solution casting, mainly with in-situ grazing-incidence X-ray scattering methods, accompanied by various optical methods, such as ellipsometry/reflectometry and UV-VIS absorption. Although these studies provided invaluable information on the matter, the development of nanoscale morphology is yet to be fully understood.

The purpose of this study is to demonstrate a portable in-situ characterization chamber, which can characterize any organic/hybrid thin film during solution casting. The chamber is a miniature doctor blade under controlled atmosphere, equipped with white light reflectometry (WLR), photoluminescence (PL) and laser light scattering (LLS). WLR was used to monitor the thickness reduction of the thin film during the drying, enabling to establish a drying curve. LLS informed the time scale of aggregate/crystallite formation. PL monitored molecular arrangement and enabled the estimation of microstructure. The combined data is used to understand the competition between thermodynamics (e.g. solubility, miscibility) and kinetics of morphology formation. In this study, we measured different BHJ systems with binary and ternary solvent mixtures under different processing conditions, from which we built a roadmap for microstructure formation in organic thin films, used in organic photovoltaics.

9558-7, Session 2

Structural and electrical properties of N doped SiC nanostructures obtained by TVA method

Victor Ciupina, Univ. Ovidius Constanta (Romania) and Academy of Romanian Scientists (Romania); Cristian P. Lungu, National Institute for Laser, Plasma and Radiation Physics (Romania); Rodica Vladoiu, Gabriel Prodan, Univ. Ovidius Constanta (Romania); Eugeniu Vasile, Univ. Politehnica of Bucharest (Romania); Corneliu Porosnicu, National Institute for Laser, Plasma and Radiation Physics (Romania); Stefan Antohe, Univ. of Bucharest (Romania); Iuliana M. Stanescu, Marius Belc, Aurelia Mandes, Virginia Dinca, Univ. Ovidius Constanta (Romania); Sorina Iftimie, Univ. of Bucharest (Romania); Valeriu N. Zarovski, National Institute for Laser, Plasma and Radiation Physics (Romania); Virginia Nicolescu, Ceronav (Romania)

Ionized nitrogen doped Si-C thin films at 200°C substrate temperature were obtained by Thermionic Vacuum Arc (TVA) method. To increase the energy of N, C and Si ions, -400V, -600V and -1000V negative bias voltages was applied on the substrate. The 200nm thickness carbon thin films was deposed on Si and glass substrate and then 400nm, 600nm and 1000nm N-SiC coatings on carbon thin films was deposed. To characterize the structure of as-prepared N-SiC coatings, Transmission Electron Microscopy (TEM), High Resolution Transmission Electron Microscopy (HRTEM) and X-Ray and Photoelectron Spectroscopy (XPS) techniques was performed. The crystallinity of N-SiC thin films increase with increasing of acceleration potential drop, i. e. with energy of N, C and Si ions.

Electrical conductivity was measured comparing the potential drop on the structure with the potential drop on a series standard resistance in a constant current mode. To justify the dependence of measured electrical conductivity by the temperature, we assume a thermally activated electrical transport mechanism.

9558-8, Session 3

Constructive and destructive routes to prepare nanostructures on surfaces by low-energy ion beam sputtering *(Invited Paper)*

Bernd Rauschenbach, Leibniz-Institut für Oberflächenmodifizierung e.V. (Germany)

Low energy ion beam induced sputtering is a versatile tool for deposition and also erosion of surface materials. In this contribution results about the evolution of the surface topography during low-energy ion beam erosion with noble gas ions will be given. The destructive route is characterized that under certain conditions, given by the self-organization processes, the ion beam induced erosion process can lead to the formation of well-ordered nanostructures (dots and ripples) on the surface. In contrast, the deposition of sputtered material under glancing angle condition is a sophisticated constructive route to create nanostructures with custom-made structure geometries. The preparation of nanostructures on the base of both routes is demonstrated. At the end, potential applications of nanostructuring in different fields of technology will be discussed.

9558-9, Session 3

Absorption intensity tunability in the near infrared region using phase-change nanostructure

Abdurrahman Ozdemir, Safak Saraydemir, Bilal Barut, Hasan Kocer, Kara Harp Okulu (Turkey)

Nanostructured thin film absorbers embedded with phase-change material (PCM) can provide large level of absorption intensity tunability in the near-infrared region. Germanium Antimonide Tellurite (Ge2Sb1Te4-GST) was employed as the phase-change material in the designed structures. The structure is composed of a periodic grating-type array of 200 nm thick Au buried with 100 nm-thick GST layer from the top of the Au layer. The period of the gratings is 2 μm and in each period, GST width is 0.5 μm. GST was selected as the active PCM because its optical properties undergo a substantial change during a structural transition from the amorphous to the crystalline phase. The optical absorption properties of the designed structures with respect to the geometric and material parameters were systematically investigated using finite-difference time-domain computations. It was shown that absorption intensity in the near-infrared region was tuned from the near-perfect to the near-zero level by switching the PCM from its amorphous to crystalline states. The distributions of the electric field and absorbed power at the resonant wavelengths with respect to different phases of the GST were investigated to further explain the physical origin of the absorption tuning. This study provides a path toward the realization of tunable infrared absorbers for the applications, such as selective infrared emitters, infrared camouflage, sensors, and photovoltaic devices.

9558-10, Session 3

Optical and structural properties of noble metal nanoisLAND

Davide Bacco, Alain J. Corso, Francesca Gerlin, Paola Zuppella, Enrico Tessarolo, Marco Nardello, Maria G. Pelizzo, CNR-IFN UoS Padova (Italy)

Metallic nanostructures are widely studied because of their peculiar optical properties. They possess characteristic absorbance spectra with a peak due to plasmonic resonance. This feature is directly dependent on the nanostructures shape, size, distribution and environment surrounding them. This makes them good candidates for a variety of applications, such as localized surface plasmon resonance sensing (LSPR), surface-enhanced Raman scattering (SERS) and photovoltaics. A well established technique used to create nanoisland on flat substrates is performing a thermal treatment after the deposition of a thin metal film. While the most widely investigated metal in this context is gold, we have extended our investigation to palladium, which is interesting for sensing applications because it has an excellent hydrogen absorption ability. The morphological properties of the nanoisland depend mainly on the starting thickness of the deposited layer and on the annealing parameters, temperature and duration. The deposition and annealing process has been investigated, and the resulting samples has been tested optically and morphologically in order to optimize the structures in view or their application for sensing purposes.

9558-12, Session 4

Axions, surface states, and the Post constraint in electromagnetics

Akhlesh Lakhtakia, The Pennsylvania State Univ. (United States); Tom G. Mackay, The Univ. of Edinburgh (United Kingdom)

Surface states exist on certain bulk materials confined to bounded regions. We have formulated boundary-value problems to explore the effects of the surface states on the scattering signatures. Their solutions will be presented with a view to explaining certain aspects of the frequency-domain Maxwell equations and constitutive relations.

9558-13, Session 4

A multiple scattering approach to solving scattering problems by complex objects

Didier Felbacq, Univ. Montpellier 2 (France); Emmanuel Kling, Sagem (France)

There are many numerical approaches to solving the problem of the scattering of a wave by a bounded body. Roughly speaking, these methods can be devided into two families : direct space methods, where space is discretized and the field is calculated at the nodes of a grid and indirect space method, where a, basically, hilbertian basis is used and the field is obtained everywhere in space as a linear combinaison of, basically, Green functions. The Finite Difference, the Finite Element Method belong to the former, whereas the Discrete Dipole Approximation, Bloch wave expansion, possibly under the guise of Rayleigh expansion, or the Boundary Element Method belong to the latter. The list is of course not exhaustive. The direct space methods have the advantage of being able to deal with complex geometry, at the price of a high algorithmic complexity : it requires the use of specific tricks, e.g. Perfectly Matched Layers, in order to deal with the infinite domain. Conversely, indirect space methods handle intrinsically the radiation conditions and are generally simple to code, but are in general not well adapted to complex bodies, whether geometrically or because of their electromagnetic properties. In the present work, we describe a modal methods for solving the problem of the scattering by a bounded body for the Helmholtz operator. The method is very simple to implement and can deal with complex shaped and/or inhomogeneous bodies. It is related to the Discrete Dipole Approximation but is more general and conceptually simpler. The basic idea is that of de-homogenization : the body is decomposed into square cells that are small with respect to the wavelength and such that the permittivity $epsilon_m$ of the medium is constant there. Let d be the side of that cell. The cell is then replaced by a a cylinder of radius r and permittivity $epsilon_c$ such that $epsilon_m=1+(epsilon_c-1)pi r^2$. The convergence of the method is ensured by the homogenization result saying that the field diffracted by the collection of cylinders converges towards that diffracted by the original body as d tends to 0.

9558-14, Session 4

Nanoengineered composite materials with giant dielectric anisotropy

Tom G. Mackay, Univ. of Edinburgh (United Kingdom)

A nanoengineered composite material was considered in the long wavelength regime. It consisted of a random mixture of two isotropic dielectric component materials. Each component material was composed of oriented spheroidal particles. The Bruggeman formalism was used to estimate the permittivity dyadic of the corresponding homogenized composite material (HCM). The HCM was an orthorhombic biaxial material if the symmetry axes of the two populations of spheroids were mutually orthogonal and a uniaxial material if these two axes were mutually parallel. The degree of anisotropy of the HCM increased as the shape of the component particles became more elongated, with the greatest degrees of anisotropy being attained when the component particles were shaped as needles or discs. Hence, nanoengineered composite materials based on simple oriented component particles may be homogenized to realize extremely large degrees of anisotropy.

Nano-heterostructures based on solid solution HgCdTe

obtained using silver ion implantation

Ruslana S. Udovytska, Alexey B. Smirnov, Rada K. Savkina, Fiodor F. Sizov, V.E. Lashkaryov Institute of Semiconductor Physics (Ukraine)

Presented in this work are the results concerning formation of nano-heterostructures Ag2O-Hg1–xCdxTe (x = 0.2) on the surface of solid solution Hg1–xCdxTe (? ~ 0.223). Modification of this ternary chalcogenide semiconductor compound was performed using the method of doping the heterostructure samples with silver ions, which was followed by low-temperature treatment. The energy and dose of implanted ions were 100 keV and 4.8?1013 ?m-2, respectively, while duration of thermal treatment was 5 hours at the temperature 75º? in Ar atmosphere with the excess pressure 4 Pa. These semiconductor nano-heterostructures were characterized using impedance spectroscopy, SEM, AFM-microscopy and X-Ray diffraction. Impedance characteristics of the samples were studied using the impedancemeter Z-3000X within the frequency range 1 Hz...3 MHz with the amplitude of a sinusoidal signal 120 mV. Studied in this work are electro-physical and structural properties of the narrow-band semiconductor compound Hg(Cd)Te with the nano-heteroarchitecture Ag2O-Hg1–xCdxTe (x = 0.2) formed on its surface by using the method of ion implantation in the top-down approach. The state of sample surface was studied using the method of NanoScope Digital Instruments. The data of modelling in the TRIM_2008 determine profile for distribution and depth of localization for the embedded impurity in the sub-surface region of MCT as close to 100 nm. The results GI XRD obtained for irradiated samples confirmed the presence of a disturbed layer with the thickness close to 100 nm as well as formation of metal-oxide nano-heterostructures Ag2O-Hg1-?Cd?Te (? ~ 0.20) on the surface of Hg(Cd)Te solid solution.

Atomically thin adhesion promoter for highly stable silver nanowire film

Sungjun Lee, Hyungseok Kang, SungKyunKwan Univ. (Korea, Republic of)

In this manuscript, we demonstrated, for the first time, the atomically-thin conductive adhesion promoter of positively-charged reduced graphene oxide (rGO-NH3+) for transparent highly-stable AgNWs TCEs. The rGO-NH3+ layer was deposited by simple spray-coating onto polymeric substrate. The insertion of the rGO-NH3+ between AgNWs and polymeric substrate dramatically enhanced both chemical and mechanical stabilities of AgNWs. The AgNWs TCEs assisted with the adhesion promoter were extremely stable under harsh conditions including ultrasonication in various solvents, mechanical bending up to 3 % strain, and fatigue over 1000 cycles. This strong adhesion enhancement was originated from the charge transfer from the negatively-charged hydroxo- and oxo-groups onto AgNWs to the positively-charged protonated amine groups in rGO-NH3+, indicating the formation of ionic bonding. For comparison, positively-charged GO-NH3+ and commercial poly(allylamine hydrochloride) (PAH) were also applied as adhesion promoters. Notably, conductive rGO contributed a uniform current distribution of the mesh-type AgNWs. In addition, the 2D layered structure of atomically-thin rGO-NH3+ adhesion promoter could enhance the water protection properties of the AgNWs films, which is one of the important performance parameters for the water-proof electronic device applications of AgNWs TCEs.

Growth of Bi2O3 nanocones over large areas by magnetron sputtering

Li-Chia Tien, Ying-Hong Liou, National Dong Hwa Univ. (Taiwan)

Bismuth oxide (Bi2O3) is a multi-functional oxide semiconductor with various properties of interest such as high reflective index, high photoconductive response, luminescence and high oxygen-ion conductivity, potentially useful as optical coatings, electrodes of solid oxide fuel cells (SOFC), supercapacitors, visible-light activated photocatalysts, and gas sensors. Large areas of bismuth oxide (Bi2O3) nanocones were grown onto Si(001) substrates by magnetron sputtering. The samples were characterized by field emission scanning electron microscopy (FE-SEM), X-ray diffraction (XRD), transmission electron microscopy (TEM), and photoluminescence (PL). The obtained tapered nanostructures consist of high-density nanocones with diameters approximately 70–130 nm and lengths of 1–3 ?m. XRD results reveal that the Bi2O3 nanocones can undergo a phase transition from the ? to the ? phase at growth temperatures over 450°C. This phase transition was confirmed by TEM and PL. The growth mechanism of Bi2O3 nanocones was identified as grain boundary-assisted growth, in which a Bi seeding layer is crucial to the formation of the nanostructures. The results herein suggest that introducing a surface seeding layer may provide an effective way to grow various 1D nanostructures over large areas in high yield by magnetron sputtering.

Surface treatment of multiferroic thin films using nano-second Nd: YAG laser

Ola G. Allam, National Research Ctr. (Egypt); Yahia Badr, Cairo Univ. (Egypt)

Recent years have seen a huge interest in multiferroic materials for their application as sensors and actuators. However, the scarcity of these materials in single phase and the weak coupling of their ferroic components have directed the research towards multiferroic heterostructures. These systems operate by coupling the magnetic and electric properties of two materials. In this paper, thin films have been grown by chemical solution deposition (CSD) using spin coating technique using rotations peed of 4500 rpm and time of 50 s and dried at 120?C for 20 min The optical, dielectric, magnetic, ferroelectric, ferromagnetic and piezoelectric properties of thin films have been investigated by Uv-Vis spectrophotometer (300-2500) nm, X-Ray Diffraction (XRD), Vibrating Sample Magnometer (VSM), Transmission Electron Microscope (TEM), and Scanning Electron Microscope (SEM) respectively. PZT/CFO thin films sintered at different temperatures from 400°C temperature to 600°C. The as-deposited PZT/CFO show week piezoelectricity and the effective piezoelectric coefficient d33 because, the materials deposited on the films not only PZT layer, but also CFO layer which decrease the piezoelectricity of these films. PZT/CFO Films were then recorded an enhancement in all physical properties (dielectric, optical, structural, surface morphology and magnetic properties) as the sintering temperature increased. The images of thin film before and after treatment with Nd:YAG laser which have Power from 10 mW to 5300 mW, Pulse width: 7 ns, Repetition Rate: 10 Hz and wavelength spectrum in (IR, Vis) laser beam indicate that sample prepared before treated has a lot of porous and

agglomeration which decreases after treatment.

Growth and characterization of La(1-x) Srx MnO3 thin film prepared by pulsed laser deposition

Ali A. A. Abdel Gaied, National Institute of Laser Enhanced Sciences (Egypt)

La(1-x) Srx MnO3 (LSMO) is interesting material for applications as a cathode for solid oxide fuel cell (SOFC), magnetic sensors, electronics, and spintronics. Hydrothermal method was established and successfully scaled up to prepare LSMO (x=0.2, 0.3) nano powder and was characterized to be applied as a target to be deposited on Si (100) substrate by pulsed laser deposition (PLD). In this work, a series of thin films on silicon substrates by PLD are studied at different deposition conditions in high vacuum of ~2´10-6 Torr. The thin films are prepared by Nd: YAG laser (1064 nm) with 10 Hz repetition rate and 6 ns pulse duration. The substrate temperature and the laser parameters are employed to grow high quality of LSMO thin films on Si(100). Nanostructure of LSMO is an objective to study the possibility of using LSMO as a cathode for the SOFC. The film structure, morphology, and elemental analysis of the films are characterized by X-ray diffraction (XRD), field emission scanning electron microscope (FESEM), high resolution transmission electron microscope (HTEM), thermo gravimetric analysis (TGA), and differential scanning calorimetric (DSC).

Simulation and analysis of back scattered light in thin film solar cells with finite difference time domain method

Birhanu Tamene Abebe, Christoph Pflaum, Erlangen Graduate School in Advanced Optical Technologies (Germany)

Recent experiments show that there are localized modes in thin film solar cells as a result of nanostructured interfaces. This will enhance the performance of thin film solar cells by increasing absorption. In this paper we discuss modelling such problem and present the result obtained. A single junction structure with amorphous silicon as an active layer is used for the modelling. The nanostructured interfaces are modelled using data measured by Atomic Scanning Microscopy(AFM). Different stack models and AFM scans are used for comparison. The input wave is Gaussian pulse in time at femtoseconnd scale. Multiple simulations are performed with various pulse width to compare with the experiments. Once the simulation is finished, spatial and temporal Fast Fourier Transform(FFT) is performed on the reflected electric field. This is to analyse the angular and spectral composition of the reflected light. The simulation is done on high performance machines with highly parallel scheme to meet the demand of the big simulation domain.

Microwave plasma chemical synthesis of nanocrystalline carbon film structures and study their properties

Valery Timoshenkov, National Research Univ. of Electronic Technology (Russian Federation); Nikolay A. Bushuev, Federal State Unitary Enterprise (Russian Federation); Ravil Yafarov, Institute of Radio Engineering and Electronics (Russian Federation); Sergey Orlov, Dmitri Starykh, Molecular Electronics Research Institute (Russian Federation)

The self-organization effect of diamond nanocrystals in polymer-graphite and carbon films is detected. The carbon materials deposition was carried from ethanol vapors out at low pressure using a highly non-equilibrium microwave plasma. Deposition processes of carbon film structures (diamond, graphite, graphene) is defined. Deposition processes of nanocrystalline structures containing diamond and graphite phases in different volume ratios is identified.

The solid film was obtained under different conditions of microwave plasma chemical synthesis. We investigated the electrical properties of the nanocrystalline carbon films and identified it's from various factors. Influence of diamond-graphite film deposition mode in non-equilibrium microwave plasma at low pressure on emission characteristics was established.

This effect is justified using the cluster model of the structure of amorphous carbon. It was shown that the reduction of bound hydrogen in carbon structures leads to a decrease in the threshold electric field of emission from 20-30 V/m to 5 V/m. Reducing the operating voltage field emission can improve mechanical stability of the synthesized film diamond-graphite emitters. Current density emission at least 100 A/cm2 was obtained.

Nanocrystalline carbon film materials can be used to create a variety of functional elements in micro- and nanoelectronics and photonics such as cold electron source for emission in vacuum devices, photonic devices, cathodoluminescent flat display, highly efficient white light sources. The obtained graphene carbon net structure (with a net size about 6 ?m) may be used for the manufacture of large-area transparent electrode for solar cells and cathodoluminescent light sources.

Arrange an asymmetrical metal-dielectric multilayer as a low loss metamaterial

Yi-Jun Jen, Ci-Yao Jheng, Kun-Han Lu, Chien-Ying Chiang, National Taipei Univ. of Technology (Taiwan)

A metal-dielectric (M-D) multilayer has been applied as a subwavelength structure to exhibit negative index of refraction. Periodic MD multilayer or symmetrical five layered MDMDM multilayer has been arranged to exhibit equivalent complex refractive index with negative real part. As the extinction coefficient is much small than the index of refraction, the wave vector and Poynting vector are in opposite directions. How to reduce the extinction coefficient and raise the transmittance becomes an issue. In this work, the metal films within the multilayer are not arranged with the same thickness as well as dielectric films. Under the condition of subwavelength requirement, the thickness of each layer is tuned to increase the transmittance. The previous example of a five layered MDMDM as a negative index metamaterial at a wavelength of 363.8nm is adopted here to do the loss improvement. The previous MDMDM as an Ag and TiO2 multilayer is modified by tuning the thickness of each layer. The figure of merit is increased by a factor of 1.4. As the multilayer is arranged on a BK7 glass as a system of Air/MDMDM/glass, the transmittance could be 70% that is increased by a factor of 1.3. The near field simulation is also adopted here to observe the backward wave propagation a negative refraction phenomenon.

Helical structured thin films deposited at a glancing angle

Yi-Jun Jen, Ci-Yao Jheng, San Chan, Chien-Hoa Tseng, National Taipei Univ. of Technology (Taiwan)

Silver nanohelical structured thin films (NHF) were tried to be deposited on a glass substrate using glancing angle deposition technique. At a deposition angle of 89°, silver NHFs were fabricated by introducing liquid

nitrogen to flow under the backside of BK7 glass substrate. The temperature of substrate was reduced to be less than -100°C before deposition. The deposition rate has to be controlled to match the rotation speed of the substrate. Therefore the rotation speed is varied to reach an optimum value. The morphology of each silver NHF was measured and compared with other samples. The screwlike silver NHF is then derived by successful shadowing effect. The circular dichroism (CD) was measured over the visible regime. It is found that the CD values are similar to a previous result which was measured from the one-turn gold NHF grown on a seeded substrate. On the other hand, a linear polarized light is introduced to illuminate the NHA to observe the transmitted polarization state. It is found that the extreme change occurred at a wavelength of 600nm, the linear state of incident light is changed to elliptical polarization state with ellipticity of 0.327. This work is an approach to spiral-like metal nanostructures.

9558-40, Session PWed

Influence of low temperature on the morphology and optical property of a deposited silver nanorod array

Yi-Jun Jen, Ci-Yao Jheng, Jyong-Wei Huang, Yuan-Tai Chang, National Taipei Univ. of Technology (Taiwan)

The substrate cooling technique was introduced in glancing angle deposition to grow slanted silver nanorod array (NRA). The substrate cooling method was applied by introducing liquid nitrogen to flow under the substrate. The morphologies of Ag NRAs deposited with cooling and without cooling are compared in this paper. During deposition, the temperature on the backside of substrate was kept at -140°. The average width of Ag rods is successfully reduced to be 40nm by substrate cooling technique. The effect of substrate cooling on the average tilt angle of silver rods with respect to the surface normal is also measured. For the same deposition angle of 86°, the average tilt angle is 68° that is larger than that of rods grown under room temperature. The tangent rule that represents the relationship between deposition angle and tilt angle of rods is then corrected for low temperature. The associated obvious polarization dependent transmittance and reflectance spectra are also measured in this work. It is found that the difference between s-polarized transmittance and p-polarized transmittance of cooling Ag NRA is larger than that of uncooling Ag NRA. The difference is increased from 8% at a wavelength of 400nm to 3% at a wavelength of 700nm.

9558-41, Session PWed

Nanoengineered hyperbolic materials for optical sensing applications

Tom G. Mackay, The Univ. of Edinburgh (United Kingdom)

Anisotropic dielectric materials characterized indefinite permittivity dyadics (known as hyperbolic materials) are invested for possible optical sensing applications. Such materials present hyperbolic dispersion relations which only allow plane waves to propagate in certain directions. In contrast, anisotropic dielectric materials characterized positive-definite (or negative-definite) permittivity dyadics present elliptical dispersion relations which generally allow plane waves to propagate in all directions. The transition between hyperbolic and elliptical dispersion relations may be exploited for optical sensing. This phenomenon is investigated theoretically by considering the homogenization of a porous hyperbolic material which is infiltrated by an analyte-containing fluid. Factors taken into consideration include the shape, size, and orientation of pores in the hyperbolic material as well as its porosity.

Realization of highly transparent conducting thin films by R.F. Magnetron sputtering for photovoltaics

Saheer Cheemadan, Amiruddin Rafiuddin, Srinivasa R. Tippasani, M.C. Santhosh Kumar, National Institute of Technology, Tiruchirappalli (India)

The outstanding electrical and optical properties of transparent conducting oxides (TCOs) have been extensively studied for several decades in the fabrication of optoelectronic devices. Among TCOs, tin-doped indium oxide (ITO) possesses the dominant role in displays (LCDs) and photovoltaic applications. Due to scarcity and toxicity of indium predominant investigation for an alternative TCO is always a keen area of interest in the field of photovoltaics. In this particular research a novel multicomponent TCO has been realized by the mixture of cadmium oxide and zinc oxide with 90:10 and 80:20 ratios respectively. The multicomponent thin film deposition is made by r.f. magnetron sputtering system upon glass substrates. The parameters such as r.f. power and substrate temperature are varied to inspect the optimum multicomponent TCO films. The structural, morphological, electrical and optical properties of the deposited TCO are investigated. Among all examined samples it is observed, CdO:ZnO with ratio of 90:10 deposited at 250 degree and r.f. power at 70W possess an average of 90% transparency in the visible region. Electrical properties reveals the optimum multicomponent TCO possess lower resistivity value in the order of 10-4?.cm. It is perceived the presence of Cd component contributes higher mobility and conductivity to the charge carriers whereas transparency of the films is benefited by the presence of Zn component. The realization of indium-free, low cost multicomponent TCO film is expected to pave path for transparent electrode applications in the area of opto-electronics.

Statistical analysis of partial discharges evolved during aging of synthetic nanofilled polypropylene

Prathap Basappa, Charles M. Taylor Jr., Antwarn E. Watson, Rohitha Dhara, Norfolk State Univ. (United States)

Nano-meter sized particles added into the polymer matrix are of growing interest in the insulation industry. Nanofilled polymer show better performance in considerably reducing the space charge and electro luminescene, and increase in electrical breakdown strength and partial discharge resistance and longer life times of electrical insulation. With the addition of natural organo clay nanocomposite particles in isotactic PP matrix, it is reported that aging decreased the remnant breakdown strength of the nanofilled samples whereas, the base polymer is unaffected. It has been reported that under similar aging conditions, the space charge formed in synthetic nanofilled PP samples is more than that in natural nanofilled samples. The aspect ratio of the synthetic nanocomposites is larger compared to the natural nanocomposites which makes their distribution in the polymer matrix more uniform. This uniform distribution of synthetic nanofillers might affect the partial discharge characteristics of synthetic nanofilled samples when compared to the base polymer. This work is intended to study the effect of the inclusion of synthetic nanofillers of different wt % in the polymer matrix on its partial discharge characteristics. The samples will be aged at a constant electric field for a duration of 8 hours. The data regarding the PD characteristics like maximum PD discharge magnitude, mean discharge magnitude, weibull scale and shape parameters will be collected at regular and consistent time intervals. The obtained parameters will be statistically analysed with Time series analyses techniques to forecast and predict the PD behavior.

9558-44, Session PWed

Partial discharge characteristics and residual breakdown strength of natural nanofilled polypropylene films when aged with different voltage profiles

Antwarn Watson, Charles M. Taylor Jr., Rohitha Dhara, Prathap Basappa, Norfolk State Univ. (United States)

It is known from literature that several electrical characteristics such as PD Resistance of Polypropylene (PP) Films can be improved by homogeneous dispersion of Nanofillers into the polymer matrix. Enhancement of PD Characteristics of PP due to the incorporation of Nanofillers indicates an improvement in electrical insulation reliability of PP under high voltage conditions. Partial Discharge measurement is a well-established technique to evaluate the condition, quality and reliability of insulation like PP. In this work, effect of variation in aging voltage on PD characteristics of PP and its remnant breakdown strength will be investigated for unfilled (PP+0%) and natural Nanofilled PP (PP+2% & PP+6%) .Using PD measurement set up several AC voltages (multiple of inception voltage, Vi) will be applied on each sample for a duration of two hours and PD parameters such as average discharge; maximum discharge, Weibull Scale (?) and Shape Factor (?) of PD distribution etc. will be continuously acquired. Variation of applied voltage will influence PD characteristics because of different space charge accumulation threshold voltages for unfilled and Nanofilled PP samples. Above a threshold voltage rate of space charge accumulation is lower in Nanofilled PP than in base PP. Percolation limit of filler concentrations will also play a vital role on the variations in PD characteristics. Above a percolation limit discharges become higher because of the presence of surpassable double layers. After the completion PD measurement experiments, surface erosion of aged PP samples will be measured using Profilometer to investigate effects of change in applied voltage and Nanofillers concentrations on the PD Resistance of PP samples. PD resistance depends on several factors such as bonding between Nanofillers and Polymer Matrix at their interface and number of PD resistive layers in PP polymer matrix. Here, the effect of increasing electrical stress on PP samples on its PD resistance will be investigated. Using microscopic analyses degradation of PP samples will be measured which will provide more accurate information of PD Resistance. At the end, Breakdown Strength Measurement experiment of all unaged and aged PP samples will be conducted to dig into the effect of aging of PP samples on their breakdown strengths .Changes in aging voltage will affect the polymer morphology which will change the breakdown strength in turn .Two parameters (Scale Factor ? and Shape Factor ?) Weibull Distribution will be used to analyze breakdown strength of all samples. Comparison of PD characteristics of all samples (unaged and aged) will be done finally.

9558-45, Session PWed

Effect of type of aging voltage on the residual breakdown strength of polypropylene films with natural and synthetic nanofillers

Charles M. Taylor Jr., Antwarn Watson, Rohitha Dhara, Prathap Basappa, Norfolk State Univ. (United States)

Current literature indicates that the addition of nanometer sized particles into polymers such as Polypropylene (PP) can improve electrical, mechanical, and thermal properties. It is known that the Nanofilled PP performs better than the unfilled PP and there is significant improvement in the electrical characteristics like breakdown strength and PD resistance with the addition of small wt-% addition of nanofiller to the pure polymer matrix. Other workers have investigated into the short term behavior of the unfilled and Nanofilled PP among other polymers and observed that the stress conditions play an important role on the Nanofilled and unfilled PP behavior. When the applied stress is enough to lead to fast breakdown, the nanofilled PP behaves worse than the unfilled PP. However, the Nanofilled PP behaves better than the unfilled PP if the stress is below a particular threshold. In this paper, the investigation into remnant breakdown strength of natural and synthetic Nanofilled and unfilled PP is observed when aged under different types of voltage profiles. Synthetic and natural organoclay samples of 2wt-%, 4wt-%, 6wt-%, and 8wt-% were used in this experiment. The nanocomposites were aged under different aging conditions. They were exposed to constant voltage electric aging (constant voltage), an electric field that increases in a step fashion (step voltage), and an electric field that increases at a constant rate with time (ramp voltage). The various types of voltages were applied to the nanocomposites to observe how they would behave under different aging conditions. The aging conditions play a prominent role on the remnant breakdown strength of the samples as the PD characteristics which affect the sample performance change drastically with the type of aging voltage. During aging, the formation of space charge that causes change in PD characteristics depends on the electric field applied during aging. In the constant electric field aging, space charges formed have more time for their redistribution and the PD characteristics are mainly affected due to the space charges formed during the PD activity. To reduce the effect of space charge redistribution on the PD activity during aging, the samples are aged under an electric field which changes in a step fashion where the applied electric field changes every 10 minutes. To minimize or make the effect of space charge redistribution negligible on the PD characteristics an electric field which constantly increases with time is used. The erosion depth will be used to evaluate the Partial Discharge Resistance. Surface analysis will be conducted using a surface profilometer to measure the erosion depth and a 3D HIROX microscope will also be used to observe and quantify the degradation volume. Breakdown strength analyses will be done on all aged and unaged samples to evaluate the effect of PD on the remnant breakdown strength of samples with and without nanocomposites

9558-15, Session 5

Plasma-etched nanostructures for optical applications *(Invited Paper)*

Ulrike Schulz, Friedrich Rickelt, Peter Munzert, Norbert Kaiser, Fraunhofer-Institut für Angewandte Optik und Feinmechanik (Germany)

A basic requirement for many optical applications is the reduction of Fresnel-reflections. Besides of interference coatings, nanostructures with sub-wavelength size as known from the eye of the night-flying moth can provide antireflective (AR) properties. The basic principle is to mix a material with air on a sub-wavelength scale to decrease the effective refractive index. To realize AR nanostructures on polymers, the self-organized formation of stochastically arranged antireflective structures using a low-pressure plasma etching process was studied. An advanced procedure involves the use of additional deposition of a thin oxide layer prior etching. A broad range of different structure morphologies exhibiting antireflective properties can be generated on almost all types of polymeric materials. For applications on glass, organic films are used as a transfer medium. Organic layers as thin film materials were evaluated to identify compounds suitable for forming nanostructures by plasma etching. The vapor deposition and etching of organic layers on glass offers a new possibility to achieve antireflective properties in a broad spectral range and for a wide range of light incidence.

9558-16, Session 5

Low temperature near infrared plasmonic gas sensing of gallium and aluminum doped zinc oxide thin films from colloidal inks

Marco Sturaro, Univ. degli Studi di Padova (Italy); Enrico Della Gaspera, Commonwealth Scientific and Industrial Research Organisation (Australia); Alessandro Martucci, Massimo Guglielmi, Univ. degli Studi di Padova (Italy)

We obtained Gallium-doped and Aluminum-doped Zinc Oxide nanocrystals by non aqueous colloidal heat-up synthesis. These nanocrystals are transparent in the visible range but exhibit localized surface plasmon resonances (LSPRs) in the near IR range, tunable and shiftable with dopant concentration (up to 20% mol nominal). GZO and AZO inks can be deposited by spin coating, dip coating or spray coating on glass or silicon, leading to uniform and high optical quality thin films. To enhance absorbtion in the infrared region, samples can be annealed in inert or reductant atmosphere (N2/Argon or H2 in Argon) resulting in plasmon intensity enhancement due to oxygen vacancies and conduction band electrons density increment. Then IR plasmon has been exploited for gas sensing application, according to the plasmon shifting for carrier density variations, due to electrons injection or removal by the target gas/sample chemical interactions. To obtain a functional sensor at low temperature, another treatment was investigated, involving surfanctant removal by dipping deposited films in a solution of organic acid, tipically oxalic acid in acetonitrile; such process could pave the way to obtain similar sensors deposited on plastics. Finally, GZO and AZO thin films proved sensibility to H2 and NOx, and in particular circumstances also to CO, from room temperature to 200°C. Sensibility behavior for different dopant concentration and temperture was investigated both in IR plasmon wavelengths (~2400 nm) and zinc oxide band gap (~370 nm). An enhancement in sensitivity to H2 is obtained by adding Pt nanoparticles, exploiting catalytic properties of Platinum for hydrogen splitting.

9558-17, Session 5

Graphene-metal interfaces for biosensors devices

Paola Zuppella, Francesca Gerlin, Alain J. Corso, Davide Bacco, Enrico Tessarolo, Marco Nardello, Maria G. Pelizzo, CNR-IFN UoS Padova (Italy)

Graphene–metals interfaces are investigated in many subject areas both applicative and speculative. The interest mainly stems from the possibility for CVD synthesis of large area graphene on metals. In this case the metal act as a catalyst for complete dehydrogenetaion of hydrocarbon precursors that leaves carbon behind at the surface. Such bilayer are also very appealing for surface plasmon resonance devices, since graphene acts both as a protective layer and biorecognition element. Several pairs of graphene/metal interfaces have been studied in terms of SPR performance and physical-chemical properties at the interface. With regard to this last aspect, NEXAFS spectroscopy is a powerful method to study single–, double–, and few– layers graphene and to illustrate any evolution of the electronic states.

9558-18, Session 5

Microfluidic control on nano-plasmonic thin films using Marangoni effect

Kyoko Namura, Kaoru Nakajima, Kenji Kimura, Motofumi Suzuki, Kyoto Univ. (Japan)

Photothermal conversion of gold nanoparticles/dielectric layer/Ag mirror multilayered thin film is highly localized in the surface layer of the gold nanoparticles because of strong interference [1]. Therefore, a focused light on the thin film can be used as a localized and mobile point-heat-source at a micrometer scale. By using this spatio-temporally controlled photothermal conversion, we demonstrated thermally driven microfluidic control around a micro bubble.

The multilayered thin film was fabricated by the dynamic oblique deposition technique. On the film, a shallow cell with 50 ?m height was prepared. The cell was filled with water in which polystyrene spheres with a diameter of 2 ?m were dispersed in order to visualize the flow. Then, we focused a laser (wavelength: 785 nm) onto the sample to manipulate the fluid. The diameter of the laser spot was less than 10 ?m and the laser power at the sample surface was 12 mW.

When the laser was irradiated around a micro bubble with a diameter of ~ 60 ?m, a strong main flow towards the bubble and two symmetric rotation flow on either side of it develop because of the Marangoni effect. The shape of the rotation flow is controllable by the relative position of the bubble and the laser spot. The flow around the micro bubble can be understood in terms of light refraction and reflection at the bubble surface and actual photothermal conversion positions.

9558-19, Session 6

The optical and electronic properties of pyrite nanocrystals and solid thin film

Guangmei Zhai, Taiyuan Univ. of Technology (China) and Changzhou Univ. (China) and State Key Lab. of Electronic Thin Films & Integrated Devices (China); Rongwei Xie, Heng Wang, Jitao Zhang, Yongzhen Yang, Hua Wang, Xuemin Li, Xuguang Liu, Bingshe Xu, Taiyuan Univ. of Technology (China)

Pyrite FeS2 has been impeded by the exciting phase purity and defect issues in its application in cost-effective photovoltaic devices since it was first used as thin light absorber for solar energy conversion application in the mid-1980s. However, with the development and progress of nanocrystal-based approach which can use much milder processing condition, and in which surface chemistry and phase impurity issues might take on entirely new character, it is well worthwhile studying the properties of pyrite nanocrystals and solid films. In this work, we report on the optical and electronic properties of phase-purity pyrite nanocrystals (NCs) synthesized via hot-injection method. Also, the effect of surface chemistry of pyrite NCs on their optical and electronic properties was investigated. Our results show that the synthesized pyrite NCs and solid thin films have absorption up to the near infrared region and have an indirect bandgap of around 1.1 eV, exhibiting favorable optical property and bandgap energy for photovoltaic applications. The electron affinity and ionization potential of pyrite NCs passivated with various ligands including organic and atomic ligands were determined by the combination of cyclic voltammetry and optical absorption spectroscopy. It is found that up to 190 mV of energy level shift of pyrite NCs can be obtained between different chemical ligands employed here, indicating a strong dependence of electronic properties of pyrite NCs on their surface chemistry. It is believed that the optical property and energy levels determined here would provide valuable information for the design and fabrication of photovoltaic devices based on pyrite NCs in the future.

9558-20, Session 6

Investigation the stress of the SiOxCyHz thin film deposited by HMDSO/O2 plasma polymerization

Wei-Bo Liao, Ching-Long Cheng, Cheng-Chung Lee, National Central Univ. (Taiwan); Cheng-Chung Jaing, Minghsin Univ. of Science and Technology (Taiwan); Chien-Cheng Kuo, National Central Univ. (Taiwan)

Stress has always had a great impact of thin films. Large stress causes cracking, wrinkling, and peeling of thin films. The total stress of thin films includes intrinsic stress and thermal stress. The intrinsic stress is influenced by the deposition parameters such as the substrate temperature, the deposition rate, the working pressure, and the ion source parameters. The thermal stress is caused by a mismatch in the coefficient of thermal expansion of the thin films and the substrate when the structure is subjected to temperature changes during its fabrication and application. How to reduce the stress of thin films has become a very important issue. There are many ways to eliminate the stress of thin films, such as coating on both sides of the substrate, choosing the thin film materials and substrate. In this work, we used an organic thin film to reduce the stress of inorganic thin films. The organic SiOxCyHz thin film was deposited by plasma polymerization process used a mixture source gas by

hexamethyldisiloxane(HMDSO) and oxygen. Growing different properties of SiOxCyHz thin film by four parameters are the flow of oxygen and HMDSO, plasma beam current (Ii) and anode voltage (Vd). The inorganic layers were coated on the SiOxCyHz thin film to reduce the stress of inorganic layers. The transmittance of thin films was measured by Hitachi U4100 spectrometer. The thin film composition and structure has been investigated by X-ray photoelectron spectroscopy (XPS) and Fourier transform infrared (FTIR) spectroscopy. Analyzing the stress of thin films was investigated by phase shift interferometer.

9558-21, Session 6

Investigation of the optoelectronic characteristics of graphene/perovskite/ porous silicon nanowires heterostructure

Wun Wei Lin, National Taipei Univ. of Technology (Taiwan)

This paper focuses on the features of a structure graphene/perovskite/ porous silicon nanowires (PSiNWs). First, the SiNWs on the Si substrate were fabricated by metal-assisted chemical etching (MACE) method in the freshly prepared dilute solution containing HF (48%) and AgNO3 (0.02 mol L-1) (1:1) with different etching time at room temperature. After dipping the wafer in the etching solution, a thick Ag layer is formed on the surface of Si wafer. The wafer is then put into a diluted HNO3 solution (50 wt%) for a short period to remove the Ag layer. It shows that the PSiNWs may have different porosities depending on the etching time and the concentration of AgNO3 in the etching solution . Next, the perovskite is coated on the PSiNWs using a spin coating process at 5000 rpm for 60 s and followed by the rapid thermal annealing (RTA) process in the air at 70oC for 10 mins. Then, the graphene were deposited on the surface of perovskite/SiNWs structure with 2 mins, 5 mins and 10 mins by RF magnetron sputtering. After all, the sample is examined by Scanning Electron Microscope (SEM), Photoluminescence (PL), Hall Measurement. As the I-V curves and PL spectrum is obtained, the optoelectronic characteristics of graphene/ perovskite/PSiNWs and perovskite/PSiNWs two structures and the impact of changes in the thickness of graphene can be discussed.

9558-22, Session 6

Surface morphology of ultrathin graphene oxide films obtained by the SAW atomization

Olga Balachova, Sergey Balashov, Ctr. de Tecnologia da Informacao Renato Archer (Brazil); C. A. S. Costa, Ctr. Nacional de Pesquisa em Energia e Materiais (Brazil); Aristides Pavani Filho, Ctr. de Tecnologia da Informacao Renato Archer (Brazil)

Lately, graphene oxide (GO) thin films have attracted much attention: they can be used as humidity-sensitive coatings in the surface acoustic wave (SAW) sensors; being functionalized, they can be used in optoelectronic or biodevices, etc.

In this research we study surface morphology of thin GO films obtained on Si, LiNbO3 and quartz substrates by successive atomization of submicroliter droplets of aqueous suspension of GO by the SAW atomizer. The advantages of this method are that it allows controlling a process of film deposition, working with microvolumes of liquids and minimizing the “coffee-ring” effect. Deposited films were examined using AFM and electron microscopy. The films may form discrete or continuous coatings at the surface of the substrates with the minimum thickness of 2.5-3 nm which corresponds to few monolayers of GO. The thickness and quality of the deposited films depend on the parameters of the SAW atomization (number of atomized droplets, a volume of the initial droplet, etc.) and on sample surface preparation (activation in oxygen plasma). We study the structure of the obtained films and discuss the uniformity and the degree of the surface coverage as a function of parameters of the film deposition process and sample preparation. Qualitative analysis of adhesion of the films is made by controllable immersion of them into water and subsequent evaluation of morphology of remained films.

9558-23, Session 7

Periodic nanostructures for tunable thin optics *(Invited Paper)*

Francesco Simoni, Univ. Politecnica delle Marche (Italy); Luigino Criante, Istituto Italiano di Tecnologia (Italy) and Univ. Politecnica delle Marche (Italy); Francesco Scotognella, Luca Passoni, Istituto Italiano di Tecnologia (Italy) and Politecnico di Milano (Italy); Francesco Fumagalli, Istituto Italiano di Tecnologia (Italy); Guglielmo Lanzani, Istituto Italiano di Tecnologia (Italy) and Politecnico di Milano (Italy); Fabio Di Fonzo, Istituto Italiano di Tecnologia (Italy)

We report here realization and characterization of porous nanostructures where a periodic refractive index modulation is achieved by stacking layers with different nano-architectures.

One multilayer photonic crystal has been fabricated starting from colloidal dispersion of silicon dioxide and zirconium dioxide using spin coating technique. Improved efficiency of Bragg reflectivity (up to 85% with submicron thickness) has been obtained by an alternative method based on self-assembly from the gas-phase. Due to the high porosity, these systems can be infiltrated with many fluids (liquid/gas). Using nematic liquid crystals, the Bragg reflection band by applying low voltages to the structure can be tuned.

9558-24, Session 7

Effects of silver-nanoparticle layer in chiral sculptured thin films for multiplasmonic sensing

Stephen E. Swiontek, Akhlesh Lakhtakia, The Pennsylvania State Univ. (United States)

Multiple surface-plasmon-polariton (SPP) waves can be guided by the interface of a metal and a chiral sculptured thin film (STF). These multiple SPP waves can be used for more reliable sensing of analytes with high sensitivity, when compared to a single SPP wave in traditional single-SPP-wave scenarios.

An ultra-thin layer of silver nanoparticles can be deposited via physical vapor deposition at different depths of the chiral STF. That layer can eventually act as a site to bind recognition molecules to which analytes of a certain type can attach.

A lanthanum-fluoride chiral STF was deposited on top of a 30-nm-thick aluminum film. An ultra-thin layer of silver nanoparticles was deposited at a certain depth of the chiral STF in order to observe the effects that the nanoparticles have on the multiple SPP waves that were launched. Several samples were then deployed in the Turbadar–Kretschmann–Raether (TKR) configuration. The effects of the depth of the silver-nanoparticle layer in the chiral STF on the angular locations of multiple SPP-wave modes were investigated to determine the optimal depth for multiplasmonic sensing of multiple analytes in aqueous solutions.

9558-26, Session 7

Phoxonic one-dimensional heterostructure with photonic and phononic band gaps at the same frequency

Jesus Manzanares-Martinez, Paola Castro-Garay, Betsabe

Manzanares-Martinez, Univ. de Sonora (Mexico); Damian Moctezuma-Enriquez, Ctr. de Investigación en Materiales Avanzados, S.C. (Mexico); Yohan Jasdid Rodriguez-Viveros, Carlos Ivan Ham-Rodriguez, Univ. de Sonora (Mexico)

The concept of phoXonic Crystals (PxC) has recently been introduced to define a novel class of composite material that allows the simultaneous existence of Photonic and Phononic Band Gaps (PtBG and PnBG, respectively). The periodicity in the dielectric function and in both the elastic constant and densities, allow under certain conditions to obtain ranges of frequency where the electromagnetic and mechanical vibrations can be forbidden.

The PxC can be designed to confine light and sound at a common wavelength. However, the confined waves are of different frequencies and therefore it is required some nonlinear mechanism to couple light and sound.

In this work, we explore for the first time the design of a thin-film based heterostructure where can be obtained a coincidence for the photonic and phononic band gaps.

Our numerical results allow to identify a narrow phoxonic band gap at the GHz regime. We have also explored the behavior of this band gap for the off-axis propagation considering the projected band structure calculation and the oblique incidence for the impinging waves. We consider that the design of an heterostructure with photonic and phononic waves at the same frequency allow to enhance the electromagnetoelastic interaction in piezoelectric materials.

9558-27, Session 8

Self-assembling of molecular nanowires for enhancing the conducting properties of discotic liquid crystals

Ji Hyun Park, Kyungho Kim, Seoul National Univ. (Korea, Republic of); Yoichi Takanishi, Jun Yamamoto, Kyoto Univ. (Japan); Yung Woo Park, Youn Sang Kim, Seoul National Univ. (Korea, Republic of); Giusy Scalia, Seoul National Univ. (Korea, Republic of) and Univ. du Luxembourg (Luxembourg)

The self-organization of discotic liquid crystal molecules in columns has enormous interest for soft nanoelectronic applications. A great advantage of discotic liquid crystal is that defects can be self-annealed in contrast to typical organic materials. Through the overlap of molecular orbitals, the aromatic cores assemble into long range one-dimensional structures. Very thin structured films can be obtained by spin-coating from solution and the resulting morphologies are strongly dependent on the interaction between discotics and solvent molecules. The presence of substrates play an important role in the formation and organization of the nanowires but other factors also contribute. In particular, we have analyzed the effect of solvents, evaporation conditions and the role of interfaces. We have evaluated the arrangement of the molecules in the as-prepared films by Atomic Force Microscopy and by polarizing optical microscopy, when the film features are optically detectable. In addition, x-ray scattering and polarized Raman spectroscopy were performed for understanding the structural organization of the molecular nanowires on substrates. Finally, high control of the overall morphology was confirmed by electrical measurements with one order of magnitude higher conductivity in an aligned sample compared to non-aligned one.

9558-28, Session 8

Room temperature deposition of highly dense TiO2 thin films by filtered cathodic vacuum arc

Elena Guillén, Irene Heras, Gonzalo Rincon Llorente, Abengoa (Spain); Frank Lungwitz, Helmholtz-Zentrum Dresden-Rossendorf e. V. (Germany); Mercedes Alcon Camas, Ramon Escobar, Abengoa (Spain)

Titanium dioxide is a wide band-gap semiconductor used in many energy-conversion and environmental applications. TiO2 properties depend to a great extent on the deposition technique applied for its fabrication. In particular, physical vapor deposition (PVD) techniques are the preferred ones for those applications in which long-term stability and controllable optical properties play an important role. By filtered cathodic vacuum arc (FCVA), it is possible to obtain films with excellent properties deposited at room temperature. This technique produces highly dense films with a good interlayer adhesion due to a high ionization during the plasma deposition. In addition, surface roughness is very low due to the use of magnetic filters. For those reasons, FCVA is a potential alternative to magnetron sputtering as a suitable technique for optical thin film deposition on an industrial scale.

In this work, we carry out a systematic study of TiO2 deposition by FCVA. We have investigated the obtained films for various deposition parameters, analyzing their composition by Rutherford backscattering spectroscopy (RBS), their structure by X-ray diffraction and Raman spectroscopy, their morphology by scanning electron microscopy (SEM) and contact angle, and their optical properties by ellipsometry and reflectance measurements. Optical constants measured by ellipsometry are used as input data for simulation with optical software CODE. RBS measurements showed that resulting films exhibit TiO2 stoichiometry, with porosity below 4%. Contrary to other deposition techniques, no post annealing treatment is needed with FCVA, obtaining transparent, dense TiO2 films in the rutile phase at room temperature.

9558-29, Session 8

Deposition and characterization of Fe-Si based ionic glass thin films

Neil R. Murphy, Air Force Research Lab. (United States); Lirong Sun, General Dynamics Information Technology (United States); John G. Jones, Air Force Research Lab. (United States); John T. Grant, General Dynamics Information Technology (United States)

Ionic glass thin films composed of iron oxides within a dielectric silicon dioxide matrix are deposited by way of reactive co-sputtering. The valence states of the iron oxides are varied through manipulation of the voltage applied to the iron cathode under a constant flow of the reactive oxygen and argon gas mixture. To fabricate these films, a continuous power of 100 watts is applied to the Si cathode, while the Fe cathode power was systematically varied between 20 and 80 watts. Increasing the power applied to the Fe cathode gives rise to an increased flux of metallic atoms, ultimately leading to reduction in the oxygen partial pressure within the chamber via chemisorption. As the oxygen partial pressure decreases, the fraction of Fe within the film increases while the valence state drops from Fe3+ to Fe2+. The transition from Fe3+ to Fe2+ is associated with a large enhancement in NIR absorption and a decreased level of visible absorption. Systematic adjustment of the fraction and valence state of the Fe cations within the dielectric SiO2 matrix allows for a large degree of control over the coloration and NIR absorption behavior of the FexSiyOz films. The ability to control the response of the spectral absorption within visible and NIR wavelengths makes the FexSiyOz thin films a promising candidate for the replacement of lossy metallic materials currently used within induced transmission filters and plasmonic applications.

9558-30, Session 8

Fabrication and characterization of film coatings of silver nanoparticles with different composite agents

Vasyl J. Syrvatka, Yurij I. Slyvchuk, Ivan I. Rozgoni, Institute of Animal Biology NAAS (Ukraine); Nestor O. Piasetskyi,

Ivan Franko National Univ. of L'viv (Ukraine); Oksana V. Shtapenko, Ivan I. Gevkan, Institute of Animal Biology NAAS (Ukraine); Oleksandr I. Bilyy, Roman Y. Serkiz, Ivan Franko National Univ. of L'viv (Ukraine); Iryna O. Matyukha, Svitlana V. Fyodorova, Institute of Animal Biology NAAS (Ukraine)

Unique chemical and optical properties make silver nanoparticles diagnostically relevant as they have the ability to interact with important biomolecules such as DNA and proteins. The main aim of the study was to investigate film coatings of silver nanoparticles with different composite agents for their prospect application as an optical sensors or biomarkers. Silver nanoparticles were prepared by using the chemical reduction of silver nitrate by sodium borohydride. Hyaluronic acid, polyvinylpyrrolidone and polyvinyl alcohol were used as composite agents. Film coatings of silver nanoparticles were done by evaporation at the different temperatures from -60° to +38° C. The structural changes of silver nanoparticles under influence of different chemicals were studied. Ultraviolet-visible spectroscopy was used for examination of surface plasmon resonance band of silver nanoparticles at the all stages of the experiment. Scanning and transmission electron microscopes were used for visualization of structures of film coatings of silver nanoparticles. Energy-dispersive X-ray spectroscopy was used for elemental analysis of the sample surface. The results showed that film coatings of silver nanoparticles have strong optical properties. Furthermore different chemicals lead to structural changes of nanoparticles and modification of their optical properties. Therefore the film coatings of silver nanoparticles have distinctive optical properties and can be applied as optical sensors or biomarkers.

9559-17, Session PMon

New trends in solar

Divya Mereddy, Mounica Gampa, Vijay Ram Raju V., Gokaraju Rangaraju Institute of Engineering & Technology (India)

Abstract— Photo voltaic cell (PV cells) is one of the methods of converting solar power to electric power. It consists of semi conductors which exhibit the photovoltaic effect and converts the solar energy to direct current. The output power of the PV cells depends on the angle of incidence of sunlight. These cells are able to produce maximum power only as long as the light rays are perpendicular to the panel's surface. The position of the sun is not stationary so the angle of incidence also changes with time, thereby performance of solar panel also changes with time. By moving the solar panel the panel plane is made always perpendicular to sun rays, so that we can get more efficiency. This is called solar tracking. Depending on the number of axes the panel is moved trackers are differentiated as dual axes and single axes mainly. Single axes tracker can give a good output when the sun's path is stationary, but as it changes with season dual axes tracker gives more efficiency irrespective of the sun's path by following the sun in two axes. In this paper, dual axes solar tracker construction and dual axes method importance over single axes tracking will be explained.

9559-1, Session 1

Fresnel lens characterization for solar concentration efficiency

Christi K. Madsen, Mark Hallam, William Harris, Texas A&M Univ. (United States)

Due to the inexpensive and light weight nature of Fresnel lenses, they are key components in many solar energy concentration systems. The ability to effectively characterize Fresnel lenses over large areas is essential to verifying their system performance and efficiency. Under high concentration, it becomes impractical to perform detailed spatial and spectral measurements under full sun conditions. We have developed a method to characterize large Fresnel lenses for concentrating solar applications. Our Lens Characterization Unit (LCU) analyzes the resultant pattern of an incident laser beam which may be scanned across the lens. Using the LCU, we can evaluate the portion of diffracted light that is concentrated on the receiver area at each incidence point. The wavelength dependence may be quantified using lasers at different wavelengths and the angle of incidence may also be varied.

9559-2, Session 1

Demonstration of an intermediate-scale lens-to-channel waveguide solar concentrator

Ran Huang, Yuxiao Liu, Christi K. Madsen, Texas A&M Univ. (United States)

Solar concentrating photovoltaic systems have the potential to reduce total cost and achieve higher efficiency by replacing a large solar cell surface with cheaper optical devices, in which a large area of light can be efficiently collected and concentrated to a small optical device and guided to an array of co-located photovoltaic cells with high optical efficiency. We will present an experimental demonstration for an intermediate-scale lens-to-channel waveguide solar concentrator, in which the sun collected area is much larger than our prior demonstration. In this work, an 8x8 60 mm diameter lens array and a PMMA multimode waveguide are used as the primary concentrator and the secondary concentrator, respectively. A 45 degree coupler is fabricated to the waveguide to reach the maximum coupling efficiency and to avoid any inherent decoupling loss. In order to achieve higher concentration and a compact structure, a tapered waveguide is integrated to this design, which allows more lenses in a row of the lens array. Simulations indicate that the newly designed lens-to-channel waveguide solar concentrator can have 400x-1000x concentration. The fabrication details of the prototype device will be presented. A critical requirement for this design is maintaining low waveguide propagation losses, which we demonstrate can be less than 0.2 dB/cm.

9559-3, Session 1

Direct transmission of concentrated solar radiation via optical fibre bundles to thermal applications

Maryam Rahou, John Andrews, Gary Rosengarten, RMIT Univ. (Australia)

A challenge in high-temperature solar thermal applications is transfer of concentrated solar radiation to the load with minimum energy loss. The use of a solar concentrator in conjunction with bundled optical fibres has advantages in terms of transmission efficiency, and cost-effectiveness compared to a conventional heat transfer system employing heat exchangers and a heat transfer fluid. In this paper, the transmission from a solar concentrator into and through an optical fibre bundle over distances of up to 100 m is estimated using simulation results. A key input to the simulation is the angular distribution of radiation intensity at each point in the aperture plane of the optical fibres. This distribution depends on the optical properties of the solar concentrator. Two different concentrators are investigated to produce the collimated beam incident on the optical fibre bundle: a parabolic dish reflector with a small secondary mirror at a common focal point, producing a collimated beam issuing from a hole at the centre of the dish; and a Fresnel lens with a point focus with a small diameter converging lens located just after this focus. Since solar radiation comprises a broad band of wavelengths, each with very limited spatial coherence, interference effects can be neglected. Hence a ray tracing model is employed covering absorption within the fibres and losses at internal reflections. The intensity of the radiation across the exit plane of the fibre is found by integrating across all directions and wavelengths at each point. For a 15 mm diameter bundle comprising some 27 000 individual low OH fibres, the average transmission per metre length of fibre was found to be 72% with the parabolic reflector, and 65% with the Fresnel lens. Around two thirds of the loss occurred at the entrance plane to the bundle, due to absorption in the packing material between the individual fibres.

Fabrication and comparison of selective, transparent optics for concentrating solar systems

Robert A. Taylor, Yasitha Hewakuruppu, The Univ. of New South Wales (Australia); Todd Otanicar, The Univ. of Tulsa (United States)

Concentrating optics enable solar thermal energy to be harvested at high temperature (>100oC). As the temperature of the receiver increases, radiative losses can become dominant. In many concentrating systems, the receiver is coated with a selectively absorbing surface (TiNOx, Black Chrome, etc.) to obtain higher efficiency. Commercial absorber coatings are well-developed to be highly absorbing for short (solar) wavelengths, but highly reflective at long (thermal emission) wavelengths. If a solar system requires an analogous transparent, non-absorbing optic – i.e. a

cover material which is highly transparent at short wavelengths, but highly reflective at long wavelengths – the technology is much less mature.

Low-e glass partially fulfills this need, but only transmits ~60% of the full solar spectrum. Optically thin metal films with hole-arrays are another feasible solution, but are often difficult to fabricate. This study investigates combinations of thin film coatings (transparent conductive oxides) and nanoparticle depositions as potential low cost solar covers which can improve upon low-e glass. To our knowledge these materials have not yet been designed and optimized for solar energy applications.

This paper experimentally compares readily available materials deposited on various substrates (quartz, low-e glass, clear glass, and acrylic) and ranks them via an 'efficiency factor for selectivity', which represents the efficiency of radiative exchange in a solar collector. Out of the materials studied, indium tin oxide and thin films of ZnS-Ag-ZnS represent the most feasible solutions for concentrated solar systems. Overall, this study provides an engineering design approach and guide for creating scalable, selective, transparent optics.

9559-5, Session 2

High-temperature selective solar thermal absorber based on Fabry-Perot resonance cavity

Hao Wang, Liping Wang, Arizona State Univ. (United States)

In this work, we will design, fabricate, and characterize a multilayer selective solar absorber made of tungsten and MgF2 thin films. Thin-film optics along with the particle-swam optimization method is used for the optimal design of this novel selective absorber. The selective absorber shows spectral absorptance within solar spectrum as high as 95% and infrared emittance as low as 4%, due to the Fabry-Perot resonance and anti-reflection effect. The designed multilayer solar absorber structure will be fabricated on wafer scale with sputtering and e-beam evaporation. Optical and radiative properties for the fabricated sample will be characterized at both room and high temperatures. An FTIR spectrometer and integrating sphere are available for measuring the specular and hemispherical reflectance at room temperature. A novel FTIR fiber optics setup will be employed to study the normal reflectance at mediate temperatures up to 400°C. More importantly, a home-built high-temperature emissometry facility will be used to directly measure the spectral-directional emittance at high temperature up to 1000°C.

Theoretical calculation estimates a solar-to-thermal efficiency of 90% with x800 concentration at an absorber temperature of 1000°C for the designed multilayer solar absorber. In order to experimentally test the conversion performance and high-temperature stability, a solar simulation with concentrating optics will be used to heat up the sample in a box vacuum chamber, and the stagnation temperature will be measured with different concentration factors. Such a high-performance, high-temperature, low-cost selective solar absorber will greatly increase the performance of various solar thermal systems, especially CSP systems.

9559-6, Session 2

Solar selective coatings based on carbon:transition metal nanocomposites

Irene Heras, Elena Guillén, Abengoa Research (Spain); Matthias Krause, Helmholtz-Zentrum Dresden-Rossendorf e. V. (Germany); AInhoa Pardo, Fundació CTM Ctr. Tecnològic (Spain); Jose Luis Endrino, Ramon Escobar, Abengoa Research (Spain)

Carbon:Transition Metal nanocomposites were grown by filtered cathodic vacuum arc (FCVA). The metal content was determined by Rutherford backscattering spectroscopy (RBS) and nuclear reaction analysis (NRA). The structure was analysed by X-Ray diffraction (XRD) and Raman spectroscopy measurements. High resolution transmission electron microscopy (HRTEM) images show the formation of multilayers in the nanocomposite. The optical properties of the deposited coatings were characterized by a combination of ellipsometry, UV-Vis spectrophotometry and FTIR measurements. The reflectance spectra of the films were simulated with the optical software CODE and good agreement between simulated and measured reflectance spectra was found.

9559-7, Session 2

Coupled optical-thermal-fluid and structural analyses of novel light-trapping tubular panels for concentrating solar power receivers

Jesus D. Ortega, Joshua M. Christian, Julius E. Yellowhair, Clifford K. Ho, Sandia National Labs. (United States)

Traditional tubular receivers used in concentrating solar power are formed using tubes connected to manifolds to form panels, which in turn are arranged in cylindrical or rectangular shapes. Previous and current tubular receivers, such as the ones used in Solar One, Solar Two, and most recently the Ivanpah solar plants, have used a black paint coating to increase the solar absorptance of the receiver. However, these coatings degrade over time and must be reapplied, increasing the receiver maintenance cost. This paper presents the thermal efficiency evaluation of novel receiver tubular panels that have a higher effective solar absorptance due to a light-trapping effect created by arranging the tubes in each panel into unique geometric configurations. Similarly, the impact of the incidence angle on the effective solar absorptance and thermal efficiency is evaluated. A goal of this work is to achieve high solar absorptances and thermal efficiencies above 90% without using an external coating on the tubes. Several panel geometries were initially proposed and were down-selected based on structural analyses considering the thermal and pressure loading requirements of molten salt and supercritical carbon-dioxide receivers. The effective solar absorptance of the chosen tube geometries and panel configurations were evaluated using the ray-tracing modeling capabilities of SolTrace. The thermal efficiency was then evaluated by coupling computational fluid dynamics with the ray-tracing results using ANSYS Fluent. Compared to the base case analysis (flat tubular panel), the novel tubular panels have shown an increase in effective solar absorptance and thermal efficiency by several percentage points.

9559-8, Session 2

Testing and optical modeling of novel concentrating solar receiver geometries to increase light trapping and effective solar absorptance

Julius E. Yellowhair, Clifford K. Ho, Jesus D. Ortega, Joshua M. Christian, Charles E. Andraka, Sandia National Labs. (United States)

Concentrating solar power receivers are comprised of panels of tubes arranged in a cylindrical or cubical shape on top of a tower. The tubes contain heat-transfer fluid that absorbs energy from the concentrated sunlight incident on the tubes. To increase the solar absorptance, black paint or a solar selective coating is applied to the surface of the tubes. However, these coatings degrade over time and must be reapplied, which reduces the system performance and increases costs.

This paper presents an evaluation of novel receiver shapes and geometries that create a light-trapping effect, thereby increasing the effective solar absorptance and efficiency of the solar receiver. Several prototype shapes were fabricated from Inconel 718 and tested in Sandia's solar furnace at an irradiance of ~30 W/cm2. Photographic methods were used to capture the irradiance distribution on the receiver surfaces. The irradiance profiles were compared to results from ray-tracing models. The effective solar absorptance was also evaluated using the ray-tracing models. Results

showed that relative to a flat plate, the new geometries could increase the effective solar absorptance from 86% to 92% for an intrinsic material absorptance of 86%, and from 60% to 73% for an intrinsic material absorptance of 60%.

Sandia National Laboratories is a multi-program laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000.

9559-9, Session 3

Design and analysis of combined photovoltaic-thermal electric systems for reducing intermittency effects of solar illumination

Silvana Ayala Pelaez, Shelby D. Vorndran, Yuechen Wu, Juan Manuel Russo, Raymond K. Kostuk, The Univ. of Arizona (United States)

In this paper we analyze the performance of a combined photovoltaic (PV) and thermal electric generator (TEG) solar energy conversion system to help mitigate the transient effects of solar illumination. The approach takes advantage of the longer time constants of thermal conversion devices to offset the immediate response of PV devices to fluctuations in solar illumination. A thermodynamic analysis of the system is presented and is used to determine the size of a thermal storage block required for different size PV systems. Different materials for the thermal block and efficiencies of the TEG are included in the analysis. A comparison of using a spectrum splitting system to dedicated PV and thermal conversion regions of the collection field is also evaluated. The spectrum splitting system filters shorter wavelengths for use by the PV system and longer wavelengths for thermal conversion. The overall system performance is evaluated using both solar irradiance data available through the SMARTS2 resource and experimental data from a field test site in Tucson Arizona. Preliminary results show that intermittent durations of 2-3 minutes can be achieved with modest size thermal blocks and 2% efficient TEGs. Results from a small scale pilot test are also presented.

9559-10, Session 3

Design and feasibility of high temperature nanoparticle fluid filter in hybrid thermal/ photovoltaic concentrating solar power

Drew DeJarnette, Nick Brekke, Ebrima Tunkara, Hari Parameswar, Kenneth Roberts, Todd Otanicar, The Univ. of Tulsa (United States)

Concentrating solar power utilizes light for both thermal and electrical energy generation through absorbed photons. A parabolic trough concentrator system has been designed for a hybrid concentrating solar thermal collector to reach temperatures up to 300° C. This design incorporates a spectrally tunable nanoparticle fluid filter to absorb sub-bandgap photons that the photovoltaic cell cannot convert to electrons. Fluid filter housing design will be presented to show how the filter can be incorporated into existing trough concentrator systems. Thermal expansion of the filter is accounted for and optical design of the concentrator is verified using the ray tracing program SolTrace. The SolTrace model shows the feasibility of the filter located between the PV cell and the concentrating mirrors. The nanoparticle fluid filter is modeled to absorb 86% of the sub-bandgap light in the fluid and transmit 82% of the above-bandgap light to the PV receiver. The current work discusses fabrication and testing of the fluid filter including feasibility of nanoparticle stability at high temperature. Incorporation of temperature variation in the operation of the PV cell which adjusts the working bandgap ensures designed filter is optimized over the entire length of the system. System efficiency is calculated based upon optical, thermal, and photovoltaic models to determine how much solar energy can realistically be converted and what percentages will be usable directly as electricity and stored as thermal energy. On sun testing will be performed using 14x concentration to verify system level modeling.

9559-11, Session 3

A high temperature hybrid photovoltaic-thermal receiver employing spectral beam splitting for linear solar concentrators

Ahmad Mojiri, Cameron C. Stanley, Gary Rosengarten, RMIT Univ. (Australia)

Linear solar concentrators such as parabolic troughs or Fresnel mirrors are used to generate high temperature heat for process applications or power generation. Thermal receivers at their focal point are essentially insensitive to the spectrum of light striking them, and can effectively absorb the whole solar spectrum. Photovoltaic devices can transform a specific range of the solar spectrum into electricity, with high efficiencies. For example, silicon cells optimised for concentrating applications can convert the wavelengths between 700 and 1100nm into electricity with an efficiency of above 30%.

In order to benefit from this, we developed a spectrally splitting hybrid photovoltaic-thermal receiver that can decompose the concentrated light in linear concentrators into different bands. The wavelength between 700 and 1100 nm are sent to silicon cells to be converted directly into electricity. The rest of the solar spectrum is absorbed by a mid-temperature absorber, with above 150°C, for process heat, solar cooling, or thermal power generation.

The proposed spectral beam splitter consists of selective volumetric absorbers including propylene glycol to absorb the wavelengths longer than 1100nm and semiconductor doped glass to absorb wavelengths shorter than 700 nm. The absorbed energy generates heat in the thermal absorber. Separating the spectral beam splitting process into the aforementioned stages helps to reduce the cost of the system and makes it suitable for commercialisation. This receiver was built and tested on a commercial parabolic concentrator generating efficiencies of about 9%for electrical and over 50% for thermal energy at 150°C.

9559-12, Session 3

Concentrating PV module output power using a wireless microcontroller based automatic sun tracker

Ali Abou-Elnour, Ajman Univ. of Science & Technology (United Arab Emirates)

Due to the increasing interest in renewable energies as the main source for future energy, an enormous number of researches are now considering renewable energy generation and applications. In all of these researches, increasing the efficiency (decreasing the costs) of the renewable energy generation is a must to compete with conventional energy resources. Photovoltaic cells are considered as important renewable solar energy elements which convert solar energy into electrical energy in an easily, directly, and environmental friendly way. The amount of the energy generated from a solar energy system depends to a large extend on the relative position of the solar energy module (collector) with respect to the sun position. The sun position with respect to the earth is continuously varying with the time of the day and with the season and consequently the amount of generated energy from a fixed solar module (collector) will be also affected. The initial costs and the output power of fixed solar sun modules are lower than those of movable modules, known as sun trackers, which are designed to follow the movement of the sun to maximize the output power of the module. The cost and the complexity of sun trackers depend on if the tracking is done in one or two dimensions. Although many tracking systems have been designed and implemented in one and two dimensions, the performance of hardware circuits and software programs of these systems can be further enhanced. Moreover, the recent developments in wireless technologies, the intranet and internet topologies, and the rapid developments of computational facilities are opening the ways to design and implement efficient real time wireless monitoring and controlling for

renewable energy systems.

In the present work, a wireless microcontroller based sun tracker is designed and implemented to concentrate the generated output power resulting from photovoltaic module. Monitoring, controlling, and recording features are fully obtained in the present system using an efficient programming environment. Design equations which are implemented allow the usage of the system anywhere anytime without extra hardware tracking circuits. A carefully design hardware motor deriving circuit is designed and implemented to simplify the controlling program without scarifying the required accuracy. The system generates the motors' controlling signals to allocate the photovoltaic module to receive the maximize amount of the solar energy on its surface from sunrise to sunset. The transmission of all controlling and monitoring signals is wirelessly done to optimize the performance of the system with minimum cost and best quality. The proposed system is successfully implemented for photovoltaic modules under realistic operating conditions

9559-13, Session 4

Simulation of an electrowetting solar concentration cell

K.I. Iftekhar Uddin Khan, Gary Rosengarten, RMIT Univ. (Australia)

Electrowetting control of liquid lenses has emerged as a novel approach for solar tracking and concentration. Recent studies have demonstrated the concept of steering sunlight using thin electrowetting cells without the use of any bulky mechanical equipment. Effective application of this technique may facilitate designing thin and flat solar concentrators. Understanding the behavior of liquid-liquid and liquid-solid interface of the electrowetting cell through trial and error experimental processes is not efficient and time consuming. In this paper, we present a novel simulation model to predict the liquid-liquid and liquid-solid interface behavior of electrowetting cell as a function of various parameters such as applied voltage, dielectric constant, fluidic properties and electrode shape. The simulation model includes measured properties of appropriate liquids. We used Comsol Multiphysics simulations incorporating experimental data of different liquids. We have designed both two dimensional and three dimensional simulation models, which predict the shape of the lenses. The model measures the contact angle using the Young-Lippman equation. The model uses a moving mesh interface with Navier-stokes equation and a Navier slip condition on cell wall. Simulation of the electric field from the electrodes is coupled with Young-Lippman equation. The model can also be applicable for other MEMS electrowetting devices.

9559-14, Session 4

Holographic lens spectrum splitting photovoltaic system for increased diffuse collection and annual energy yield

Shelby D. Vorndran, Yuechen Wu, Silvana Ayala Pelaez, Raymond K. Kostuk, The Univ. of Arizona (United States)

Concentrating and spectrum splitting photovoltaic (PV) modules have a limited acceptance angle and thus suffer from optical loss under off-axis illumination. This loss manifests itself as a substantial reduction in energy yield in locations where a significant portion of insulation is diffuse. In this work, a spectrum splitting PV system is designed to efficiently collect and convert light in a range of illumination conditions. The system uses a holographic lens to concentrate short-wavelength light onto a smaller, more expensive indium gallium phosphide (InGaP) PV cell. The high efficiency PV cell near the axis is surrounded with silicon (Si), a less expensive material that collects a broader portion of the solar spectrum. Under direct illumination, the device achieves increased conversion efficiency from spectrum splitting. Under diffuse illumination, the device collects light with efficiency comparable to a flat-panel Si module. Design of the holographic lens is discussed. Optical efficiency and power output of the module under a range of illumination conditions from direct to diffuse are simulated with non-sequential raytracing software. Using direct and diffuse Typical Metrological Year (TMY3) irradiance measurements, annual energy yield of the module is calculated for several installation sites. Energy yield of the spectrum splitting module is compared to that of a full flat-panel Si reference module.

9559-15, Session 4

Compound Holographic concentrating system for laterally arranged multiple band gap solar cells

Hiralal L. Yadav, Shivam Nigam, National Institute of Technology, Jamshedpur (India); Asghar Khan, Karim City College (India); N. R. Cakraborty, Kolhan Univ., Chaibasa (India)

To reduce the cost of solar photovoltaic power generation use of concentrators is an attractive proposition. This scheme replaces costly solar cell area with relatively smaller cell area still achieving same out-put power. However, such concentrators concentrate the entire solar spectrum on cells. The portion of solar radiation which does not match the band gap of solar cells degrades the absorber material by overheating. This also leads to fall in efficiency of performance of solar cells. To get rid of absorption of unwanted potion of solar spectrum, spectral splitting and their concentration on laterally arranged multiple band gap solar cells has been proposed and are being extensively investigated both using conventional optical elements and holographic optical elements.

In the present work, use of a compound holographic system consisting of diffraction grating and holographic lens has been proposed to disperse and focus different portion of solar spectrum on laterally arranged solar cells of different band gaps to achieve maximum efficiency operation. Recording, playback geometry and experimental results have been presented in detail. This system is light weight, low cost and can be produced easily.

9559-16, Session 4

Design of a holographic micro-scale spectrum-splitting photovoltaic system

Yuechen Wu, Shelby D. Vorndran, Silvana Ayala Pelaez, Juan Manuel Russo, Raymond K. Kostuk, The Univ. of Arizona (United States)

Micro-scale concentrating PV technology combines the high conversion efficiencies of concentrated photovoltaics (CPV) with the low costs and the simple form of flat panel PV. Some of the benefits of micro-scale PV include: reduced semiconductor material usage; improved heat rejection capacity; and more versatile PV cell interconnect configurations. Spectrum-splitting is also a beneficial technique to increase the efficiency and reduce the cost of photovoltaic systems. It spatially separates the incident solar spectrum into spectral components and directs them to PV cells with matching bandgaps. This approach avoids the current and lattice matching problems that exist in tandem multi-junction systems. In this paper, we apply the ideas of spectrum-splitting in a micro-scale PV system, and demonstrate a holographic micro-scale spectrum-splitting photovoltaic system. This system consists of an off-axis hologram in combination with a micro-lens array. An analysis methodology is developed to determine the optical efficiency of the resulting system, the special characteristics of the dispersed spectrum, and the overall system conversion efficiency when used with different PV cell combinations. Preliminary experimental system performance is also presented.

Conference 9560: Solar Hydrogen and Nanotechnology X

SPIE. OPTICS+ PHOTONICS OPTICS+PHOTONICS FOR SUSTAINABLE ENERGY

Sunday - Thursday 9 –13 August 2015

Part of Proceedings of SPIE Vol. 9560 Solar Hydrogen and Nanotechnology X

9560-1, Session 1

Low-cost and high-efficiency solar hydrogen conversion: On materials design and pilot-scale demonstration *(Keynote Presentation)*

Liejin Guo, Shaohua Shen, Xi'an Jiaotong Univ. (China)

Solar hydrogen conversion via water splitting is an important technology for energy and environment sustainability. Since the pioneering work of Fujisima and Honda in 1972, tremendous research on semiconductor-based photocatalytic and photoelectrochemical water splitting has yielded better understanding of the processes involved in solar hydrogen production, as well as encouraging development of high efficiency photocatalysts/ photoelectrodes for solar hydrogen generation. In the past 15 years, aiming at applicable solar hydrogen conversion in the near future, we have been focusing on the design of low cost and high efficiency semiconductors, which are completely composed of earth-abundant elements, as well as pilot-scale demonstration for large scale solar hydrogen production. In this article, we give a brief overview of recently developed all oxide-based photoanodes and cheap photocatalytic materials without any noble metals for solar water splitting, and also the principles and examples of pilot-scale demonstration for large scale solar hydrogen production.

9560-2, Session 1

Kinetically optimised sensitized TiO2 structures for solar energy conversion *(Keynote Presentation)*

Yasuhiro Tachibana, RMIT Univ. (Australia)

Sensitisation of nanocrystalline metal oxide has shown great potential as an efficient charge separation system for solar energy conversion devices. Following light absorption by the sensitizer, an electron and a hole can efficiently be separated at the sensitizer/metal oxide interface. A TiO2 nanocrystalline structure was typically employed as an electron acceptor material from the sensitiser. In contrast, a wide variety of sensitisers have been investigated to find a suitable combination with a TiO2 film. After the initial success with a ruthenium complex, typically organic dyes in addition to semiconductor quantum dots and a perovskite film have indicated superior performance as a suitable sensitiser.

To design efficient photovoltaic devices, one could improve photocurrent, however the open circuit photovoltage (Voc) was often decreased. For example, extension of a light absorption wavelength range increased light harvesting efficiency, and thus generated the increased number of photo-electrons (photocurrent). However, the cell often forfeited the Voc by this photocurrent increase. Thus, the design of an interfacial structure is required to increase Voc, while the photocurrent is maintained. In this presentation, we will show some designs to increase Voc without losing the photocurrent. Also, some novel systems to synthesize semiconductor nanocrystals will be demonstrated.

This work was financially supported by JST PRESTO program, Japan. The author also acknowledges Australian Research Council (ARC) LIEF grant (LE140100104) and the Office for University-Industry Collaboration, Osaka University, for the financial supports.

9560-3, Session 1

A theoretical study of photo-induced electron kinetics in composite photocatalytic system *(Invited Paper)*

Jun Jiang, Univ. of Science and Technology of China (China)

In any optoelectronic applications utilizing photo-excitations of functional materials, one has to efficiently harvest photo-excited electronic states in the materials towards high quantum efficiency. Using first-principle based theoretical tools, we have performed theoretical investigations on the photo-induced electron kinetics behavior in composite structures, including: 1) Develop a quantum mechanics/molecular mechanics simulation protocol for nonlinear spectroscopy of interesting composite-structures under the environmental fluctuations; 2) Develop a rate equation model based on density matrix to capture electronic movements and transitions in the photo-excited material and thereby reflect the inter- and intra-system interactions. Theoretical simulations together with experimental non-linear spectroscopy characterizations, reveal information for photon-electron interactions, electron–hole recombination, and charge migrations, most of which are of key importance for the design of composite photocatalytic systems.

In situ/operando soft x-ray spectroscopy characterization of interfacial phenomena in energy materials and devices *(Keynote Presentation)*

Yi-Sheng Liu, Per-Anders Glans, Jinghua Guo, Lawrence Berkeley National Lab. (United States)

In many important energy systems such as energy conversion, energy storage and catalysis, advanced materials and functionality in devices are based on the complexity of material architecture, chemistry and interactions among constituents within. To understand and thus ultimately control the energy conversion and energy storage applications calls for the in-situ/ operando characterization tools. Soft X-ray spectroscopy offers some unique features. We will present the instrumentation development of the in-situ/operando soft X-ray spectroscopic in the studies of catalytic and electrochemical reactions in the recent years, and reveal how to overcome the challenge that soft X-rays cannot easily peek into the high-pressure catalytic cells or liquid electrochemical cells. The unique design of in-situ/ operando soft X-ray spectroscopy instrumentation and fabrication principle are presented, and a number of experimental examples are given, including the nanocatalysts and the recent experiment performed for studying the hole generation in a specifically designed photoelectrochemical cell under operando conditions.

9560-5, Session 2

Metal-complex/semiconductor hybrids for carbon dioxide fixation *(Invited Paper)*

Kazuhiko Maeda, Tokyo Institute of Technology (Japan)

Recently, we reported that carbon nitride (C3N4) functions as a stable photocatalyst for water reduction and oxidation under visible light (> 420 nm). Even though C3N4 is an organic semiconductor, it is capable of oxidizing water into O2 with the aid of a water oxidation cocatalyst like RuO2. The ability of C3N4 to produce O2 from water is very attractive when we construct a CO2 reduction photosystem that is workable using water as an electron source. On the other hand, certain metal complexes based on rhenium or ruthenium are known to catalyze CO2 reduction to CO or HCOOH photocatalytically or electrochemically with high selectivity and quantum yields, although the oxidation ability is relatively low. With these backgrounds, we studied C3N4 as a component of a CO2 photoreduction system that operates under visible light using a metal complex as a cocatalyst. It was found that a hybrid photocatalyst consisting of C3N4 and a small fraction of a ruthenium(II) complex having proper reduction potential and an anchoring group, which respectively work as light-harvesting unit and a catalytic center for CO2 reduction. This simple binary composite, is capable of converting CO2 into HCOOH with a selectivity of >80% and a turnover number of >1000, both of which are the highest among heterogeneous photocatalytic CO2 reduction systems reported to work under visible light.

9560-6, Session 2

The heteropolyacid based photocatalytic intercalated nanomaterials

Jihuai Wu, Jianming Lin, Miaoliang Huang, Huaqiao Univ. (China)

Energy and environment are two issues of the human's top ten problems for the next 50 years. It is indispensable to search new photocatalytic materials in order to solve the issues. The photocatalytic production of hydrogen from water using semiconductor materials is of great interest due to its possible application for converting the sunlight energy into chemical energy. Incorporation of a semiconductor catalyst in the interlayer region of a lamellar compound is a promising method for fabricating an intercalated nanomaterial consisting of host layers with ultrafine particles in the interlayer and enhancing photocatalytic activity of the semiconductor. We have done the researches on the heteropolyacid-based (such as HTaWO6, H2Ca4Ta2Nb4O20, HLaNb2O7, HLaTaxNbyO7, etc) photocatalytic intercalated nanomaterials, including in intercalating type, doping type and loading type nanocomposites. Owing to their layered structure, large specific surface area, small semiconductor size, host-guest coupling effect and quantum size effect, these intercalated nanomaterials show eminent photocatalytic activities. For instances, under irradiation with wavelength less than 290 nm from a 450-W mercury arc, photocatalytic hydrogen yield reach 240, 232, and 220 cm3•h–1?g–1 for photocatalytic materials HLaNb2O7/(Pt,TiO2), H2Ca4Ta2Nb4O20, and HTaWO6/(Pt, TiO2), respectively, which are higher 70 times than the commercial TiO2 (P25) photocatalyst. Meanwhile, these heteropolyacid-based intercalated nanomaterials have excellent ability for photocatalytic degradation of wastewater, which can be used in environmental improvement. The preparation, composition, structure, properties, formation and photocatalytic mechanism are discussed in this paper.

9560-42, Session 2

Developing plasmonic nanostructures towards enhanced photocatalytic activity *(Invited Paper)*

Dongling Ma, Institut National de la Recherche Scientifique (Canada)

Plasmonic metallic (e.g. Au & Ag) nanostructures have attracted extensive interest in the last decade due to their unique surface plasmon resonance (SPR). SPR arises from collective oscillations of free electrons in plasmonic structures, which can interact with light in a resonant manner and scatter light strongly. It is also characterized by the generation of intense electric fields near the surface. The recent application of plasmonic nanostructures in photocatalysis (including solar water splitting) has led to a new, active research area of plasmon-enhanced photocatalysis. Although exact mechanisms remain elusive in many cases and sometimes can be even controversial for the same materials, the performance enhancement has been confirmed. Herein, I will present some of our recent development in plasmonic nanostructures, their hybridization with semiconductor nanomaterials and the applications of these nanohybrids in photocatalysis. One specific example is about the development of a simple and functionalization-step-free solution process to fabricate nanocomposites made of BiFeO3 nanowires and Au nanoparticles fabricated by pulsed laser ablation in water. The Au nanoparticle-decorated BiFeO3 nanowires exhibit ~30 times higher photocatalytic activity for water oxidation than that exhibited by the Au-free nanowires. Another example is about an integrated nano-architecture, rationally designed to include wide wavelength absorbing nanomaterial, visible-absorbing plasmonic nanocomponent, and high surface-area semiconductor component all in one single structure to maximize photon harvest, beneficial component interactions and thereby photocatalytic efficiency. In addition to introducing new nanohybrids and their photocatalytic activity, the relevant mechanisms (charge transfer and energy transfer) in these specific systems will also be discussed.

9560-204,

Solar hydrogen: harvesting light and heat from sun

Liejin Guo, Xi'an Jiaotong Univ. (China)

My research group in the State Key Laboratory of Multiphase Flow in Power Engineering (SKLMF), Xi'an Jiaotong University has been focusing on renewable energy, especially solar hydrogen, for about 20 years. In this presentation, I will present the most recent progress in our group on solar hydrogen production using light and heat. Firstly, "cheap" photoelectrochemical and photocatalytic water splitting, including both nanostructured materials and pilot-scale demonstration in our group for light-driven solar hydrogen (artificial photosynthesis) will be introduced. Then I will make a deep introduction to the achievements on the thermal-driven solar hydrogen, i.e., biomass/coal gasification in supercritical water for large-scale and low-cost hydrogen production using concentrated solar light.

9560-48, Session PMon

Preparation of N2-plasma assisted visible light active ordered mesoporous nitrogen doped TiO2 thin films for solar energy conversion

Syed Z. Islam, Allen D. Reed, Doo-Young Kim, Stephen E. Rankin, Univ. of Kentucky (United States)

The optical and electronic properties of TiO2 thin films provide tremendous opportunities in several applications including photocatalysts, photovoltaics and photoconductors for energy production and environmental remediation. Despite the attractive features of TiO2 such as low cost and stability under a wide range of conditions, one critical challenge is the innate inability of TiO2 to absorb visible light from the solar spectrum due to its high band gap. In this study, this shortcoming is addressed by doping cubic ordered mesoporous TiO2 thin films (N-TiO2) using nitrogen/argon (N2/Ar) plasma. This represents a rapid, scalable approach to high surface, controlled nanostructure thin films for photocatalytic applications. First, cubic ordered nanoporous TiO2 thin films are prepared by a surfactant templated sol-gel method using TiCl4 as precursor and triblock copolymer Pluronic F-127 as the template. Subsequently, the calcined TiO2 films are treated with N2/Ar

plasma under controlled conditions of reaction gas pressures, microwave power, and plasma exposure duration. The primary variable studied here for N-TiO2 films is the duration of plasma exposure (0-210 min). After doping, the films are confirmed to have an accessible, well-ordered cubic mesopore structure by SEM, TEM, STEM and XRD analyses. XPS analysis shows that 2-3% substitutional nitrogen is present in the doped films and that the doping level increases with plasma treatment duration. UV-visible absorbance spectra of N-TiO2 films indicate the enhancement of absorption of visible light and reduction of the bandgap. Finally, the visible-light photocatalytic activity of N-TiO2 films is determined from the photocatalytic degradation of methylene blue under illumination with a visible-light LED. The N-TiO2 films prepared with 150 min plasma treatment show the best photocatalytic activity, with a first-order methylene blue rate coefficient that is 6 times greater than that of undoped TiO2 films. Preliminary experiments also show that the plasma-processed N-TiO2 films on conductive substrates show better visible-light photoelectrochemical activity than undoped TiO2 for hydrogen generation by water splitting.

9560-8, Session 3

A dynamic perspective on charge carriers in quantum-dot sensitized metal oxide nanostructures for photoelectrochemical solar hydrogen generation *(Keynote Presentation)*

Jin Zhong Zhang, Univ. of California, Santa Cruz (United States)

Small bandgap semiconductor quantum dots (QDs) are promising sensitizers for metal oxide nanostructures in photoelectrochemical water splitting for hydrogen generation by expanding light absorption into the visible region. Among the several critical steps for charge carriers in this approach, electron transfer (ET) from the QD to MO and charge transport (CT) inside the MO are two of the most important. In one example, we have studied how linker molecules between QD and MO can affect the ET based on ultrafast laser studies. Arene substituted (ortho, meta and para) bifunctional molecular linkers of the HS-[C6H4]-COOH type are designed and employed to link CdSe QDs to TiO2. Interestingly, the CdSe-TiO2 sample with a para substituted linker (representing the longest distance between CdSe and TiO2) shows the best PEC performance as compared to ortho and meta substituted linkers. The ET rate is consistent with PEC measurements in that the CdSe-TiO2 sample with a para substituted linker shows the highest ET rate. Density functional theory (DFT) calculations have been carried to gain insight into the ET mechanism behind. In the meantime, we have explored how to use chemical treatment of the MO to improve CT by introducing bandgap states that serve to mediate electron and hole transport. Furthermore, we have recently started to explore the possibility of using organolead halide peroskite QDs (PQDs) as sensitizers for MO with a focus on understanding the role of bandgap states and their relation to instability of the PQDs, which has important implication for photovoltaic as well as PEC applications.

9560-9, Session 3

Enabling overall water splitting with hematite and Si *(Invited Paper)*

Dunwei Wang, Boston College (United States)

An important challenge in fulfilling the promises held by photoelectrochemistry water splitting as a solar energy harvesting technology is the mismatch of photocathode and photoanode performance. Often, the photovoltages of the photoanodes are too low, and the turn-on potentials are too positive. Similarly, the turn-on potentials of the photocathodes are too negative, making it difficult, sometimes impossible, to achieve complete water splitting without applying external potentials. Here using hematite as a study platform, we examine what limits the turn-on potentials in photoelectrochemistry water splitting. Our results show that the poor performance is a combination of unwanted potential drop in the Helmholtz layer that does not contribute to charge separation within the semiconductor photoelectrode and potential loss on the surface the photoelectrode due to structural disorders. We present our strategies to correct these deficiencies. The potential drop in the Helmholtz layer can be harnessed and put back into the semiconductor by depositing catalytic layers such as amorphous NiFeOx. The structural disorders can be readily fixed by a regrowth strategy. Through these simple treatments, we are able to increase the photovoltage of hematite from 0.24 V to 0.80 V, and the turn-on voltage of hematite is lowered to 0.45 V. Complete water splitting at an overall efficiency of 0.91% is achieved by combining hematite with amorphous Si photocathode.

9560-10, Session 3

Insight into materials properties for a photo electrochemical based solar refinery *(Invited Paper)*

Joan Ramón Morante, Institut de Recerca en Energia de Catalunya (Spain) and The Univ. de Barcelona (Spain)

Photo electrochemistry, PEC, processes have attracted great attention as an effective procedure for convert solar photon energy to chemical one. PEC units can produce different solar fuels such as hydrogen, formic acid, methanol, methane or syngas depending on the selected catalyst and the used feed stocks of H2O and CO2. It is always produced with an improved energy balance compared with dark electro catalysis processes. Moreover, it shows a high throughput depending on the used photons absorbed material as well as on the capacity for charge separation and effective role of the used catalyst for cathode and anode electrodes. Different routes for reaching efficiency higher than 10-12% of efficiency have been promoted.

In this contribution, different electrode material option will be reviewed. Example will be presented and charge transfer coefficient discussed from the fine surface characterization. Moreover, the potential use of earth abundant alternative will be discussed considering costs, life time and high yield in the solar fuel production according to the different used catalyst for CO2 reduction. Special attention will be paid on the application of initially photovoltaic absorber materials like silicon, kesterite or CIS combined with protective and photo catalytic active metal oxide layers in order to scale up PEC systems in order to achieve solar refinery yields.

9560-11, Session 4

Surface science insights into surface and interface properties of photoelectrocatalysts for solar fuels *(Keynote Presentation)*

Bruce E. Koel, Coleman X. Kronawitter, Peng Zhao, Zhu Chen, Princeton Univ. (United States)

A surface science approach can greatly advance understanding of the structure and reactivity of photoelectrocatalysts for solar fuels. Such experiments use well-defined model catalysts under controlled conditions and utilize a range of spectroscopic techniques for characterization of surface and interface properties and the nature and reactivity of surface-bound species. We report on several of our recent studies, which include investigations of the effects of dopant incorporation on the structural and chemical properties of the ?-Fe2O3(0001) surface for water oxidation catalysis, facet-dependent activity and stability of Co3O4 nanocrystals towards OER, and the interaction of water with GaP(110), a semiconductor that is known to enable selective CO2 reduction to methanol in aqueous solutions of CO2 and nitrogen-containing heteroaromatics. For water oxidation on ?-Fe2O3, we found that Ni doping in thin films of model catalysts caused a new termination for the films and induced formation of more stable surface-bound OH groups. For the Co3O4 system, we used the well-defined morphologies of nanocubes and nanooctahedra to demonstrate that the (111) surfaces vastly out-perform the (100) surfaces for OER activity (overpotential and current density). Finally we have

spectroscopically identified in situ the surface-bound species on GaP(110) associated with exposure to water using ambient pressure photoelectron spectroscopy (APPES). These observations on model systems afford further analysis and discussion of the role of surface-bound species in mechanisms for catalyzed water oxidation and CO2 reduction.

9560-12, Session 4

Surface chemistry of molecular catalysts on model photoelectrodes for solar fuels by CO2 reduction *(Invited Paper)*

Coleman X. Kronawitter, Peng Zhao, Bruce E. Koel, Princeton Univ. (United States)

The surface chemistry of catalyst and solvent molecules on photoelectrodes relevant to the production of solar fuels by CO2 reduction is explored by analysis of model systems. At its heart the electroreduction of CO2 is an electrochemical process, but assessing the mechanism of CO2 reduction at semiconductor/catalyst junctions using electrochemistry techniques alone is challenging because of the complex physical chemistry involved in chemical synthesis. Using the presented experimental surface science approach, ultrahigh vacuum conditions are used to facilitate the fabrication of highly characterizable electrode-adsorbate systems, and the use of single crystal surfaces permits analysis of surface chemistry independent of complicating factors such as grain boundaries and morphology. Surface-sensitive core-level and vibrational spectroscopy measurements on the model systems are used to supplement electrochemistry investigations, and generate unique information describing the role of the electrode surface in CO2 reduction. Specifically the preferential adsorption sites and bonding interactions and reactivities of catalysts and intermediates on III-V semiconductors are considered. Conclusions from experimental results are supported by calculations using density functional theory. This work assists in generating a molecular-level understanding of the heterogeneous processes important to the reaction mechanism of efficient photoelectrocatalytic fuel generation.

9560-13, Session 4

Photocatalytic hydrogen production over CdS: Effects of reaction atmosphere studied by in situ Raman spectroscopy

Lijing Ma, Liejin Guo, Xi'an Jiaotong Univ. (China)

CdS is a well-known efficient photocatalyst for photocatalytic hydrogen production. However, CdS is prone to photocorrosion in the photocatalytic reaction where CdS itself is oxidized by the photogenerated holes. Most of the work reported up to now only focused on the structure of CdS itself. Less attention was, however, paid to the kinetic changes of CdS during photocatalytic reaction, which, in our opinion, is crucial step for its practical utilization. In this report, we developed a facile in situ Raman analysis, aiming to clarify the microstructure changes of CdS during the photocatalytic reaction process. In this study, photocatalytic hydrogen production over CdS in Ar or air atmosphere was studied by various techniques besides of the in-situ Raman. With Raman spectrum, a significant increase in surface lattice strain of CdS is observed only when it is exposed to air, while electron-phonon interactions remain the same regardless of the atmosphere. A direct correlation between interfacial crystal lattice and photo-corrosion of sulfide photocatalyst during its photocatalytic hydrogen production was found based on our in-situ Raman investigation. Finding of photo-corrosion of sulfide photocatalyst at its very early stage with our in-situ Raman technique is expected to provide meaningful guidance for the design of active and stable chalcogenide photocatalysts, which, however, cannot be achieved by traditional characterizing techniques.

9560-14, Session 5

Synchrotron-based spectroscopy for solar energy conversion *(Keynote Presentation)*

Franz J. Himpsel, Univ. of Wisconsin-Madison (United States)

This overview talk illustrates how synchrotron-based spectroscopy with soft X-rays can contribute to the discovery of new materials for solar cells and solar fuel synthesis. The primary techniques are photoelectron spectroscopy and absorption spectroscopy with soft X-rays, which complement each other in probing occupied and empty electronic states. Both are element- and bond-specific, with absorption spectroscopy also sensitive to the bond orientation [1]. Close coupling with density functional calculations enables discovery and exploitation of systematic trends. Case studies will be presented, such as donor-pi-acceptor complexes for solar cells [2] and hematite nanorod arrays for water splitting [3]. In addition to the energy levels one has to consider the lifetime of the photo-generated carriers. Fourth-generation laser-like synchrotron light sources are on their way which are capable of pump-probe experiments that follow excited charge carriers in real time across a molecular complex or through the charge transport layers in a device.

9560-15, Session 5

Interfacial atomic and electronic structure of energy-related material characterized by synchrotron x-ray spectroscopy *(Invited Paper)*

Chung-Li Dong, National Synchrotron Radiation Research Ctr. (Taiwan)

Owing to the global energy crisis, the scientists are devoted to search new sources of clean energy that meet the human demand for energy. The search for new energy materials that have efficient energy conversion/generation/storage is one of the most pressing technological challenges. In many promising energy systems such as solar hydrogen, nanostructured catalysts, and smart materials, the interfacial atomic and electronic structure provide the fundamental understanding of the physical and chemical properties of a material. Understanding of these interfacial phenomena is critical and thus can pave a way to better design the material and control the performance. Synchrotron-based x-ray spectroscopy, including x-ray absorption and x-ray emission spectroscopies can be used to investigate the local unoccupied and occupied electronic states. The electronic structure in the conduction band and valence band thus can be obtained. With in situ/in operando technique, it is possible to monitor the change of atomic/electronic structures of an energy material under its working environment. This presentation will report the emerging in situ/in operando characterization based on synchrotron x-ray spectroscopy. A number of recent studies of human-engineered photosynthesis, smart materials, catalytic and electrochemical reactions will be presented.

9560-16, Session 5

Thin film catalyst integration onto silicon: Engineering materials and interfaces for efficient and stable photoanodic water oxidation *(Invited Paper)*

Ian D. Sharp, Jinhui Yang, Lawrence Berkeley National Lab. (United States)

We provide an overview of different approaches to achieving durable silicon photoanodes and highlight two specific examples of how catalyst integration can be used to improve activity and chemical stability. In the first example, we show that plasma-assisted atomic layer deposition (PE-ALD) of cobalt oxide onto silicon enables efficient and sustained photoelectrochemical water splitting under alkaline conditions. While ALD has recently emerged as a powerful tool for protection of photoelectrodes from corrosion, the composition and structure of deposited materials often differ significantly from those synthesized by other methods. We find that low temperature PE-ALD provides access to structurally disordered, yet conformal, layers that are characterized by higher concentrations of active sites. Engineering the catalyst and the semiconductor/catalyst interface at the nanoscale is essential for simultaneously achieving efficient charge extraction and chemical stability. This work offers insight into the role of structural disorder on catalytic activity and provides a path to higher performance photoelectrodes for solar fuels systems. In the second example, we investigate water oxidation using silicon photoanodes under acidic conditions; at present, the only known catalysts this reaction under acidic conditions are based on iridium or ruthenium. Therefore, it is important to develop integrated semiconductor/catalyst assemblies that minimize the total quantity of catalyst, retain photocatalytic activity, and promote chemical stability. To this end, we have developed multi-layer coatings on silicon that allow photogenerated charge to be efficiently transferred between the light absorber and an ultrathin surface layer of iridium oxide, without adversely affecting the generated photovoltage. In this way, we are able to achieve stable and efficient water oxidation under acidic conditions, while substantially reducing the required quantity of extremely rare iridium in the system. The examples presented here highlight that, although few materials are inherently stable under conditions required for artificial photosynthesis, controlled catalyst integration provides a viable approach to sustained operation in a variety of harsh environments.

9560-17, Session 5

High aspect ratio WO3 nanorod arrays based WO3/BiVO4 Heterojunction for photoelectrochemical water splitting

Jinzhan Su, Xi'an Jiaotong Univ. (China)

Recently, WO3/BiVO4 heterojunction have been investigated and proved to be a good structure for photoelectrochemical water splitting under visible-light irradiation. In this report, we grew high aspect ratio by annealing ammonium tungsten bronze ((NH4)0.33•WO3) nanorods grown on FTO substrate via a modified solvothermal method and followed with BiVO4 coating by pulse laser deposition. The WO3/BiVO4 heterojunction was characterized by X-ray diffraction (XRD), Raman spectroscopy, and scanning electron microscopy (SEM) and X-ray Photoelectron Spectroscopy (XPS). WO3 nanorod arrays are conformally covered with a BiVO4 layer and a core-shell structure was formed. The WO3/BiVO4 heterojunction promoted the charge carrier separation due to their appropricate band edge positions alignment. The high aspect ratio WO3 nanorod arrays provided larger surface for heterojunction formation which further enhance the performance of nanostructural heterojunction. The photoelectrochemical results showed that the photocurrent was improved compared to bare WO3 nanorod arrays.

9560-18, Session 6

Rational design of titania-based functional nanostructures *(Keynote Presentation)*

Yadong Yin, Univ. of California, Riverside (United States)

We discuss our recent efforts in the design and architectural control of titania nanostructures and their applications. We first review the synthesis, crystallinity control, and photocatalysis of TiO2 porous nanostructures by discussing several methods for changing the structures from amorphous to crystalline and subsequently ways for enhancing the crystallinity, including those involving the "silica-protected calcination" and "partial etching and re-calcination" strategies. We also discuss the photocatalytic applications of the TiO2 nanoshells and the methods for improving their catalytic activities. In particular, we demonstrate a sandwich-structured photocatalyst that shows an excellent performance in degradation reactions of a number of organic compounds under UV, visible light, and direct sunlight. We will also report a new color switching system based on reversible redox reaction that could be initiated by photocatalytic response of TiO2 nanocrystals. With the assistance of TiO2 nanocrystal-based photocatalysts, UV light irradiation can rapidly reduce the imaging materials and result in obvious color change, while the recoloration can be achieved by re-oxidizing the system with the assistance of visible light irradiation or heating. The excellent performance of the new color switching system promises their potential applications as attractive rewritable media to meet our society's increasing needs for sustainability and environmental conservation.

9560-19, Session 6

From UV/visible to near-infrared light activity: Recent progress in photocatalysis *(Invited Paper)*

Hong Liu, Shandong Univ. (China)

Photocatalysis is a practical methodology for degradation of organic pollutant for environmental application and hydrogen generation for renewable power source application. Although in most cases the light used for photocatalysis research and application is still artificial light sources at present, the solar light is the real target for for practical photocatalysis. However, up to now, most available photocatalysts are UV and visible or UV-visible light active semiconductor with broad band gap, and there is only a few methods or photocatalyst can realize NIR photocatalystic activity. Therefore, design or find NIR light active photocatalysts and building UV-Vis-NIR full solar light photocatalysis system is great challenge for full utilization of solar energy in environmental and clean energy fields.

Recent years, several methods have been suggested to convers NIR light to visible or UV light and realized NIR light photocatalysis by light conversion nanoparticle-semiconductor hybrid photocatalysts. Most recently, our group proposed to use some semiconductor with impurity energy level, and semiconductor with narrow band gap to achieve NIR light photocatalysis. Based on this mechanism, some oxides, such as Ag2O and Bi2WO6, and some cholcogenides, such as WS2 and In2S3, were discovered to possess high NIR light photocatalytic activity, and some of them possess high photocatalytic properties in UV-Vis-NIR full solar spectrum photocatalytic property.

In this talk, we will summary the principle for design full solar light spectrum photocatalysis systems, or finding new NIR photocatalyst. Several new NIR and full solar spectrum light photocatalysts will be introduced. In addition, the application of full solar light photocatalysts will be reviewed.

9560-20, Session 6

Preparation of Cu2O/TiO2 nanotube arrays and its photoelectrochemical properties as hydrogen-evolving photoanode

Lixia Sang, Jing Zhang, Beijing Univ. of Technology (China)

Cu-based nanomaterials have become a popular sensitizer of TiO2 due to their advantages of low cost, non-toxic, good catalytic activites, narrow band gap, which can replace quantum dots CdS and PbS containing toxic elements Cd and Pb. Cu2O is an environment-friendly p-type semiconductor with narrow band gap (2.0~2.2eV). The present work is focus on the preparation of Cu2O/TiO2 nanotube arrays heterostructures via electrochemical deposition. TiO2 nanotube arrays were prepared by anodic oxidation method and calcined at 450?, then Cu2O were deposited on TiO2 nanotube arrays in a three-electrode system with or without surfactants PVP at different deposition voltages (-0.2V,-0.3V,-0.4V) and different deposition time (5min, 10min, 15min). The results show that the size of Cu2O nanoparticles remarkable decreased with the help of surfactants PVP, and Cu2O deposited on the inner and outer walls of TiO2 nanotube. The resulting Cu2O/TiO2 nanotube arrays have the significant photo response in visible light region. Under irradiation of solar simulator (AM1.5,100mW/cm2), the photocurrent density of the Cu2O/TiO2 nanotube arrays is more than that of pure TiO2 nanotube arrays when Cu2O was deposited at a voltage of -0.3V. In addition, combined with the calculation and analysis of flat band potential, charge carrier density and electron lifetime, the effects of different deposition time and voltage on the photoelectrochemical properties of Cu2O/TiO2 nanotube arrays were further dissicussed.

9560-21, Session 7

Electron dynamics at semiconductor-molecule interfaces: Insights from first-principles dynamics simulation *(Keynote Presentation)*

Yosuke Kanai, The Univ. of North Carolina at Chapel Hill (United States)

Dynamics of excited electrons at semiconductor-molecular interfaces is responsible for a number of key interfacial processes of various solar energy conversion and opto-electronic technologies. These processes include interfacial electron transfer and non-radiative recombination. In this talk, I will discuss our recent efforts in my group for addressing several challenges in understanding how atomistic details influence these processes using analytical models with inputs from first-principles calculations and also with first-principles electron dynamics simulations. I will discuss several key aspects of the electron transfer and hot electron relaxation in context of EFRC on Solar Fuels at UNC Chapel Hill. I will also discuss how the results from atomistic theories pose a conceptual challenge when characterizing these interfacial electron processes with a simple kinetic model at these complex interfaces.

9560-22, Session 7

Solution-processed photocathodes for solar water splitting tandem cells *(Invited Paper)*

Kevin Sivula, Néstor Guijarro, Florian Le Formal, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

A practical solar water splitting device that can produce H2 at a cost less than PV + electrolysis is difficult to envision without it possessing a simple construction that employs widely available materials and inexpensive processing techniques. A tandem cell consisting of 2 solution-processed photoelectrodes (photoanode/photcathode) can reasonably reach this goal. While n-type oxide semiconductors have been established as viable photoanode materials, cheap and stable p-type photocathodes are less developed. In this presentation our groups' progress in the development of solution-processed stable photocathodes is presented and their application toward overall photoelectrochemical water splitting tandem cells is demonstrated. Three classes of promising materials are discussed: copper-based oxides in the delafossite phase, ternary and quaternary chalcogenides, and 2D transition metal chalcogenides. In each case the challenges to maximize photogenerated charge collection in thin films prepared by solution-based deposition approaches are highlighted and the use of bottom-up nanostructuring to gain insight into routes for improvement and overcome these challenges are established. The optimization of these materials for solar water reduction using overlayers and catalysts, and the stability under reasonable operation conditions are addressed. Routes to improve the unassisted and overall solar water splitting performance in tandem cells with commonly used oxide photoanodes are finally outlined.

9560-23, Session 7

Exploring the time-scale of photo-initiated interfacial electron transfer through first-principles interpretation of ultrafast X-ray spectroscopy *(Invited Paper)*

David Prendergast, Lawrence Berkeley National Lab. (United States)

With the advent of X-ray free electron lasers and table-top high-harmonic-generation X-ray sources, we can now explore changes in electronic structure on ultrafast time scales -- at or less than 1ps. Transient X-ray spectroscopy of this kind provides a direct probe of relevant electronic levels related to photoinitiated processes and associated interfacial electron transfer as the initial step in solar energy conversion. However, the interpretation of such spectra is typically fraught with difficulty, especially since we rarely have access to spectral standards for nonequilibrium states. To this end, direct first-principles simulations of X-ray absorption spectra can provide the necessary connection between measurements and reliable models of the atomic and electronic structure. We present examples of modeling excited states of materials interfaces relevant to solar harvesting and their corresponding X-ray spectra in either photoemission or absorption modalities. In this way, we can establish particular electron transfer mechanisms to reveal detailed working principles of materials systems in solar applications and provide insight for improved efficiency.

9560-24, Session 8

Nanoscale junctions for water splitting photocatalysis *(Keynote Presentation)*

Frank E. Osterloh, Benjamin A. Nail, Jing Zhao, Jiarui Wang, Kathryn A. Newton, Yuxin Yang, Po Wu, Zongkai Wu, Geetu Sharma, Univ. of California, Davis (United States)

Photochemical charge generation, separation, and transport at nanocrystal interfaces are central to photoelectrochemical water splitting, a pathway to hydrogen from solar energy. Here we use surface photovoltage spectroscopy (SPS) to probe these processes in nanocrystal films of photoanode and photocathode materials, incl. WO3, NiO, C3N4, M:SrTiO3, HCa2Nb3O10, CdSe, p-Si, and BiVO4. Charge injection between nanoparticles can be observed, as well as redox reactions at nanocrystal-liquid interfaces. The ability to monitor these voltage-generating processes with SPS provides new insight into nanoscale charge separation and promotes the development of nanocrystal applications in photoelectrochemical cells, photovoltaics, and as solar fuels photocatalysts.

9560-25, Session 8

Rapid flame processing of metal oxides photoanodes for enhanced solar water-splitting *(Invited Paper)*

Xiaolin Zheng, Stanford Univ. (United States)

Photoelectrochemical (PEC) water splitting is the simplest and cleanest route that directly converts sun light to hydrogen and potentially it will

enable a low cost production of hydrogen. One of the biggest challenges for the realization of the PEC water splitting is to develop an efficient photoanode having a good light absorption, fast charge transport and transfer properties simultaneously. Typically metal oxides are considered to be good candidates because of their excellent photochemical stability and low cost. However, their poor material quality, such as large amount of defects, low surface area, low charge carrier's mobility/conductivity, which largely originated from the preparation method, limits the charge transport and transfer properties.

In this talk, I will present two novel flame processing techniques, i.e., flame reduction and doping, for metal-oxide photoanodes that allows to greatly improve the charge transport and transfer properties, hence improving the PEC water-splitting performance. First, we developed a rapid flame reduction method to generate controllable amount of oxygen vacancies in TiO2 nanowires (NWs) that leads to nearly three times improvement in the PEC water-splitting performance. The flame reduction method has unique advantages of a high temperature (>1000 oC), ultra-fast heating rate, tunable reduction environment, and open-atmosphere operation, so it enables rapid formation of oxygen vacancies (<1min) near the surface region without damaging the nanowire morphology and crystallinity, and even applicable to various metal oxides. Second, we designed an ex-situ novel doping method which combines versatile solution phase chemistry and rapid flame annealing process (i.e., Sol-Flame) to dope TiO2 NWs with cobalt (Co). The sol-flame doping method not only preserves the morphology and crystallinity of the TiO2 NWs, but also allows fine control over the Co dopant profile by varying the concentration of Co precursor solution. Finally, we extended the sol-flame doping method to codope TiO2 NWs with tungsten and carbon (W, C) by sequentially annealing W-precursor coated TiO2 nanowires in flame and CO gas. This is the first experimental demonstration that codoped TiO2:(W, C) nanowires outperform monodoped TiO2:W and TiO2:C and double the saturation photocurrent of undoped TiO2 for PEC water-splitting.

9560-26, Session 8

NH3-treated MoS2 nanosheets for enhanced H2 evolution under visible-light irradiation

Jinwen Shi, Yazhou Zhang, Liejin Guo, Xi'an Jiaotong Univ. (China)

Energy shortage and environmental pollution have become two urgent problems that restrict social development and endanger human survival. In order to resolve the two issues to realize the sustainable development of society, the most effective route is the active development and utilization of clean and renewable energy sources. Exploring and realizing the conversion and storage of solar energy as hydrogen energy is a powerful route to develop and utilize renewable energy. Correspondingly, it is a key task to exploit photocatalysts with high stability, high efficiency, low cost for visible-light-driven H2 evolution.

Herein, a series of novel photocatalysts (designated as MoS2-N) were explored by treating the MoS2 nanosheets (designated as MoS2), which were prepared by a hydrothermal reaction using Na2MoO4•2H2O as Mo source and CH3CSNH2 as S source, in a tube furnace under flowing NH3 atmosphere at different temperatures. The physiochemical properties of samples were systematically investigated by different instrumental characterizations, and the H2-evolution photocatalytic properties of samples were evaluated, by using HCOOH as the sacrificial reagent and using in-situ photodeposited Pt as the cocatalyst, under visible-light irradiation (? > 420 nm). It was found that, compared with MoS2 that showed no photocatalytic activity due to the lower conduction band position than the redox potential of H+/H2, MoS2-N showed considerable photocatalytic activity due to the high-temperature NH3 treatment that evidently modified the physiochemical properties of pristine MoS2 nanosheets and thus was beneficial for photocatalytic H2 evolution.

9560-27, Session 9

On the surface, confinement, and dimensionality effects of large bandgap oxide semiconductors *(Keynote Presentation)*

Lionel Vayssieres, Xi'an Jiaotong Univ. (China)

An overview and the latest achievements in surface, dimensionality and confinement effects on large bandgap oxide semiconductors will be presented. The development of low cost visible light-active metal oxide heteronanostructures consisting of earth abundant elements is of crucial importance for the large scale implementation of hydrogen-based energy. Controlled aqueous-based solution chemistry allows the growth of transition metal oxides with tailored orientation, dimensionality and surface chemistry onto various substrates with great purity. For instance, quantum dots grown on the surface of vertically oriented quantum rods can be entirely fabricated from aqueous metal salts without surfactant and at low temperature. These all-oxide heteronanostructures show intermediate bands for efficient visible-light conversion and highly quantized band structure for band/bandgap engineering. Such unique characteristics, combined with the in-depth investigation of their electronic structure at synchrotron radiation facilities, optical, structural and transport properties provide better fundamental understanding of the energetics and structure-property relationships as well as key trends for efficiency optimization of solar water splitting in neutral aqueous solutions.

9560-28, Session 9

Photocatalytic water splitting: Using a 2-photon approach *(Invited Paper)*

Brian J. Seger, Bastian Timo Mei, Dowon Bae, Mauro Malizia, Thomas Pedersen, Peter C. Vesborg, Ole Hansen, Ib Chorkendorff, Technical Univ. of Denmark (Denmark)

Modelling has shown that to optimize photoelectrolysis efficiency, a 2 photon tandem device (back to back photocatalysts) should be used. The underlying principle is that one photocatalyst should absorb high energy photons (large band gap) while the other absorbs the low energy photons (small band gap). In theory, either the H2 evolution reaction or the O2 evolution can take place on the large band gap material with the opposite reaction taking place on the small band gap material. I will discuss both possibilities and show how this affects optimal material properties needed for the photocatalysts.

Finding an optimal photocatalyst system can be very difficult, thus we break the water splitting process into 3 parts: 1) Photoabsorption, 2) Photoabsorber/Electrolyte interface and 3) H2 or O2 evolution catalysis. In this talk I will discuss our use of Si, GaP, and Perovskites as photoabsorbers and what we do to maximize photovoltage. To prevent corrosion at the photoabsorber/electrolyte interface we use corrosion protection layers. I will show how TiO2 is a great material for protecting the H2 evolution photocatalyst, whereas NiO is excellent at protecting the O2 evolution catalyst. I will also show our work on improving both the H2 evolution and O2 evolution catalysts.

9560-29, Session 9

Photocatalytic evolution of molecular hydrogen and oxygen over La-doped NaTaO3 particles: Effect of different cocatalysts *(Invited Paper)*

Irina Ivanova, Leibniz Univ. Hannover (Germany); Tarek Kandiel, Sohag Univ. (Egypt); Amer Hakki, Ralf Dillert, Detlef W. Bahnemann, Leibniz Univ. Hannover (Germany)

To solve the global energy and environmental issues highly efficient systems for solar energy conversion and storage are needed. One of them involves the photocatalytic conversion of solar energy into the storable fuel molecular hydrogen via the water splitting process utilizing metal-oxide semiconductors as catalysts. Since photocatalytic water splitting is still a rather poorly understood reaction, fundamental research in this field is required.

Herein, the photocatalytic activity for water splitting was investigated utilizing La-doped NaTaO3 as a model photocatalyst. The activity of La-doped NaTaO3 was assessed by the determination of the overall quantum yield of molecular hydrogen and molecular oxygen evolution. In pure water La-doped NaTaO3 exhibits rather poor activity for the photocatalytic H2 evolution whereby no O2 was detected.

To enhance the photocatalytic activity the surface of La-doped NaTaO3 was modified with various cocatalysts including noble metals (Pt, Au and Rh) and metal oxides (NiO, CuO, CoO, AgO and RuO2). The photocatalytic activity was evaluated in pure water, in aqueous methanol solution, and in aqueous silver nitrate solution. The results reveal that cocatalysts such as RuO2 or CuO exhibiting the highest catalytic activity for H2 evolution from pure water, possess, however, the lowest activity for O2 evolution from aqueous silver nitrate solution.

La-doped NaTaO3 modified with Pt shows the highest quantum yield of 33 % with respect to the H2 evolution in the presence of methanol. To clarify the role of methanol in such a photocatalytic system, long-term investigations and isotopic studies were performed. The underlying mechanisms of methanol oxidation were elucidated.

9560-30, Session 9

Effect of potential on the conductivity of electrodeposited Cu2O film

Ying Yang, Juan Han, Xiaohui Ning, Hongsheng Tang, Northwest Univ. (China)

The conductivity (i.e., n-type of p-type) of Cu2O films is controlled by the electrodeposition potential. A slightly acidic solution (pH 4.93) containing cupric acetate and sodium dodecyl sulfate (SDS) is used. Photoelectrochemical measurements at zero bias indicate that the Cu2O films deposited at the potentials of 0.00 V and -0.05 V generate the n-type photocurrents and the films deposited at the potentials negative than -0.10 V generate the p-type photocurrents. The X-ray diffraction (XRD) results show that the n-type films are pure Cu2O, however, the metallic copper appear in the p-type Cu2O films. Mott-Schottky measurements show that the donor concentrations of the n-type Cu2O films decrease and the acceptor concentrations of the p-type Cu2O films increase with the decrease of the deposition potential. The SDS molecules adsorbed on FTO surface and the SDS micelles block the diffusion of Cu2+ ions, resulting in a low diffusion rate of Cu2+ ions. Under this circumstance, the growth of Cu2O films are affected significantly by the overpotential. When the potential is positive than -0.05 V, oxygen vacancies are formed in the films leading to the n-type conductivity; however, when the potential is negative than -0.10 V, the Cu2+ ions are reduced to Cu+ rapidly and part of Cu2+ are reduced to metallic copper, the diffused Cu2+ ions to supply to the growth of Cu2O films are insufficient, hence copper vacancies are formed in the films resulting in the p-type conductivity.

9560-31, Session 10

Materials and devices for efficient solar-to-hydrogen production *(Keynote Presentation)*

Heli Wang, National Renewable Energy Lab. (United States); Joel W. Ager III, Joint Ctr. for Artificial Photosynthesis (United States) and Lawrence Berkeley National Lab. (United States); Nicolas M. Gaillard, Univ. of Hawai'i (United States) and Hawaii Natural Energy Institute (United States); Eric L. Miller, U.S. Dept. of Energy (United States)

High solar-to-hydrogen (STH) efficiency and high durability has been a significant challenge for hydrogen production via photoelectrochemical (PEC) water splitting. Semiconductor materials' band gap, band edge, optoelectronic efficiency, and stability must be satisfied simultaneously to tackle the challenge.

Metal oxides may be stable, STH efficiencies have been limited by issues related to the wide band gap, absorption, charge mobility, recombination, interfacial kinetics, etc. III-V materials offer an alternative pathway to efficient STH conversion, with stability remains an issue.

Besides the materials requirement, the challenge also requires effective usage of solar spectrum. To address the band-edges mismatch, structures and configurations have been developed for unbiased PEC water splitting. This presentation will discuss different semiconductor materials, STH structures and devices, as well as their STH efficiencies.

9560-32, Session 10

Simultaneous photocharging and photoelectrochemical water splitting over oxide semiconductor thin films *(Invited Paper)*

Yun Hau Ng, The Univ. of New South Wales (Australia)

Most photoactive semiconductors work under illumination. When the source of light is absent, excited charges recombine instantaneously and photoactivity ceases immediately. Research strategies to extend the applicability of photoactive semiconductors in dark conditions have been formulated by developing multiple-material systems to store the photoexcited charges for later usage. Typically it involves an integrated system to combine a photocatalyst and a battery. In this work, we develop a single oxide material system to achieve the excitation and energy storage. WO3 and MoO3 are the two examples that exhibited the ability to photoexcite thus driving the photoelectrochemical water splitting. At the same time, a portion of the photoexcited charges can be stored within the crystal structure of the oxide, stabilised by the cations in the electrolyte, and subsequently delivered the stored energy in dark condition. A systematic investigation has revealed that a balance between the storage or instant consumption can be achieved by changing the sizes of the cation in the electrolyte, modulating the crystal structure distortion and optimising the crystal facet responsible for each function. This work offers an alternative method in achieving solar energy conversion and storage using a simple single oxide system.

9560-33, Session 10

Efficient and low-cost photoelectrodes for solar water splitting *(Invited Paper)*

Wenjun Luo, Nanjing Tech Univ. (China)

The consumption of fossil fuels creates energy shortage and serious environment issues, which limits sustainable development of the society. Solar energy is the most abundant renewable energy in the world. However, it needs to be stored as chemical energy due to its low energy density, uneven distribution and discontinuous radiation. Hydrogen is considered as a promising clean energy carrier for the future. Different a conventional PV cell, in a photoelectrochemical water splitting cell, a Schottky-like junction forms at the solid-electrolyte interface and separates photo-generated carriers. Since Fujishima and Honda originally reported that a TiO2 based photoelectrochemical cell could be used to split water into hydrogen and oxygen in 1972 [1], intensive researches have been done to improve the performance of the photoelectrochemical cell in the past forty years [2-3]. However, the solar energy conversion efficiency is still low. Exploring efficient photoelectrodes is a key challenge in solar water splitting for hydrogen production.

In this talk, I will present several kinds of methods to improve a photoelectrode's performance, including heterojunction [4], shallow level doping [5-7], removal of surface recombination centers [8-9], morphology control [10], and suppressing back reaction [11]. After modifying, we have obtained record solar photocurrent on BiVO4 and Ta3N5 photoelectrodes for water splitting.[6] , [9] Moreover, we have used the BiVO4 photoelectrode to split natural seawater outdoors, which is more attractive because solar energy and seawater are the most abundant renewable energy source and the most abundant natural resource on the earth, respectively. Our findings are important progress in this field and offer guindance to improve photoelectrochemical performance of other materials.

Hydrogen production from water by thermal and photo-excited methods *(Keynote Presentation)*

Hicham Idriss, SABIC (Saudi Arabia)

Hydrogen production from water is at the essence of the energy system needed for a sustainable economy. Many methods for making hydrogen from water are pursued. Among the most promising of them are thermal- and photo-reactions. In thermal reactions the main challenge is making reducible materials at temperatures low enough to warrant applications while in photoreactions the main challenge is in the developments of photocatalytic materials with charge carriers' life time long enough affording high rates of electron transfers to and from the valence and conduction bands of the semiconductor.

In this work we are discussing our recent progress on both fronts. For thermal reactions a case study of the effect of doping CeO2 with metal cations on its reducibility and therefore activity based on experimental and computational results is presented. The incorporation of iso-valent metal cations of similar size to Ce4+ can enhance the reduction of CeO2 due to charge transfer and not to size effect. We correlate the extent of reduction of CeO2 to its redox/activity for hydrogen production using core level spectroscopy and thermal gravimetric analyses. For photo-catalytic reactions we focus in particular on the effect of metal particle size and dispersion (Au and Pd) on the reaction rate. We have found for example a finite range for metal coverages affecting the rate of reaction by over an order of magnitude. These may be linked to charge transfer properties increasing/decreasing the charge carriers' life time and therefore the rate of reaction.

9560-35, Session 11

Functional NiOx catalyst protected small band gap semiconductors for efficient and stable solar driven water oxidation *(Invited Paper)*

Ke Sun, Nathan S. Lewis, California Institute of Technology (United States)

One promising strategy for the development of an integrated artificial photosynthetic device involves the protection of traditional, high-efficiency small band-gap semiconductors, such as Si, Group II-VI and Group III-V compound semiconductors, for use in fuel-forming half reactions such as the oxidation of water or the reduction of H2O or H2O/CO2 to useful fuels. Stabilization of technologically important semiconductors against photocorrosion and photopassivation would have a significant impact on photoelectrochemical energy conversion, and could enable the development of a new generation of robust integrated devices for efficient solar-driven water splitting and solar-driven CO2 reduction. Previous efforts have been extensively dedicated on elongating the lifetime of semiconductors under harsh fuel forming reaction conditions especially during the water oxidation half reaction. To date, the energy conversion performances (energy conversion figure-of-merit < 1%) and stability (<100 h) were limited on these systems, obscuring the realization of integrated solar fuel devices. In this work, we presented our recent effort on the preparation of a functional NiOx catalyst, which provides multiple important functions on semiconductor photoelectrodes surfaces as a window layer, including chemical/corrosion protection, electrically conducting, optically transparent/antireflective, and inherent electrocatalytic active. The combination of the extraordinary film properties has resulted benchmark performances and stability on Si photoanodes. We also demonstrated that this strategy can be also used on other group II-VI and group III-V semiconductors that have never been able to be protected in relevant water oxidation conditions before. Results presented here indicated a viable strategy that is a promising approach and should be readily applied to other otherwise unstable semiconductors to achieve the long-term stability for use in solar fuel applications.

9560-36, Session 12

Synthesis and assembly of 1D inorganic semiconductor for solar energy conversion *(Invited Paper)*

Xinjian Feng, Suzhou Institute of Nano-tech and Nano-bionics (China)

Nanoscale inorganic semiconductors have become promising low-cost high surface area electrode materials for solar cell and solar fuel productions. Charge transport within electrode materials is a major determinant of these device performances. However, high surface area electrode is normally associated with small size of randomly packed nanoparticles (NPs) and exhibits significantly low electron mobility. To address these challenges, we fabricated ordered single-crystal 1D TiO2 nanowire (NW) arrays. We first demonstrated that their electron transport is 200-fold higher than that in NP films.1 Although 1D NW arrays have marked improved electron transport, the large volume of free space between NWs limits its surface area. We have reported the fabrication of oriented assembled TiO2 hierarchical nanoarrays consisting of 1D branch epitaxially grown from the primary trunk. The 3D NW arrays show 71% higher surface area related to 1D NW arrays, which leads to 52% improvement in solar convention efficiency without affecting electron collection2. To further increase the surface area, we fabricated [10-10] oriented multichannel ZnO NW arrays. The NW exhibits 2-3 orders of magnitude faster electron transport rate than that in NP films. Moreover, the surface area of the as-prepared NW arrays is comparable to that of commonly used NP films3. The high surface area and rapid charge transport properties make these NW arrays ideal electrode structures for future various optoelectronic device applications.

9560-38, Session 12

Photoelectrochemical water splitting and hydrogen generation using InGaN/GaN nanowires grown directly on Si *(Invited Paper)*

Zetian Mi, Bandar M. AlOtaibi, Shizhao Fan, McGill Univ. (Canada)

Hydrogen generation under sunlight offers great potential for a sustainable fuel production system. Here we report on the design, fabrication, and performance characterization of multi-band InGaN/GaN nanowire photoelectrodes. InGaN/GaN core/shell nanowire arrays on Si can function as a double band photoanode in acidic solution, and relatively high incident-photon-to-current-conversion efficiency (up to 37%) is measured under ultraviolet and visible light irradiation. We have further developed p-type InGaN/GaN nanowire photocathodes, which are monolithically integrated on n-type Si substrate through a polarization-enhanced tunnel junction. The devices exhibit relatively stable hydrogen generation under simulated sunlight illumination.

9560-39, Session 12

Design of inorganic hybrid structures for photocatalytic energy conversion *(Invited Paper)*

Yujie Xiong, Univ. of Science and Technology of China (China)

Mastery over the surface of a nanocrystal enables control of its properties in molecular adsorption and activation, and enhances its usefulness for catalytic applications. On the other hand, hybrid systems based on semiconductors and noble metals may exhibit improved performance in photocatalysis such as water splitting, mainly determined by the efficiency in generating carriers. In the systems, perfect interface is certainly the key to efficient carrier separation and transport. Taken together, the surface and interface modulation holds the key to materials design for photocatalytic applications. Here, we will demonstrate several different approaches to designing nanocrystal-based systems with improved photocatalytic performance. For instance, a semiconductor-metal-graphene design has been implemented to efficiently extract photoexcited electrons through the graphene nanosheets, separating electron-hole pairs. Ultrafast spectroscopy characterizations exclusively demonstrate that the charge recombination occurring at interfacial defects can be substantially avoided, enabling superior efficiency in water splitting. It is anticipated that this series of works open a new window to rationally designing hybrid systems for photo-induced applications.

9560-7, Session 13

Electrophoretic deposition of composition-tunable (Cu2Sn)xZn3(1-x) S3 nanocrystal films as efficient photocathodes for photoelectrochemical water splitting

Yubin Chen, Zhixiao Qin, Liejin Guo, Xi'an Jiaotong Univ. (China)

P-type semiconductor Cu2ZnSnS4 has been considered as one of the most promising light-absorbing materials for solar energy conversion due to its high absorption coefficient, suitable band gap, low toxicity, and elemental abundance. Herein, we apply a low-cost electrophoretic film preparation method to develop composition-tunable (Cu2Sn)xZn3(1-x) S3 films as efficient photocathodes for photoelectrochemical (PEC) water splitting. Firstly, a series of (Cu2Sn)xZn3(1-x)S3 ($0 \le x \le 0.75$) quaternary nanocrystals with tunable optical band gaps are synthesized. Morphologies including particles, rods, and wires are obtained by tuning the composition of the nanocrystals. (Cu2Sn)0.75Zn0.75S3 (Cu2ZnSnS4) has a pure kesterite structure but an increase in the Zn content results in a kesterite-wurtzite polytypism. Subsequently, (Cu2Sn)xZn3(1-x)S3 films are fabricated from their colloidal solutions via electrophoretic deposition and the PEC properties of these films with p-type character have been examined under water splitting conditions. It is shown that the photocurrent varies as a function of film thickness as well as chemical composition. The produced (Cu2Sn)0.45Zn1.65S3 (x = 0.45) film has the highest photocurrent. Furthermore, n-type metal oxide layer is deposited on top of (Cu2Sn) xZn3(1-x)S3 film to modify the surface structure. By forming the efficient p-n junction, photogenerated charge separation is effectively promoted, leading to the much enhanced PEC activity.

9560-40, Session 13

Complex composition and shape materials for renewable energy applications *(Keynote Presentation)*

Gunnar Westin, Uppsala Univ. (Sweden)

The demands on catalysts for solar fuels, solar cells and photo-assisted water and air cleaning are becoming more complex in composition and structure with design requirements down to a few nm to utilise quantum size effects. This put great demands on the precision of the preparation routes. At the same time the process and materials have to be of very cost for any societal impact to occur. For such tough demands solution based routes are often the best suited. Here solution based processing routes to doped and non-doped oxide nano-particles, thin- and ultra thin films are presented. The oxide systems involve doped and non-doped Fe2O3, TiO2, ZnO, WO3, spinel and perovskite nano-particles, films and ultra-thin films, as well as metal nano-particles and ultra-thin films. The synthesis and products are described by a wide array of techniques including; SEM, TEM, XRD, TGA, DSC/DTA, IR-, Raman and UV-Vis-NIR spectroscopy.

9560-41, Session 13

New III-V semiconductor alloys for solar hydrogen production *(Invited Paper)*

Mahendra K. Sunkara, Harry B. Russell, Alejandro Garcia, Swathi Sunkara, Jacek B. Jasinksi, Univ. of Louisville (United States); Madhusudan K. Menon, Univ. of Kentucky (United States)

Dilute III-V alloys have garnered immense interest as suitable materials for solar hydrogen generation due to their compositional tunable band gaps, high carrier mobilities and high absorption coefficients. Till date there are no III-V materials that can satisfy all the stringent criteria for photoelectrochemical water splitting. In this presentation, we report two new III-V materials GaSbN and GaSbP that addresses current materials bottleneck for photoelectrochemical water splitting is developed for photoelectrochemical water splitting. Applicability of the Ga(Sbx)N1?x alloys for practical realization of photoelectrochemical water splitting is investigated using first-principles density functional theory and experiments. Theoretical results predict that Ga(Sbx)N1?x , GaSbP alloys with 2 eV band gaps straddle the potential window at moderate to low pH values, thus indicating that dilute Ga(Sbx)N1?x alloys could be potential candidates for splitting water under visible light irradiation.1,2 Theoretical computations with Sb composition beyond 7% change the electronic band gap from direct to indirect. In the case of GaSbP a small amount of Sb incorporation will

change the indirect GaP band gap to direct band gap.3

Experimental synthesis is carried out using metal organic chemical vapor deposition using trimethyl gallium (TMGa) and Trimethyl Antimony (TMSb) and ammonia. Crystalline GaSbxN1-x films were obtained at x values ranging from 0-5%. The synthesis was carried out on different planar substrates and GaN nanowires. Optical measurements confirm that severe band gap reduction occurs with incorporation of antimony in to GaN as predicted by the theoretical calculations. X-Ray Diffraction (XRD) results confirm the lattice expansion at small concentrations of antimony. This work is the first successful attempt on the experimental synthesis of crystalline GaN and GaP based alloy in the low antimonide regime and photoelectrochemical data on activity, band edge energetics and stability show high suitability for direct solar water splitting. The fundamental insights gained from this work on the growth mechanisms and formation of stacking faults can be extended to other ternary alloy nanowires of interest. From a scientific point of view, the large band gap bowing and corresponding optical properties with very small alloying compositions is interesting and can be exploited for band gap engineering. This presentation will highlight our results with both synthesis and photoelectrochemical characterization of GaSbN and GaSbP alloys.

Plasmonic metal nanostructures as photosensitizers *(Invited Paper)*

Nianqiang Wu, West Virginia Univ. (United States)

To data, no single semiconductors can meet the requirements of photocatalysis. Generally semiconductors with narrow band gap have a wide sunlight absorption spectral range but suffer from instability in photocatalysis. In contrast, semiconductors with wide band gap exhibit good stability but have a narrow spectral light absorption range. Organic dyes and quantum dots have been used as photosensitizer to extend the spectral range of light absorption. However, instability and band alignment constraints limit the practical use of organic dyes and quantum dots in photosensitization. Recently, plasmonic metal nanostructures emerged as a new type of photosensitizers. Compared to conventional photosensitizers, plasmonic metal nanostructures are stable and have a large light absorption cross-section and are able to transfer the solar energy to plasmonic energy. The critical issue is how to efficiently transfer the plasmonic energy from the metallic photosensitizer to the semiconductor. This talk will present the underlying mechanism and the strategy of the plasmonic energy transfer from a metallic photosensitizer to a semiconductor.

9560-44, Session 14

Ag-Au bimetallic nanocubes with excellent SERS activity and chemical stability *(Invited Paper)*

Dong Qin, Yin Yang, Xiaojun Sun, Jiawei Zhang, Georgia Institute of Technology (United States)

Silver nanocrystals have fascinating optical properties known as localized surface plasmon resonance (LSPR), which is essential to applications in surface-enhanced Raman scattering (SERS), optical sensing, and biomedical imaging. Silver nanocubes, in particular, have strong electromagnetic field enhancements at their sharp corners, which can drastically increase the Raman scattering cross sections of molecules at these sites for ultrasensitive detection and imaging. However, the susceptibility of elemental Ag to oxidation often leads to corner truncation and thus deterioration of SERS activity. One potential solution to improve the chemical stability of Ag nanocrystals is to form alloys with a more stable metal such as Au. In this talk, I will begin with a co-reduction strategy for transforming Ag nanocubes into Ag-Au hollow nanocubes with enrichment of Ag on their surfaces to greatly enhance their SERS activity. Additionally, I will discuss a new approach to the fabrication of Ag@Au core-shell nanocubes with superb SERS activity and chemical stability. The success relies on the introduction of a fast reduction by ascorbic acid at pH 11.6 to compete with and thereby block the galvanic reaction. An ultrathin Au shell of only 0.6 nm thick was able to protect the Ag in the core from dissolution in an oxidative environment such as 2.3% aqueous H2O2. Significantly, the core-shell nanocubes exhibited LSPR properties essentially identical to those of the original Ag nanocubes while the SERS activity showed an additional 5.4-fold increase owing to the improvement in chemical enhancement.

9560-45, Session 14

Experimental and numerical study on an annular fluidized-bed photocatalytic reactor *(Invited Paper)*

Dengwei Jing, Xi’an Jiaotong Univ. (China)

Photocatalytic technology has received increasing attention owing to its various advantages. In this work, we designed a fluidized-bed photocatalytic reactor using model reaction of H2S simultaneously employed as the bubbling gas for catalyst suspension and the feed for hydrogen production. The photocatalyst distribution was simulated by CFD with an Eulerian model. The simulation results indicated that the fluidizing time showed a linear relationship with the inlet gas velocity and that the optimal inlet gas velocity was between 30 and 50 mL/min. Further, light energy absorption characteristics, in both homogeneous and heterogeneous media, were simulated by the Monte Carlo method. Our study showed that light energy absorption is affected by the nonuniform distribution of the catalyst particles and that finding the optimum optical thickness in chemical reaction space and the optimal height for catalyst fluidization is essential for reactor design. Based on these numerical simulation results, experimental studies were conducted. Hydrogen productions in a batch photocatalytic reactor (BPR) and a fluidized-bed photocatalytic reactor with H2S bubbling (FBPR) were compared. The reaction rate constant was 1.12 for the FBPR, whereas it was only 0.083 for the BPR case. The similar hydrogen productions and significant difference in reaction rate constants for the two reactors indicates that an increase in the effective initial reactant concentration in FBPR is essential. In this regard, a circulating fluidized bed with recycling use of H2S gas is preferred. Our study is expected to provide useful guidance for the development of a direct photocatalytic H2S decomposition technology.

9560-46, Session 14

Hydrogen storage in high surface area materials: Amorphous graphene oxide and hybrid nanoporous oxides *(Invited Paper)*

Vassilios D. Binas, Foundation for Research and Technology-Hellas (Greece) and Univ. of Crete (Greece)

Until now, the main energy source was fossil fuels. The last 30 years have appeared the following unpleasant prospects: 1st petroleum stocks will be exhausted within the next few decades, and the reason is the continuous growth of the global population and the continued growth of the industry in developing Eastern European and East Asian countries, which has resulted in the continued increase in the consumption of these sources. 2nd the environmental pollution has increased to dangerous levels. The public health is adversely affected by the emission of smoke, dangerous gases (sulfur dioxide, nitrogen oxides, carbon monoxide and ozone) and the temperature of the earth rises from the increasing concentration of carbon dioxide in the

atmosphere (global emissions).

Hydrogen storage is one of the key issues for the realization of fuel-cell powered vehicles using hydrogen as the energy carrier. Porous carbon materials are a candidate for hydrogen storage and attracted extensive attention as a result of the advantages associated with its light weight, fast kinetics, complete reversibility, low cost, and high surface area.

We present here a high surface area materials and espessially Amorphous Graphene Oxide and Hybrid Nanoporous Oxides. All this materials were successfully synthesized using solvothermal method and characterized with XRD, FT-IR, RAMAN, BET, SEM, TEM, and TGA.. Also we study the gas sorption properties of H2 in different temperatures.

9561-1, Session 1

A combined optical-electrical finite-element simulation of nonhomogeneous thin-film solar cells

Tom H. Anderson, The Univ. of Edinburgh (United Kingdom); Muhammad Faryad, Lahore Univ. of Management Sciences (Pakistan); Tom G. Mackay, The Univ. of Edinburgh (United Kingdom); Akhlesh Lakhtakia, The Pennsylvania State Univ. (United States)

A two-dimensional finite-element model has been developed to simulate the optical and electrical properties of thin-film p-i-n junction solar cells. In the thickness direction, the i-type layers for these solar cells are optically and electrically nonhomogeneous. In the simulation, this nonhomogeneity is engineered by varying the fractional composition of an amorphous-silicon-germanium alloy. An empirical model relates the energy-gap of the alloy to its complex permittivity. A transparent conducting-oxide layer is welded to the p-type layer, and the n-type layer is backed by a corrugated metallic back reflector which is periodic perpendicular to the thickness direction. Periodic boundary conditions consistent with Floquet theory simulate thin-film solar cells which are unbounded in directions perpendicular to the thickness. Multiple surface-plasmon-polariton waves as well as waveguide modes are excited in the solar cell, thereby increasing the generation rate of electron-hole pairs. A nonhomogeneous drift-diffusion model provides the charge-carrier distribution at steady state. For example, the effective electric field acting on the electrons includes a contribution from the electron affinity of the alloy, while the effective electric field acting on the holes includes contributions both from the electron affinity and the band-gap of the alloy. High-field compatible expressions for the electron and hole mobilities are used. Mid-band Shockley-Read-Hall, Auger and radiative recombination rates are taken to be the dominant methods of carrier recombination. The current density-voltage characteristics of the solar cell are determined, and the maximum efficiency point of the nonhomogenous cell may then be compared to that of a related homogeneous cell.

9561-2, Session 1

Theoretical limits of the multistacked 1-D and 2-D microstructured inorganic solar cells

Emre Yengel, Çankaya Univ. (Turkey); Hakan Karaagac, Istanbul Technical Univ. (Turkey); Logeeswaran Veerayah Jayaraman, M. Saif Islam, Univ. of California, Davis (United States)

Recent studies in monocrystalline semiconductor solar cells are focused on mechanically stacking multiple cells from different materials to increase the power conversion efficiency. Although, the results show promising increase in the device performance, the cost remains as the main drawback. In this study, we calculated the theoretical limits of multi-stacked 1D and 2D microstructered inorganic monocrstalline solar cells. This system is studied for Si and Ge material pair. The results show promising improvements in the surface reflection due to enhanced light trapping caused by photon-microstructures interactions. The theoretical results are also supported with surface reflection and angular dependent power conversion efficiency measurements of 2D axial microwall solar cells. We address the challenge of cost reduction by proposing to use our recently reported mass-manufacturable fracture-transfer- printing method which enables the use of a monocrystalline substrate wafer for repeated fabrication of devices by consuming only few microns of materials in each layer of devices. We calculated thickness dependent power conversion efficiencies of multistacked Si/Ge microstructured solar cells and found the power conversion efficiency to saturate at %26 with a combined device thickness of 30 ?m. Besides having benefits of fabricating low-cost, light weight, flexible, semi-transparent, and highly efficient devices, the proposed fabrication method is applicable for other III-V materials and compounds to further increase the power conversion efficiency above 35% range.

9561-3, Session 1

On the broadband continuous excitation of surface-plasmon-polariton waves in an amorphous silicon solar cell

Mahmoud Atalla, The Pennsylvania State Univ. (United States)

Currently, the surface-plasmon-polariton (SPP) waves can be excited only at certain wavelength and certain incidence angle. It is remarkably noticed that the wavenumber of the SPP waves decreases as the incident wavelength increases. This stands against the continuous excitation of SPP waves at certain incidence angle using a practical grating configuration. We hypothesized that the theoretical modeling of SPP waves guided by the interface of a dielectric grating and a metal will help to solve that problem. The aim of the study is to prove that the proposed grating/metal configuration has propensity of guiding SPP waves of relative wavenumber that increases as the incident electromagnetic wavelength increases. This may enable the continuous excitation of SPP waves. The successful attempt of proving the aim of this study will validate the excitation of SPP waves at certain incidence angle but at wider range of incident wavelength. This result will have a great impact on the communication and energy harvesting applications.

The rigorous coupled wave analysis (RCWA) is used to solve the Maxwell equations in its differential form. The Newton-Raphson method is used to solve the dispersion equation at the grating/metal interface for the SPP wavenumber. This provides the wavenumber of the SPP waves that can propagate at the grating metal interface. A study for the SPP wave energy decay will also be made through the calculation of the Poynting vector, and show that the propagating SPP waves decay away from the grating/metal interface, which infers the surfacing property of the propagating waves.

9561-6, Session 2

Manipulate the grain size and crystallinity of hybrid perovskite films for device efficiency and stability improvement

Jinsong Huang, Univ. of Nebraska-Lincoln (United States)

Large aspect ratio grains with minimal surface defects are needed in polycrystalline thin-film solar cells for reduced charge recombination at grain boundaries, however small grain size in organolead trihalide perovskite (OTP) films is generally observed, and the surfaces are generally rich in charge trap states. Here we report two strategies in reducing the charge recombination at OTP surface and grain boundaries.

First, we demonstrated that charge extraction length in CH3NH3PbI3 without Cl can also be increased to above 1 μm by a solvent-annealing process, which increases both the grain size and crystallinity of perovskite films to the film thickness. The average grain sizes were increased to be comparable to film thickness so that most photo-generated charges can be extracted within single grain without crossing grain boundaries. The device efficiency was increased to 15.6% under one sun illumination, and kept above 14.5% when the thickness is increased to 1 μm.

Second, we will introduce a new method to increase the grain lateral size to be more than ten times of the film thickness so that total grain boundary area is dramatically reduced. It effectively reduces the total trap density in the device by 10~100 times to the level in OTP single crystals, and

increased the device efficiency to 19% in low-temperature processed planar-heterojunction OTP devices. The charge trap passivation at grain boundaries and film surface by the double fullerene layers also effectively reduced the trap density, contributing the elimination of the photocurrent notorious hysteresis.

9561-7, Session 2

Novel materials for stable perovskite solar cells

Antonio Abate, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Organic-inorganic perovskites are quickly overrunning research activities in new materials for cost-effective and high-efficiency photovoltaic technologies. Since the first demonstration from Kojima and co-workers in 2009, several perovskite-based solar cells have been reported and certified with rapidly improving power conversion efficiency. Recent reports demonstrate that perovskites can compete with the most efficient inorganic materials, while they still allow processing from solution as potential advantage to deliver a cost-effective solar technology.

Compare to the impressive progress in power conversion efficiency, stability studies are rather poor and often controversial. An intrinsic complication comes from the fact that the stability of perovskite solar cells is strongly affected by any small difference in the device architecture, preparation procedure, materials composition and testing procedure.

In the present talk we will focus on the stability of perovskite solar cells in working condition. We will discuss a measuring protocol to extract reliable and reproducible ageing data. We will present new materials and preparation procedures which improve the device lifetime without giving up on high power conversion efficiency.

9561-8, Session 2

Investigation of degradation mechanisms of perovskite-based photovoltaic devices using LBIC mapping

Zhaoning Song, Suneth C. Watthage, Adam B. Phillips, Brandon L. Tompkins, Randy J. Ellingson, Michael J. Heben, The Univ. of Toledo (United States)

Solution processed thin film photovoltaic devices incorporating organohalide perovskites have progressed rapidly in recent years and achieved more than 20% energy conversion efficiencies. However, an important issue limiting their commercialization is that device efficiency often drops within the first few hundred hours plausibly due to the presence of moisture. To explore the origin of device degradation and failure in perovskite solar cells, we investigate the homogeneity evolution at different stages of aging using two-dimensional laser beam induced current (LBIC) mapping. We demonstrate that local decomposition of perovskites due to moisture is likely responsible for early device degradation by comparing photocurrent collection of perovskite devices in different controlled environments. We show that the addition of a poly(methyl methacrylate)/ single-wall carbon nanotube (PMMA/SWNT) encapsulation layer prevents degradation of the device in moist air. This suggests a route toward perovskite solar cells with improved operational stability and moisture resistance.

9561-4, Session 3

A novel method for mapping open-circuit voltage in solar cells with nanoscale resolution

Elizabeth Tennyson, Joseph L. Garrett, Univ. of Maryland, College Park (United States); Jesse A. Frantz, Jason D. Myers, Robel Y. Bekele, U.S. Naval Research Lab. (United States); Jasbinder S. Sanghera, Univ. Research Foundation (United States); Jeremy N. Munday, Marina S. Leite, Univ. of Maryland, College Park (United States)

The electrical characteristics of thin-film compound semiconductor solar cells have been successfully probed by scanning probe microscopy. Nevertheless, a direct relationship between the measured signals and the figures of merit that define the device performance is still missing. Here we present a novel method to image and spatially resolve the Voc of solar cells with truly nanoscale resolution (<100 nm), based on a variant of illuminated Kelvin probe force microscopy (KPFM) [1]. We map the Voc by measuring the difference between the contact potential difference under illumination and in the dark, which is equal to the photo-generated voltage of the device (and is proportional to the Fermi level splitting). We complement our new metrology by applying scanning photocurrent microscopy using near-field scanning microscopy (NSOM) probes as a local source of excitation to image local variations in Jsc within the material, also with nanoscale resolution. Further, we spatially and spectrally resolve the external quantum efficiency (EQE) within the devices, also with nanoscale resolution, while mimicking the power density operation conditions of real devices [2]. Combined, these new tools provide a complete picture of the local optoelectric characteristics of PV devices, including an indirect measurement of the centers for non-radiative recombination, and a direct mapping of the local collection properties of the material, respectively. We apply our novel metrology to polycrystalline solar cells, where we find Voc local variations of >200 mV.

9561-5, Session 3

Robust measurement of thin-film photovoltaic modules exhibiting light-induced transients

Michael G. Deceglie, Timothy J. Silverman, Bill Marion, Sarah R. Kurtz, National Renewable Energy Lab. (United States)

Light-induced changes to the current-voltage characteristic of thin-film photovoltaic modules (i.e. light-soaking effects) frustrate the repeatable measurement of their operating power. We describe best practices for mitigating, or stabilizing, light-soaking effects for both CdTe and CIGS modules to enable robust, repeatable, and relevant power measurements. We motivate the practices by detailing how modules react to changes in different stabilization methods. For example we find that a 20°C variation in temperature during light soaking can cause > 5% variation in measured power.

Reliable measurements of module power are critical for qualification testing, reliability testing, and power rating. Thus we developed a two-stage light-soaking method. It begins with an extended, loosely controlled, light exposure to saturate most of the transient. This step is complete when module power is changing by less than 1% per 20 kWh m-2; we describe how this can be reliably determined even in variable outdoor conditions. The second step is a tightly temperature-controlled uninterrupted 5-hour

light exposure to ensure the stabilization concludes with the module in a repeatable state.

We also describe a method for validating alternate stabilization procedures, such as those involving forward bias in the dark, to ensure they result in an outdoor-relevant module state. We have found that alternate procedures, when not applied carefully, can overestimate the light-exposed state power production of a module by as much as 10%. To prevent this, we present a validation method based on subsequent light exposure and power measurement to ensure that a relevant state has been reached.

9561-9, Session 3

sol-gel deposition and plasma treatment of intrinsic, aluminum-doped and gallium-doped zinc oxide thin films as transparent conductive electrodes

Zhaozhao Zhu, Trent Mankowski, Kaushik Balakrishnan, College of Optical Sciences, The Univ. of Arizona (United States); Ali Sehpar Shikoh, Farid Touati, Mohieddine A. Benammar, Qatar Univ. (Qatar); Masud Mansuripur, Charles M. Falco, College of Optical Sciences, The Univ. of Arizona (United States)

We have fabricated transparent conductive electrodes (TCEs) using sol-gel deposition of Aluminum Zinc Oxide (AZO) thin films followed by thermal annealing and plasma treatment. These TCEs exhibit high optical transmittance (over 90%) and good electrical conductivity (sheet resistance below 100 ohms/square). The dopant concentration and film thickness as well as pre- and post-annealing conditions are adjusted for optimum transparency and electrical conductivity. Plasma treatment is found to enhance the desirable characteristics of our fabricated TCEs. The measured optical transmittance spectra are in good agreement with calculations that account for interference effects arising from the TCE's layered structure as well as its index-mismatch with the substrate. We also assembled functioning solar cells using our AZO thin films as the transparent conductive electrode.

9561-10, Session 3

Cd-Zn-O-S alloys for optimal buffer layers in thin-film photovoltaics

Joel B. Varley, Lawrence Livermore National Lab. (United States); Xiaoqing He, Univ. of Illinois at Urbana-Champaign (United States); Neil Mackie, MiaSolé Hi-Tech Corp. (United States); Angus A. Rockett, Univ. of Illinois at Urbana-Champaign (United States); Vincenzo Lordi, Lawrence Livermore National Lab. (United States)

Advances in thin-film photovoltaics have largely focused on modifying the absorber layer(s), while the choices for other layers in the solar cell stack have remained somewhat limited. In particular, cadmium sulfide (CdS) is widely used as the buffer layer in typical record devices utilizing absorbers like Cu(In,Ga)Se2 (CIGSe) or Cu2ZnSnS4 (CZTS) despite leading to a loss of solar photocurrent due to its band gap of 2.4 eV. While different buffers such as Zn(S,O,OH) are beginning to become competitive with CdS, the identification of additional wider-band gap alternatives with electrical properties comparable to or better than CdS is highly desirable.

Here we use hybrid density functional calculations to characterize CdxZn1-xOyS1-y candidate buffer layers in the quaternary phase space composed by Cd, Zn, O, and S. We focus on the band gaps and band offsets of the alloys to assess strategies for improving absorption losses from conventional CdS buffers while maintaining similar conduction band offsets known to facilitate good device performance. We also consider additional criteria such as lattice matching to identify regions in the composition space that may provide improved epitaxy to CIGSe and CZTS absorbers. Lastly, we incorporate our calculated alloy properties into device model simulations of typical CIGSe devices to identify the CdxZn1-xOyS1-y buffer compositions that lead to the best performance.

This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344 and funded by the Department of Energy office of Energy Efficiency & Renewable Energy (EERE) through the SunShot Bridging Research Interactions through collaborative Development Grants in Energy (BRIDGE) program.

9561-11, Session 3

Eco-friendly spray coating of organic solar cells through water-based nanoparticles ink

Jeroen Stryckers, Lien D'Olieslaeger, Jean Manca, Univ. Hasselt (Belgium) and IMEC (Belgium); Anitha Ethirajan, Univ. Hasselt (Belgium) and IMEC (Belgium); Wim Deferme, Univ. Hasselt (Belgium) and IMEC (Belgium)

Ultrasonic spray coating is currently proven to be a reliable, flexible and cost efficient fabrication method for printed electronics [1-2]. Ultrasonic nozzles are by design especially well-suited to deposit nano-suspension dispersions. Due to the ultrasonic vibration of the nozzle, droplets having a median diameter of 20 μm are created in a homogeneous droplet cloud and directed towards the substrate. When one prepares an ink having the right wetting properties, thin and homogeneous layers, fully covering the surface, can be achieved. Together with conjugated polymer nanoparticles (NPs), emerging as a new class of nanomaterials, [3] it opens possibilities towards eco-friendly roll-to-roll processing of state-of-the-art organic bulk heterojunction solar cells.

A ultrasonic spray coater was used to print the conjugated polymer NP layers under different conditions. A first optimization of the spray coater settings (flow rate, spray speed and temperature) and the ink formulation (water and co-solvent mixture and NP content) was performed for polystyrene particles dissolved in a water-ethanol mixture. As a next step, the low bandgap donor polymer poly[[9-(1-octylnonyl)-9H-carbazole-2,7-diyl]-2,5-thiophenediyl-2,1,3-benzothiadiazole-4,7-diyl-2,5-thiophene-diyl] (PCDTBT) [4] and the fullerene acceptor phenyl-C71-butyric acid methyl ester (PCBM[70]) were combined in a water-based blend NP dispersion which was prepared using the mini-emulsion technique. [5,6] Optical Microscopy, profilometry and Scanning Electron Microscopy (SEM) are performed to study the roughness, surface structure, thickness and coverage of the spray coated layers. Finally the printed NP layers are integrated in organic bulk heterojunction solar cells and compared to spin coated reference devices.

9561-12, Session 4

On the interplay of light trapping and plasmonic losses in honeycomb textured silicon thin film solar cells

Asman Tamang, Jacobs Univ. Bremen (Germany); Hitoshi

Sai, National Institute of Advanced Industrial Science and Technology (Japan); Vladislav Jovanov, Jacobs Univ. Bremen (Germany); Koji Matsubara, National Institute of Advanced Industrial Science and Technology (Japan); Dietmar Knipp, Jacobs Univ. Bremen (Germany)

Microcrystalline silicon thin film solar cells on honeycomb textured substrates exhibit short circuit currents exceeding 30 mA/cm2 and energy conversion efficiencies exceeding 10 % [1]. In this study the manufacturing process and the light trapping of the honeycomb textured solar cells was investigated by numerical simulations. The interface morphologies of the individual layers of the solar cells were modeled by an etching and growth model [2]. By controlling the fabrication process the period and height of the honeycomb texture can be varied. The influence of the manufacturing process on the silver back reflector morphology and the quantum efficiency was determined. The optical wave propagation was calculated in 3D by Finite Difference Time Domain (FDTD) simulations. A very good agreement between the optical simulations and the experimental results was obtained. The short circuit current is maximized if the period of the honeycomb texture is approximately equal to the thickness of the solar cell. The short circuit current increases with increasing height up to a height/period ratio of 1/4. For larger height/period ratios the short circuit current and plasmonic losses of the silver back reflector remain unchanged.

9561-14, Session 4

Light trapping enhancement in elliptical nanohole array thin film silicon solar cell

Zihuan Xia, Yonggang Wu, Yongdong Pan, Xuefei Qin, Jian Zhou, Zhongyi Zhang, Tongji Univ. (China)

Various structures employing nanorod or nanohole provide promising approaches to trap and absorb incident light in a semiconductor layer. Nanohole arrays have been found comparable to or even better than nanorod counterparts in terms of light absorption, and exhibit superior mechanical robustness in comparison with the latter. Here, we propose a perpendicular elliptical silicon nanohole (PE-SiNH) array for light absorption in thin film silicon solar cells. The lattice spacing of the array is chosen to be 500 nm, and the overall thickness of the Si thin film is fixed at 2.33?m. The major axis of each elliptical nanohole is perpendicular to that of the four nearest ones. Rsoft DiffractMod module based on rigorous coupled wave analysis (RCWA) is used in the simulation. Results show that an ultimate efficiency of 29.4 % is achieved for the optimal PE-SiNH array, which is 17.4 % and 10.8 % higher than that of the circular SiNH array with the same fill fraction and the optimal circular SiNH array respectively. Fourier analysis reveals that the optimal PE-SiNH structure show additional (11) and (22) components compared with the circular SiNH structure of the same fill fraction, which helps to couple incident light into slow Bloch modes and therefore contribute to the light trapping enhancement in the wavelength region between 700 and 1100 nm. The light trapping property of the nanohole arrays below the wavelength corresponding to the lattice spacing is dominated by the Mie scattering. It is found that high eccentricity of the elliptical nanohole is in favor of the reduction of the back scattering and therefore enhances the light trapping in this wavelength region. The relative low absorption of the optimal PE-SiNH array in the short wavelength range is partly compensated by the low transmission in the long wavelength range, though the optimal PE-SiNH array show less coupling of incident light into channeling modes than the circular SiNH one does between 500 and 730 nm.

9561-15, Session 4

Design of broadband omnidirectional antireflection coatings using ant colony algorithm

Xia Guo, Beijing Univ. of Technology (China)

Optimization method which is based on the ant colony algorithm (ACA) is described to optimize antireflection (AR) coating system with broadband omnidirectional characteristics for silicon solar cells incorporated with the solar spectrum (AM1.5 radiation). It's the first time to use ACA method for optimizing the AR coating system. In this paper, for the wavelength range from 400 nm to 1100 nm, the optimized three-layer AR coating system could provide an average reflectance of 2.98% for incident angles from 0° to 80° and 6.56% for incident angles from 0 to 90 .

9561-16, Session 4

Efficiency enhancement of semitransparent organic solar cells by using printed dielectric mirrors

Carina Bronnbauer, Karen K. Forberich, Fei Guo, Nicola Gasparini, Christoph J. Brabec, iMEET (Germany)

Building integrated thin film solar cells are a strategy for future eco-friendly power generation. Such solar cells have to be semi-transparent, long-term stable and show the potential to be fabricated by a low-cost production process. Organic photovoltaics are a potential candidate because an absorber material with its main absorption in the infrared spectral region where the human eye is not sensitive can be chosen. We can increase the number of absorbed photons, at the same time, keep the transparency almost constant by using a dielectric, wavelength-selective mirror. The mirror reflects only in the absorption regime of the active layer material and shows high transparencies in the spectral region around 550 nm where the human eye is most sensitive. We doctor bladed a fully solution processed dielectric mirror at low temperatures below 80 °C. Both inks, which are printed alternatingly are based on nanoparticles and have a refractive index of 1.29 or 1.98, respectively, at 500 nm. The position and the intensity of the main reflection peak can be easily shifted and thus adjusted to the solar cell absorption spectrum. Eventually, the dielectric mirror was combined with different organic solar cells. For instance, the current increases by 20.6 % while the transparency decreases by 23.7 % for the low band gap absorber DPP and silver nanowires as top electrode. Moreover we proved via experiment and optical simulations, that a variation of the active layer thickness and the position of the main reflection peak affect the transparency and the increase in current.

9561-201,

Status and challenges of CdTe photovoltaics

Wyatt K. Metzger, National Renewable Energy Lab. (United States)

Current research in CdTe solar cells is targeting 24% efficiency to drive cost to less than 40 cents/W, displace silicon market share, and reach grid parity. By maximizing photocurrent, CdTe cell efficiency has recently reached 21.5% and surpassed multicrystalline silicon. There is still headroom to increase performance further by improving hole density, lifetime, and thereby photovoltage. However, this will require changing a stubborn defect chemistry that has caused photovoltage to be stagnant for decades. We will describe new work on single-crystal and polycrystalline CdTe designed to understand and overcome this challenge.

9561-18, Session PMon

Influence of Se interlayer in CIGS absorption layer for solar cell devices

Suthan Kissinger Nallathambi Jones, Jubail Univ. College (Saudi Arabia); Jae Kwan Sim, Cheul-Ro Lee, Chonbuk National Univ. (Korea, Republic of)

A CIGS absorber layer with high gallium contents in the space-charge region can reduce the carrier recombination and improve the open circuit voltage Voc. Therefore, controlling Ga grading on top of CIGS thin film solar cells is the main objective of this experiment. To reduce Selenium (Se) vacancy, it is important that the diffusion of Ga elements into Se vacancy between Mo back contact and CIGS absorption layer would be controlled. In order to reduce Se vacancy and confirm Ga inter-diffusion, two CIGS solar cells were fabricated by converting CIG precursor with and without Se interlayer. The copper-indium metallic precursors were fabricated corresponding to the sequence CuIn/In/Mo/STS on stainless steel (STS) substrates by sequential direct current magnetron sputtering and Se layer was evaporated by rapid thermal annealing (RTA) system to obtain a Se/CuIn/In/Mo/STS stack. CuGa precursor layer was also fabricated on the Se/CuIn/In/Mo/STS stack. Finally, both CuGa/Se/CuIn/In/Mo/STS and CuGa/CuIn/In/Mo/STS stacks were selenized at 500? for 1 hour. It is observed from the secondary ion mass spectroscopy (SIMS) and X-ray diffraction (XRD), there is a change between the fabricated CIGS absorption layers and the amount of Ga elements. Furthermore, the Ga elements gradually decrease from the top to bottom layer of the CIGS absorption layer. We also discussed the effect of Se interlayer in CIGS absorption layer and its influence on the solar cell performance.

9561-19, Session PMon

Simple ‘one step’ spray process for CuInS2 / In2S3 heterojunctions on flexible substrates for photovoltaic applications

Titu Thomas, K. P. Vijayakumar, Cochin Univ. of Science & Technology (India)

Flexible semiconducting devices as solar cells and displays have been a recent attraction. Unlike heavy, brittle glass substrates, plastics and metallic foils have advantage of flexibility. This allows a low cost mass production of devices by roll-to-roll processes. Among these, metal foils have added advantages like good thermal stability and high melting point. In this paper we present a very simple method for the growth of CuInS2 (CIS) thin films on flexible Cu foil. CIS is one of the leading candidates for photovoltaic applications due to its optimum band gap and higher absorption coefficient. Interestingly, in the present work, we prepared CIS films by depositing merely InS directly over the Cu foil using simple and economical chemical spray pyrolysis technique. The effects of volume of precursor solution on structural, optical and electrical properties of the films were studied. Improvement in crystallinity and morphology was observed for higher volumes. All the films showed good diode characteristics. Thus for the first time with a single spray, a diode is obtained and this could be the first step towards the fabrication of flexible solar cells with the structure of Cu foil/ CuInS2/InS/Ag. Photo voltaic activity of the device can be expected by optimizing the deposition parameters.

9561-20, Session PMon

A comparison between Zn rich and Zn poor Cu2ZnSnS4 thin film solar cells fabricated by one step electrodeposition method

Ye Chan Kim, Gwangju Institute of Science and Technology (Korea, Republic of); Ho Jung Jeong, Guk Jin Jeon, Gwangju Institute of Science and Technology (Korea, Republic of); Jae Hyung Jang, Gwangju Institute of Science and Technology (Korea, Republic of)

Cu2ZnSnS¬4 (CZTS) thin film has received a lot of attention in the recent years due to its great potential for eco-friendly and low-cost absorber materials. Various deposition techniques have been investigated to realize high quality CZTS materials, and they include vacuum and non-vacuum methods such as spray pyrolysis, electrodeposition and sol-gel process. The electrodeposition technique is one of the most promising methods to manufacture low cost manufacturing of CZTS based thin film photovoltaic devices.

In this report, the CZTS thin films were synthesized by one step electrodeposition method on Mo coated soda-lime-glass. The as-deposited CZTS films were subsequently annealed in Ar ambiance at 550? without any other toxic gases to crystalize CZTS films. The resulting film exhibited Zn/(Cu+Sn) ratio varying between 0.15 to 0.60. The structural and optical properties of the Zn rich and Zn poor CZTS thin film were investigated by using Energy dispersive spectroscopy, X-ray diffraction, scanning electron microscopy, atomic force microscopy, and UV-VIS spectrometer. The quality of films was improved as the Zn/(Cu+Sn) ratio was increased. However, the excessive Zn composition resulted in aggravation of performance of CZTS solar cells due to the formation of secondary phase.

Finally, both types of films were utilized to fabricate CdS/CZTS solar cells and the resulting solar power conversion efficiency was measured. The highest efficiency of 2.1 % was achieved from the single step deposited CZTS film.

This work was supported by the Core Technology Development Program for Next-generation Solar Cells of Research Institute for Solar and Sustainable Energies (RISE), GIST.

9561-21, Session PMon

Characterization of Cu2ZnSnS4 thin films prepared by the sulfurization of co-sputtered metal precursors

Mohamed Abusnina, Univ. of Denver (United States) and National Renewable Energy Lab. (United States); Mohammad Matin, Univ. of Denver (United States); Helio R. Moutinho, Mowafak M. Al-Jassim, National Renewable Energy Lab. (United States)

In this work, we report the synthesis and characterization of Cu2ZnSnS4 (CZTS) thin films prepared by annealing of co-sputtered metal precursors in sulfur atmosphere. Radio frequency magnetron sputtering was applied to deposit the metal layers from single metal targets on Mo-coated soda-lime glass substrates. The chemical composition of the precursors was controlled by varying the sputtering working power resulting in films with various compositions. X-ray fluorescence (XRF) was used to determine the elemental concentration of these metal films. The metal precursors were thereafter converted into CZTS in a tube furnace using different sulfurization conditions in order to investigate the effect of the annealing process on the properties of the final CZTS films. The composition of the CZTS films was carried out by XRF and energy-dispersive spectroscopy (EDS). Film structural characterization and phase identification results were supported by X-ray diffraction (XRD) and Raman spectroscopy. Surface and cross-sectional film morphology was carried out by scanning electron microscopy (SEM). For the sulfurized films, XRF showed significant Sn loss which was successfully controlled by depositing precursors with excess of Sn. After optimizing the composition of the metal precursor, XRD and Raman scattering results revealed single-phase CZTS films without clear signs of the existence of secondary phases. SEM showed improved morphology in form of dense structures and smooth surface for the films sulfurized at 600 ºC. Our first solar cell, based on CZTS film originated from a precursor sulfurized at 550 ºC for 60 min, showed an open-circuit voltage of 471 mV, a short-circuit current density of 9.92 mA/cm-2, a fill factor of 36.9%, and an efficiency of 1.72%.

9561-23, Session PMon

Tunability of graphene: Utilizing multilayered nanoclusters

Shivani Bhardwaj, Alok Ji Shukla, Nilesh Patak, R. P. Sharma, Indian Institute of Technology Delhi (India)

Graphene plays influencive role to the coupling of the electromagnetic field to sub wavelengths structure and this field further may be merge to a thin film for various applications. Here we have studied using in quasi-static electricity, to expose coupling at nanoscales, the Aluminium, Silver and Gold nanoparticles (NPs) support localised surface plasmon resonance (LSPR) which can be resonantly coupled to a system and seizes enhanced local field, tuned reflective losses at the thin film/air interfaces, total transmittance and controlled resonant band width and height. The thickness of single layer graphene film, size of NPs and multi layered core shell thickness/multi layered dielectric core shell thickness were varied to understand the coupling of the electromagnetic field to sub wavelengths and applicability of such systems.

The optical parameters were studied from ultraviolet domain to near infrared domain, which steer a wide range of bandwidth that may suit distinct applications. The increased size of NPs or multilayered system, red shifts the resonance occurs due to damping effects and graphene facilitaty. The conductivity of the graphene is highly tuneable parameter due to the tunability of thickness of graphene since the graphene itself is having plasmonic as well as semiconductor properties. This model was developed using effective medium theory and conductivity of two dimension single layer graphene. The study of such coupled system is useful to understand the physics and may guide the experimental aspects. Without graphene, LSPRs of NPs do not show appreciable shift in resonance wave lengths as well as broad band width and height, which supporting the role of graphene as an electromagnetic field coupling agent.

9561-24, Session PMon

Device characteristics of antenna-coupled metal-insulator-metal diodes (rectenna) using Al2O3, TiO2 and Cr2O3 as insulator layer for energy harvesting applications

Mesut Inac, Atia Shafique, Meriç Özcan, Yasar Gurbuz, Sabanci Univ. (Turkey)

Demand for the inexpensive devices operating at room temperature for broadband sensing and imaging applications are increasing in the last years. Due to the small sizes and the integration capabilities, antenna coupled metal-insulator-metal (MIM) diodes are one of the potential candidates for sensing, imaging and energy harvesting in IR and solar range of spectrum. The antenna coupled diodes are already illustrated in the literature for energy harvesting applications, wireless power transmission and detection. As matter of fact, functionality of MIM diodes based on quantum tunneling leads to device time constant in the order of femtoseconds. The smaller sizes of these devices enable to place more pixels in detectors and harvesters. Due to speed and size of these devices, antenna-coupled MIM diode is thought to be a better choice as an ultrafast and highly responsive harvesting device; these devices can be an alternative to low efficiency energy harvesters: photovoltaic (PV) and thermo-photovoltaic (TPV) devices.

In this work, it is aimed to design and develop a device that can operate in the IR regime of light spectrum. The model formation is based on electron tunneling in MIM diode devices. It includes three different insulators (Al2O3, Cr2O3 and TiO2) and different sizes of devices. First the preliminary DC characterization of individual MIM diodes have been carried out, afterwards, joint characterization of antenna along with diode has been performed. Device characteristics such as responsivity and I-V results are reported.

9561-25, Session PMon

The electrodeposition of multilayers on a polymeric substrate in flexible organic photovoltaic solar cells

Andre Guedes, Idaulo Cunha, Simone Tartari, Vilmar P. Guedes, Monica L. Souza, INTELLECTOS (Brazil)

Flexible organic photovoltaic solar cells have drawn intense attention due to their advantages over competing solar cell technologies. The method utilized to deposit as well as to integrate solutions and processed materials, manufacturing organic solar cells by the Electrodeposition System, has been presented in this research. In addition, we have demonstrated a successful integration of a process for manufacturing the flexible organic solar cell prototype and we have discussed on the factors that make this process possible. The maximum process temperature was 120°C, which corresponds to the baking of the active polymeric layer. Moreover, the new process of the Electrodeposition of complementary active layer is based on the application of voltage versus time in order to obtain a homogeneous layer with thin film. This thin film was not only obtained by the electrodeposition of PANI-X1 on P3HT/PCBM Blend, but also prepared in perchloric acid solution. Furthermore, these flexible organic photovoltaic solar cells presented power conversion efficiency of 12% and the inclusion of the PANI-X1 layer reduced the effects of degradation on these organic photovoltaic panels induced by solar irradiation. Thus, in the Scanning Electron Microscopy (SEM), these studies have revealed that the surface of PANI-X1 layers is strongly conditioned by the dielectric surface morphology.

Photochemical upconversion of light for renewable energy and more

Timothy W. Schmidt, The Univ. of New South Wales (Australia)

It has been abundantly demonstrated that certain molecular compositions are capable of photochemical upconversion (PUC), where lower energy photons are converted to higher energy photons, sometimes with quantum efficiencies approaching 50%. PUC has been applied to solar cells, increasing the EQE of the devices in the region below the bandgap of the device. There remain challenges, though, to the realisation of efficient photochemical upconversion under low levels of incident light, and the incorporation of a liquid upconversion medium into a device. This talk will address these challenges and our progress towards meeting them.

Theoretical calculation of light trapping enhancement in Si SiO2 core shell nanowires

Weijian Chen, Jianfeng Yang, Santosh Shrestha, Shujuan Huang, Gavin Conibeer, The Univ. of New South Wales (Australia)

Nanophotonic light trapping for photovoltaics cell is of extensive interest recently. Semiconductor nanowires could act as optical cavity and strongly promote light trapping on certain wavelength. However, as ray theory is not applicable in nanophotonic, one central problem in nanostructure design is how to accurately analyze light trapping enhancement without making the actual cell. We apply two rigorous models to the Si-SiO2 core-shell nanowire on light trapping property compared to single crystalline Si nanowire. The first model is based on the statistical temporal couple-mode theory which is popular in analyzing planar structure but rarely applied to the core-shell cylinder configuration. In this method the enhancement factor is calculated by specifying the all resonant modes and the coupling between each resonant mode and total channels. Meanwhile, the local density of states (LDOS) elucidates the filed behavior and field-matter interaction in the nanostructure. It has been proposed that the LDOS can be a critical figure of merit in nanoscale light management. In this second model, the eigenmodes of the proposed structure are calculated by finite element method. The light trapping enhancement can be calculated by the product of the LDOS and modal occupation numbers. The results from the two models will be carefully discussed, as well as the needed calculation power. Large light trapping enhancement from the core-shell nanowires is expected and the results within reasonable error range from the two models are anticipated. The optimization of nanowires structure will be further reported in the SPIE conference.

Analysis of metallic nanoantennas for solar energy conversion

Brhayllan Mora Ventura, Univ. de Guadalajara (Mexico); Ramón Díaz de León, Univ. Autónoma de San Luis Potosí (Mexico); Guillermo Garcia-Torales, Jorge L. Flores-Nuñez, Univ. de Guadalajara (Mexico); Javier Alda, Univ. Complutense de Madrid (Spain); Francisco Javier González, Univ. Autónoma de San Luis Potosí (Mexico)

Recently thermo-electrical nanoantennas, also known as Seebeck nanoantennas, have been proposed as an alternative for solar energy harvesting applications. In this work we present the optical and thermal analysis of metallic nanoantennas operating at infrared wavelengths, this study is performed by numerical simulations using COMSOL Multiphysics. Several different nanoantenna designs were analyzed including dipoles, bowties and square spiral antennas. Results show that metallic nanoantennas can be tuned to absorb at thermal-infrared wavelengths, and that numerical simulation can be useful in optimizing the performance of these types of nanoantennas at optical and infrared wavelengths

Charge recombination dynamics of perovskite solar cells

Hee Won Shin, Tae Kyu Ahn, Sungkyunkwan Univ. (Korea, Republic of)

Perovskite materials are promising candidates for realizing efficient, flexible, and lightweight solar cells. Herein, we present the fabrication of perovskite solar cells consisting of mesoporous TiO2, blocking layer, and hole transport materials (HTM), and also explain the excellence of solar cell performance in terms of the charge recombination and extraction times which verified by several spectroscopic techniques. First of all, in order to confirm the dynamics of the transient species, we have used the nanosecond transient absorption (TA) which consists of nanosecond pulse and Xe lamp as the pump and probes lights, respectively. Second, we have utilized the time-resolved photoluminescence (TRPL) to understand the excited charged carrier behaviors such as exciton generation, charge separation, and recombination which depend on the nanostructure and composition of the devices. Finally, the transient photovoltage (TPV) and transient photocurrent (TPC) techniques have been applied to directly get the recombination and extraction times in the devices. In case of TPV, nanosecond pulse and Xe lamp were used for small perturbation light source and bias light one, respectively. The device was directly connected to a digital oscilloscope and the input impedance of the oscilloscope was set to 1 M? for open circuit condition. Bias light intensity was controlled by neutral density filters for various open circuit voltages (Voc) and laser pulse was strongly attenuated to not exceed 30 mV of voltage transient (?V). Overall analysis of spectroscopic results, we can conclude that slow recombination and fast extraction rates are indispensable for highly efficient solar cells.

Mie-resonance-mediated enhanced light trapping in Si nanopillar arrays

Eunah Kim, Yunae Cho, Ahrum Sohn, Ewha Womans Univ. (Korea, Republic of); Hyeong-Ho Park, Korea Advanced Nano Fab Ctr. (Korea, Republic of); Joondong Kim, Incheon National Univ. (Korea, Republic of); Dong-Wook Kim, Ewha Womans Univ. (Korea, Republic of)

Si-wafer based solar cells show predominant photovoltaic (PV) market share. The advantages of Si, as an active material for a PV device, include abundance on earth, very competitive fabrication cost, and superior device performance. Further efforts to lower the cost to generate electricity have led to light trapping strategies to improve optical absorption in Si. Nanostructures have exhibited quite remarkable absorption enhancement. We have investigated optical characteristics of Si nanopillar (NP) array surface patterns, fabricated by e-beam lithography and dry etching. Optical reflectance measurements were carried out for NP arrays with various diameter and period. The reflectance spectra showed that the NP array exhibited remarkable antireflection effects in broad wavelength range. The finite-difference time-domain (FDTD) simulations and analyses showed that

lowering of the effective refractive index, diffraction, and Mie resonance enabled the improved light trapping. It is very important to design desirable nanostructures to realize both enhanced light trapping and carrier collection capability. Surface photovoltage (SPV) behaviors of the NPs were compared with those of a planar counterpart by Kelvin probe force microscopy measurements. Surface or defect states can trap carriers and cause band bending at surface. Perturbation by light illumination changes the surface band profile, inducing SPV. The SPV studies could help to improve collection efficiency of photo-excited carriers.

On the road to hot carrier solar cells
(Invited Paper)

P. Craig Taylor, Reuben T. Collins, Colorado School of Mines (United States)

Standard solar cells have limitations on their theoretical efficiencies in part due to the fact that carriers excited by light with energies above the semiconductor's band gap quickly lose some of their energy to heat, which can be overcome by collecting the carriers before they thermalize. However, since carriers thermalize over very short times and distances, one must employ a nanostructured morphology. We report results that provide a new paradigm for solar cells that uses a nanostructured crystalline silicon in an amorphous absorber matrix (hydrogenated amorphous silicon). Previously amorphous absorbers have received no serious consideration because of their low carrier mobilities. We demonstrate that carriers generated in the amorphous region are transported out of this region before losing their energy to heat. This result establishes the possibility of using a wide range of nanostructured amorphous matrices to dramatically increase the efficiencies of solar cells. Since hot carrier solar cells ultimately rely on selective collectors that pick off the excited carriers at the peak of their energetic distribution, the task is difficult with crystalline semiconductors where momentum and energy must be conserved during the transfer but easier for amorphous absorbers where crystal momentum is not applicable. Therefore, the use of an amorphous absorber provides a highly desirable and flexible approach to producing low-cost, hot carrier solar cells. Since amorphous materials can be grown over a much wider composition space than crystalline materials, this result greatly broadens the absorbing materials that can be used to dramatically increase the efficiencies of solar cells.

9562-2, Session 1

Carrier multiplication and energy dissipation in Si and Ge nanocrystals
(Invited Paper)

Tom Gregorkiewicz, Saba Saeed, Univ. van Amsterdam (Netherlands)

Carrier-carrier and carrier-phonon scattering in semiconductors involves multiple physical processes which become seriously modified in nanocrystals. In particular quantum confinement strongly affects properties of hot carriers, enhancing their effective lifetime – by reduction of phonon emission, and promoting impact excitation rates – by enabling multiple exciton generation and energy transfers to the outside of the nanostructure. In my presentation, I will discuss some results of investigations of these effects in Si and Ge nanocrystals embedded in large bandgap solid state matrices. The motivation for these investigations is provided by possible application of Si and Ge nanocrystals for modification of solar spectrum with an eye on future, highly efficient photovoltaics.

In particular, I will review the most recent progress in following specific subjects:

1. Carrier multiplication in Si nanocrystals. Here I will present results as obtained by calibrated ultrafast transient absorption and advanced photoluminescence quantum yield spectroscopies. These will be supported by theoretical modeling of the relevant energy transfer processes. I will also discuss the on-going investigations towards a spectral finger fingerprint of the carrier multiplication process.

2. Energy recycling process for hot carrier in Si nanocrystals. This effect is enabled by simultaneous occurrence of impact excitation and Auger recombination of multiple excitons co-localized within the same nanostructure.

3. Energy exchange between neighboring Si nanocrystals, leading to peculiarities in the exciton lifetime and offering potential of long-range energy diffusion.

4. Excitation of Er emitters by hot carriers generated in Si nanocrystals upon absorption of highly energetic photons. I will demonstrate that this energy transfer path is sufficiently efficient to overcome hot carrier cooling by phonon emission.

9562-3, Session 1

Ultrafast carrier dynamics study in zirconium nitride

Neeti Gupta, Xiaoming Wen, Shujuan Huang, Simon Chung, Santosh Shrestha, Gavin Conibeer, The Univ. of New South Wales (Australia)

Hot carrier solar cell (HCSC) is a promising third generation photovoltaic device and potentially able to overcome the Shockley–Queisser limit. HCSC aims to circumvent the fundamental loss mechanism by extracting carriers before thermalization also minimize the non-absorbed sub-bandgap losses. The theoretical efficiency for an ideal HCSC is predicted to be 65% under 1 sun solar radiation or 85% under maximal concentration. HCSCs have potential advantage of consisting of only few layers of materials and therefore can conceptually be made relatively simply compared to a multi-junction solar cell possibly. Moreover, the HCSC can potentially be made from abundant and non-toxic materials using low cost, high throughput thin film fabrication techniques. HCSC has two main parts: An absorber and an energy selective contact. A critical requirement of the absorber is to slow down the cooling rate of photoexcited hot carriers, from few ps to hundreds of ps or a few ns. ZrN theoretically have a large phononic bandgap and thus a much slowed cooling rate may be expected. In this investigation ZrN thin films were deposited by RF sputtering and characterized by a range of techniques. The carrier dynamics have been studied using ultrafast transient absorption (TA) experiments which shows excited state absorption peaks in visible and near infrared regions. Hundreds of ps cooling time were observed in ZrN by fitting TA spectra. The slowed thermalization process in ZrN suggests that it is a promising material for use as a HCSC absorber.

9562-4, Session 1

Photovoltage transients in GaAs/InGaAs solar cells

Roman Holubenko, Artem Yakovliev, Sergey V. Kondratenko, National Taras Shevchenko Univ. of Kyiv (Ukraine)

A study of the photovoltaic properties of the GaAs-based solar cells with InGaAs quantum wire had been conducted. The research included the investigation of the photovoltage rise and decay transients, spectral photovoltage dependences at different temperatures. The objects investigated were GaAs-based solar cells with InGaAs quantum wire (QWR) embedded into space-charge-region of p-i-n junction. Samples with different In content and size of InGaAs nanoobjects had been created using molecular beam epitaxy. Unlike the reference cell, the ones containing the InGaAs QWR had shown higher sensitivity in the energy range 1.2 – 1.38 eV. This is caused by the spatial separation of electron-hole (e-h) pairs excited

in the QWR due to band-to-band transition. Under selective excitation of the e-h pairs only in the InGaAs quantum wire the photovoltage rise transient is slower compared to the e-h generation in GaAs. This effect is explained by charge carriers release from the InGaAs quantum well into delocalized states of the surrounding GaAs. It was determined that the InGaAs quantum wires increase the recombination rate of the non-equilibrium carriers in the temperature range 80 to 290 K, which means that the quantum wires are the additional recombination centers.

9562-5, Session 2

Quantifying energy transfer in semiconductor nanocrystals using coherent phonon manipulation and ultrafast spectroscopy *(Invited Paper)*

Bryan T. Spann, U.S. Naval Research Lab. (United States) and Purdue Univ. (United States); Xianfan Xu, Purdue Univ. (United States)

One potential way to increase photovoltaic efficiency is to take advantage of hot-carriers. Nanocrystal based solar cells aim to take advantage of hot-carrier capture to boost device performance. The crucial parameter for gauging a given nanocrystal material for this application is the electron-phonon coupling. The electron-phonon coupling will dictate the thermalization time of hot-carriers. In this study we demonstrate a method of quantifying the electron-phonon coupling in semiconductor nanocrystals. By employing ultrafast transient absorption spectroscopy with temporal pulse shaping, we manipulate coherent phonons in CdTe_{1?x}Se_{x} nanocrystals to quantify the efficiency of the electron-phonon coupling. The Raman active longitudinal optical phonon (LO) modes were excited and probed as a function of time. Using a temporal pulse shaper, we were able to control pump pulse pairs to coherently excite and cancel coherent phonons in the CdTe_{1?x}Se_{x} nanocrystals, and estimate the relative amount of optical energy that is coupled to the coherent CdSe LO mode which is the dominant thermalization pathway for the hot-electrons in this system.

9562-6, Session 2

Hot carrier solar cell absorbers: Investigation of phonon properties of candidate materials *(Invited Paper)*

Gavin Conibeer, Santosh Shrestha, Shujuan Huang, Robert Patterson, Hongze Xia, Yu Feng, Suntrana Smyth, Simon Chung, Neeti Gupta, Yi Zhang, Jianfeng Yang, Weijian Chen, Xi Dai, The Univ. of New South Wales (Australia)

The key property for a hot carrier absorber is to slow the rate of carrier cooling from the picosecond timescale to at least 100s of ps, but preferably ns to be similar to the rate of radiative recombination. Hot carriers cool primarily by emission of LO phonons. The general properties of phonons and carriers required of a hot carrier absorber have been defined. Materials and structures that exhibit some of these properties fall into three categories:

(a) Bulk materials with large difference in mass between constituent atoms such that there is a large difference between optical and acoustic phonon energies. These suppress the main carrier cooling mechanism of decay of optical phonons. Hence information on phonon dispersion across all momenta is critical to deeper understanding and prediction of appropriate materials.

(b) Low dimensional multiple quantum well (MQW) systems have also been shown to have lower carrier cooling rates. Theories vary as to the importance of carrier or of phonon confinement in this effect. Information on folded phonon modes would help to distinguish between them.

(c) Nanoparticles have also exhibited long hot carrier lifetimes. This is due to confinement of optical phonons and folding of acoustic phonon modes leading to restriction in the allowed decay paths for hot optical phonon populations. These result in longer hot carrier lifetimes.

Knowledge of the phonon energies and dispersion with momentum in these materials is important to understand phonon interaction with carriers. Measurement of these is challenging as very few techniques can map phonon energies across the whole Brillouin zone. Raman spectroscopy is used to measure close to zone centre phonon energies, principally optical phonons; FTIR is used to measure zone edge energies, primarily acoustic phonons. But for the whole zone only inelastic X-ray scattering or neutron scattering have a wide enough range of momentum. In order to achieve required momenta, very high energy photons are required, only available in 4th generation synchrotron and hence in very few beamlines.

Results on phonon dispersion are presented comparing Raman, FTIR and IXS data on a range of bulk, MQW and QD samples. The implications for appropriate application as hot carrier absorbers is discussed.

9562-7, Session 2

Surface passivated colloidal CuIn(S,Se)2 quantum dots for quantum dot heterojunction solar cells

Emre Yassitepe, Univ. Estadual de Campinas (Brazil); Oleksandr Voznyy, Edward Sargent, Univ. of Toronto (Canada); Ana Flavia F. Nogueira, Univ. Estadual de Campinas (Brazil)

Colloidal quantum dot heterojunction thin film solar cells (CQD-TFSC) utilize facile thin film deposition methods and promise high photon conversion efficiencies (PCE) to cost ratio which is highly desired for commercialization. So far, surface passivated PbS CQD-TFSCs show the highest PCE results, reaching 9.2% with good stability. Among other potential candidates, CuInSe2 CQDs stand out as a non-toxic material with high potential for performance, judging on bulk Cu(Ga,In)(S,Se)2 TFSCs reaching 20% PCE, with high stability. CuInSe2 CQDs has advantage over bulk films, mainly the much less expensive manufacturing cost of uniform deposition on large areas. Ga is known to cause phase separation in the bulk CIGS system. In a CQD form, CuInSe2 band gap can be tuned between 1 to 1.6 eV by quantum confinement without need for Ga and this eliminates the phase separation issue. Within our best knowledge, there are no reports on surface trap passivated CuInSe2 CQD-TFSCs. However Cu(In,Ga)(S,Se)2 colloidal particles were cast in thin film form and fused to form bulk-like crystals by various annealing conditions for solar cell devices.

In this work, we investigated well-passivated CuInSe2 CQDs on n-type TiO2 and ZnO layers to form depleted heterojunction structure. We prepared luminescent CuInSe2 CQDs by synthetic wet chemistry methods and passivated the surface with 3-mercaptopropionic acid or tetrabutylammonium iodide using solid-state ligand exchange. X-ray photoelectron spectroscopy was used to confirm the ligand boding and surface coverage of the quantum dots. We will present the effect of synthesis and thin film preparation conditions on the solar cell device performance

9562-8, Session 2

Charge carriers recombination and photogeneration in p-i-n solar cells with InAs quantum dots grown on GaAs substrate

Artem Yakovliev, Sergiy V. Kondratenko, Roman Holubenko, National Taras Shevchenko Univ. of Kyiv (Ukraine)

Experimental results of electric and photovoltaic studying of p-i-n solar cells with InAs quantum dots grown on GaAs substrate are presented. The GaAs intrinsic region contains 20 stacks of quantum dots, separated by a GaAs spacer layer and Si dopants giving 0 – 24 electrons per quantum dot, carried out during quantum dots growth. Photovoltage spectra of samples give information about main types of electron-hole photogeneration in the

structure: band-to-band transitions through states of InAs quantum dots, weighting layer and GaAs substrate. Photovoltage transients of samples were measured at 80 – 290K temperature range using excitations by quanta with different energy. The decay time was found to be higher for samples with higher doping level. Dark and light current-voltage characteristics as well as photovoltage spectra give information about the mechanisms of charge carriers recombination and photogeneration in solar cells.

9562-9, Session 3

Quasi-random nanopatterns in Blu-ray movie discs for photon management *(Invited Paper)*

Jiaxing Huang, Northwestern Univ. (United States)

Quasi-random nanostructures have generated great interest for photon management in recent years. Such patterns typically require expensive fabrication processes to create pre-designed, sub-wavelength nanostructures. Interestingly, these patterns can also be found in Blu-ray movie discs, a low-cost consumer product that is mass-produced and readily available. We have discovered that the patterns on all pre-written Blu-ray movie discs are surprisingly well suited for light trapping applications due to their quasi-random nature. The algorithms that encode data found on such Blu-ray discs were developed in order to optimize data compression and error-tolerance. These algorithms coincidentally also create quasi-random arrangements of islands and pits on the final media discs, which are are optimized for photon management over the entire solar spectrum, regardless of the information stored on the discs. As a proof-of-concept, we imprinted polymer solar cells with the Blu-ray patterns, yielding devices with increased absorption and power conversion efficiencies. Simulation suggests that Blu-ray patterns could be broadly applied for the enhancement of solar cells made of many other photoactive materials.

9562-10, Session 3

High efficiency photonic nanostructures for thin film solar cells

Xiaowei Guo, Jia Liu, Univ. of Electronic Science and Technology of China (China)

Enhanced light absorption is a requirement to realize cost-effective photovoltaics. To absorb light more efficiently, thin film solar cells strongly rely on light-trapping schemes. The simplest light-trapping scheme was realized by building solar cells on top of randomly textured substrates capable of redirecting incident sunlight into the plane of the semiconductor. For this scheme it is often hard to predict the performance of a solar cell. Light-trapping scheme employing plasmonic nanostructures has gained significant attentions over the past decade due to their strong light concentration and scattering properties. However, there are only a limited number of cases where the beneficial impact has been experimentally demonstrated on realistic cell designs. More recently, high-index insulating and semiconducting photonic nanostructures were introduced into solar cells to achieve significant absorption enhancement. When properly sized and shaped, they can also exhibit very strong optical resonances that can further boost light-matter interaction compared with bulk materials. The PV community has started engineering these resonances with the aim to improve solar cell performance. Some typical periodic lattice structures such as triangular, square, and hexagonal were proposed as the light trapping layers.

To further improve our ability to trap light in this scheme, it is important to understand which scattering nanostructures are optimal and how they are best arranged spatially on the cell surface. So far, this question remains unanswered. In this paper, we present a method to design high efficiency photonic nanostructures for thin film solar cells based on the coupled mode theory. Using this method, we predicted the absorption limits for solar cells with different lattice light trapping structures. It was demonstrated triangular lattice exhibits highest absorption enhancement. Then we explored the optimal spatial arrangement of unit cell. Our results show that the pentagon-block-like spatial arrangement inside a solar cell promises good absorption, approaching the predicted limit.

9562-11, Session 3

Singlet-based photon upconversion in multichromophore organic thin films

Daniel H. Weingarten, Univ. of Colorado at Boulder (United States); Michael LaCount, Colorado School of Mines (United States); Garry Rumbles, Jao van de Lagemaat, National Renewable Energy Lab. (United States); Mark T. Lusk, Colorado School of Mines (United States); Sean E. Shaheen, Univ. of Colorado at Boulder (United States)

Solid-state energy upconversion has many potential applications, from nonlinear photonics and biophotonics to expanding the spectrum available for solar energy harvest. In organic molecular systems, upconversion is frequently done in solution to mitigate aggregation-induced photoluminescence quenching or to facilitate the diffusion of triplet donors in Triplet-Triplet Annihilation (TTA) systems. Here we demonstrate an organic thin film upconversion system utilizing two-photon absorption (TPA) properties to improve upconversion efficiency. In blend films of Stilbene-420 and Rhodamine 6G we observe a tenfold increase in up-converted fluorescence compared to the fluorescence yield of TPA in pristine stilbene films. While TPA normally has quadratic dependence on excitation intensity, these blend films exhibit sub-quadratic intensity dependence, indicating a combination of linear and quadratic upconversion processes and dramatically improving upconversion efficiency at lower excitation intensities. This improvement in intensity dependence allows for relatively efficient upconversion upon excitation by a nanosecond laser pulse, in contrast to the more expensive femtosecond lasers generally required for excitation in TPA microscopy and similar systems. Time-resolved photoluminescence decay measurements reveal that all excited states involved in this upconversion process are singlets, which indicates the potential for reduced energy losses when compared to TTA upconversion systems and their inherent intersystem-crossing energy losses. We observe emission from both the Rhodamine 6G donor molecules and Stilbene-420 acceptor molecules, indicating the presence of prompt fluorescence from the donor as well as upconversion to the acceptor, and FRET losses from acceptor back to donor. By fitting to a kinetic model we extract rates for these competing processes.

9562-12, Session 3

Surface plasmon enhanced infrared absorption in P3HT-based organic solar cells: The effect of infrared sensitizer

Sungmo Ahn, Univ. of Colorado at Boulder (United States); Alexandre M. Nardes, National Renewable Energy Lab. (United States); Devin Rourke, Univ. of Colorado at Boulder (United States); Jao van de Lagemaat, Nikos Kopidakis, National Renewable Energy Lab. (United States); Wounjhang Park, Univ. of Colorado at Boulder (United States)

We have theoretically and experimentally investigated the effects of Ag-grating electrode on the performance of polymer:fullerene based bulk heterojunction organic solar cells. First, an integrated numerical model has been developed, which is capable of describing both the optical and the electrical properties simultaneously. The Ag-grating patterned back electrode was then designed to enhance the absorption in sub-bandgap region of P3HT:PCBM binary devices. Laser interference lithography and metal lift-off technique were adopted to realize highly-uniform and large-area nanograting patterns. We measured almost 5 times enhancement of the external quantum efficiency at the surface plasmon resonance wavelength. However, the overall improvement in power conversion

efficiency was not significant due to the low intrinsic absorption of active layer in this sub-bandgap region. We, then, investigated about the effect of surface plasmon on the ternary device of P3HT:Si-PCPDTBT:ICBA. It was demonstrated that the infrared absorption by the Si-PCPDTBT sensitizer can be substantially enhanced by matching the surface plasmon resonance to the sensitizer absorption band. Besides, we also observed an additional enhancement in the visible range which is due to the scattering effect of the gratings. An overall short-circuit current enhancement of up to 40% was predicted numerically. We have then fabricated the device by the lamination technique and observed a 30% increase in the short circuit current. Plasmon enhancement of sensitized organic solar cell presents a promising pathway to high-efficiency, broadband-absorbing polymer:fullerene bulk heterojunction organic solar cells.

9562-13, Session 3

Novel down-converter architecture for Si-based solar efficiency enhancement based on silicon-carbon-oxynitride (SiCxOyNz) nanowire arrays

Vasileios Nikas, Brian Ford, Natasha Tabassum, Mengbing Huang, John G. Hartley, Alain E. Kaloyeros, Spyros Gallis, SUNY CNSE/SUNYIT (United States)

A significant source of efficiency losses in Si-based solar cells is associated to thermalization of high-energy absorbed photons in the ultraviolet (UV)-blue range. An approach to improve this spectral mismatch and enhance the efficiency is to use high-efficiency wavelength-conversion materials to better match the solar cell's bandgap to the radiation spectrum of the sun. The present authors have shown that silicon-oxycarbide (SiCxOy) thin films synthesized by thermal chemical vapor deposition (TCVD) can intensively luminescence upon UV-blue excitation in a broad visible (VIS) and even near-infrared spectral range, when doped with erbium. Herein, we report the design, fabrication and optical characteristics of sub-100nm TCVD-grown silicon-carbon-oxynitride (SiCxOyNz) nanowire (NW) array systems fabricated by e-beam lithography and reactive ion etching. Studies on their structural and optical characteristics with UV-VIS spectroscopic ellipsometry, Fourier transform infrared and photoluminescence (PL) spectroscopies showed enhanced light emission tunability of such SiCxOyNz nanosystems (480 – 700 nm), which also exhibited high UV/ thermal stability (150 oC, 100 W/cm2) and a blue-shifted broad absorption (230 - 430 nm) allowing a high efficient down-conversion of UV-blue photons. Pertaining to furthering the efficiency yield, we fabricated a one-dimensional (1D) photonic lattice constructed by periodically arranging SiCxOyNz (C:12%; O:53%; N:1%) 1D-NW arrays on a Si substrate. Compared to its thin film counterpart, the integrated PL yield of the 1D-NW architecture exhibited a ~four-fold enhancement. Our spectral-conversion approach based on nontoxic SiCxOyNz NWs may offer an alternative pathway for high solar-efficiency enhancement with potential reduced process complexity, cost and environmental impact.

9562-14, Session 4

Embedding solar cell materials with on-board integrated energy storage for load-leveling and dark power delivery

Cary L. Pint, Andrew S. Westover, Adam P. Cohn, William R. Erwin, Keith Share, Thomas Metke, Rizia Bardhan, Vanderbilt Univ. (United States)

This work will discuss our recent advances focused on integrating high power energy storage directly into the native materials of both conventional photovoltaics (PV) and dye-sensitized solar cells (DSSCs). In the first case (PV), we demonstrate the ability to etch high surface-area porous silicon charge storage interfaces directly into the backside of a conventional polycrystalline silicon photovoltaic device exhibiting over 14% efficiency. These high surface area materials are then coupled with solid-state ionic liquid-polymer electrolytes to produce solid-state fully integrated devices where the PV device can directly inject charge into an on-board supercapacitor that can be separately discharged under dark conditions with a Coulombic efficiency of 84%. In a similar manner, we further demonstrate that surface engineered silicon materials can be utilized to replace Pt counterelectrodes in conventional DSSC energy conversion devices. As the silicon counterelectrodes rely strictly on surface Faradaic chemical reactions with the electrolyte on one side of the wafer electrode, we demonstrate double-sided processing of electrodes that enables dual-function of the material for simultaneous energy storage and conversion, each on opposing sides. In both of these devices, we demonstrate the ability to produce an all-silicon coupled energy conversion and storage system through the common ability to convert unused silicon in solar cells into high power silicon-based supercapacitors. Beyond the proof-of-concept design and performance of this integrated solar-storage system, this talk will conclude with a brief discussion of the hurdles and challenges that we envision for this emerging area both from a fundamental and technological viewpoint.

9562-15, Session 4

Organic photovoltaic devices with concurrent solar energy harvesting and charge storage capability

Arash Takshi, Anand K. Santhanakrishna, Tete Tevi, Houman Yaghoubi, Univ. of South Florida (United States)

Due to large variation of the solar energy availability in a day, energy storage is required in many applications when solar cells are used. However, application of external energy storage devices, such as batteries and supercapacitors, increases the cost of solar energy systems and requires additional charging circuitry. This combination is bulky and relatively expensive which is not ideal for many applications. In this work, a novel idea is presented for making two-terminal electrochemical devices with dual properties of solar energy harvesting and internal charge storage. The device is essentially a supercapacitor with a photoactive electrode. Energy harvesting occurs through light absorption at one of the electrodes made of a composite of a conducting polymer (i.e. PEDOT:PSS) and a Porphyrin dye. Upon exposure to AM1.0 solar irradiation, an open circuit voltage as large as 0.49 V was achieved across a cell with ~1 mF capacitance. The device showed a reasonable charge stability in dark when it took more than 30 min to drop the voltage. A short circuit current density of 0.12 mA/cm2 was obtained under illumination. The device characteristics can be tuned to be more efficient in light absorption or enhance the capacitance by changing the ratio of the polymer and dye molecules in the composite film. Our study shows a great potential of this approach for concurrent solar energy harvesting and charge storage in a two-terminal device.

9562-16, Session 4

Monolithically self-assembled organic active materials integrated with thermoelectric for large spectrum solar harvesting system

Tito L. Busani, Olga Lavrova, Matthew Erdman, Julio Martinez, The Univ. of New Mexico (United States)

We designed and studied a radial junction composed by a photovoltaic and thermoelectric array based on ZnO and CdTe nanowires surrounded by an absorbing organic self assembled in order to efficiently convert UV-visible and IR energy into electricity.

The hot anode of n-type ZnO nanowires was fabricated using a thermal process on pre-seeded layer and results to be crystalline with a transmittance up to 92 % and a bandgap of ~ 3.32 eV. Conductivity measurements reveal diode-like behavior for the ZnO nanowires.

The organic layer was deposited between the anode and cathode at room temperature The organic layer is composed of oppositely charged porphyrin

metal (Zn(II) and Sn(IV)(OH)2) derivatives that are separately water soluble, but when combined form a virtually insoluble solid. The electron donor/acceptor properties (energy levels, band gaps) of the solid can be controlled by the choice of metals and the nature of the peripheral substituent groups of the porphyrin ring. A defect free sub nanometer deposition was achieved using a layer-by-layer deposition onto both ZnO and Bi2Te3 nanowires.

The highly thermoelectric structure, which acts as a cold cathode, is composed of p-type Bi2Te3 nanowires with a thermoelectric efficiency (ZT) between ~0.7 to 1, values that are twice that expected for bulk Bi2Te3.

Optoelectronic and structural properties shows that with 6 nm of organic layer it is possible to form a 3% efficient solar device with an enhanced thermo electric effected with a temperature gradient of 300 C.

Hot-phonon bottleneck in lead iodide perovskites *(Invited Paper)*

Matthew C. Beard, Ye Yang, National Renewable Energy Lab. (United States)

Carriers with excess kinetic energy (hot-carriers) are generated from absorption of photons with energy larger than the semiconductor bandgap. In a typical semiconductor, the excess kinetic energy is quickly dissipated as carriers thermalize to the lattice and this process accounts for ~50% of the free-energy loss in current solar energy conversion strategies. Gaining control and preventing such thermalization could result in ~doubling of the limiting efficiencies for solar energy conversion technologies. We found an efficient hot-phonon bottleneck in planar Pb iodide perovskite films using transient absorption (TA) spectroscopy. The hot-phonon bottleneck occurs above a critical injection carrier density of ~5x1017 cm-3, an order of magnitude lower than found in GaAs and thermalization times increase by 3-4 orders of magnitude beyond that found in GaAs. The hot-phonon bottleneck found here is of similar magnitude to that found in highly engineered III-V based multiple quantum wells.

9562-18, Session 5

Plasmonic enhancement of mesoporous solar cells with shape controlled nanostructures

Rizia Bardhan, Vanderbilt Univ. (United States)

Next generation mesoporous solar cells (MSCs) including dye-sensitized solar cells (DSSCs) and perovskite-sensitized solar cells (PSSCs) have rapidly emerged with efficiencies reported up to 13% for DSSCs and 19% for PSSCs. Current efforts to improve the performance of MSCs are focused on altering the photoanode morphology, and manipulating the sensitizer composition. In contrast to these approaches that often lead to incremental improvement tailored to each MSC system, plasmonic enhancement provides a universal route applicable to the whole family of MSCs that can significantly boost the optical absorption and carrier generation. Through small additions of metal nanoparticles to MSCs (< 2%), the amount of sensitizer required to achieve high efficiency can be drastically reduced enabling thin film architectures. Here we demonstrate enhanced light harvesting in both DSSCs and PSSCs by embedding silica-coated gold nanocubes (Au@SiO2-NCs) in the photoanodes. In DSSCs Au@SiO2-NCs led to 7.8% efficiency relative to 5.8% for reference (no nanocubes) devices, resulting in 34% improvement in performance; while in PSSCs Au@SiO2-NCs resulted in 8.6 % efficiency relative to 7.5 % for reference devices giving rise to 16% enhancement. Photocurrent and IPCE spectra revealed that device performance in MSCs is controlled by particle density of Au@SiO2-NCs and monotonically decreases at high concentrations. FDTD simulations demonstrated that the nanocubes predominantly absorb incident light giving rise to lightning rod-effect which results in intense electromagnetic fields at the edges and corners. These intense fields increase the plasmonic-sensitizer coupling, amplifying carrier generation in MSCs. This work shows that shape-controlled plasmonic nanostructures can be employed as a universal platform for enhanced light-trapping in a range of solar devices.

9562-19, Session 5

Ultrafast time-resolved spectroscopy of lead halide Perovskite films

Mopelola A. Idowu, Federal Univ. of Agriculture (Nigeria) and Univ. of Michigan (United States); Oleg P. Varnavski, Theodore G. Goodson III, Univ. of Michigan (United States)

Recently, lead halide perovskites which are organic-inorganic hybrid structures, have been discovered to be highly efficient as light absorbers in solar cells [1]. They exhibit broad absorption below 800 nm and have an absorption coefficient far greater than conventional organometallic dyes used in dye sensitized solar cells [2,3]. Non-stoichiometric precursor formed lead halide perovskites grown by the inter-diffusion method were investigated to probe their fundamental excited state dynamics and emission properties using steady-state and time-resolved spectroscopic measurements. The use of a non-stoichiometric precursor solution ratio resulted in films with good morphology and better ultrafast measurement results. Steady state fluorescence was observed at ~ 760 nm for the perovskites with a weaker emission observed at 820 nm when the perovskite was excited at the band edge. Femtosecond transient absorption experiments revealed spectral features of the perovskite material. Excited state absorption was observed within the first 1 ps of the transient [4]. This was followed by a bleach with a short rise time. The long lived bleach process also had another shorter rise time feature which was observed. Measurements of the femtosecond photoluminescence upconversion were also carried out with the perovskite films of varying ratios of the precursor solution.

Emitter thickness optimization for GaSb thermophotovoltaic cells grown by molecular beam epitaxy

Shaimaa A. Abdallah, Daniel J. Herrera, Nassim Rahimi, Luke F. Lester, Virginia Polytechnic Institute and State Univ. (United States)

Thermophotovoltaic (TPV) cells can convert long-wavelength radiation from a variety of sources into an electrical current. Among the potential materials for TPV diodes, GaSb grown via the Molecular Beam Epitaxy (MBE) method is a promising candidate due to its relative simplicity as a binary semiconductor compared to InGaAs or InGaAsSb. However, MBE growth of GaSb with low shunt defect density over a large area is still relatively challenging, which can limit TPV device performance. In particular, the emitter thickness (de) in MBE-grown GaSb TPVs is a crucial point that is not well studied. MBE-grown GaSb TPVs with a 5E18/cm3 p-type emitter were fabricated with a de of approximately 0.5 ?m. The as-grown de was chosen to be sufficiently thin to avoid shunt defect formation and thick enough to prevent the emitter ohmic contacts from shorting the pn junction and to provide low emitter sheet resistance. However, further reduction of de is necessary to minimize the transit length of the minority electrons through the short carrier lifetime emitter. Therefore, initial AM1.5 simulations were performed to find the particular de that maximizes the short circuit current

density. These simulations indicated an optimal de = 0.2 ?m at which a maximum short-circuit current density around 35 mA/cm2 can be achieved. The theoretical results for AM1.5 and longer wavelength radiation will be compared to experimental data including quantum efficiency, short circuit current density and open circuit voltage from fabricated GaSb TPVs in which the emitter is incrementally etched and characterized at each de.

Performance comparison of front-side silver pastes using polyalkylene carbonates for cleaner burning binder system

Richard Stephenson, Stephenson & Associates, Inc. (United States); Peter Ferraro, Empower Materials, Inc. (United States)

Extensive work has been done over the last fifteen years toward improving efficiencies, capacities, and reliability of solar cells. Rapid decline in the cost per watt has promoted increased deployment. Given the significance of metallization process and its potential to improve solar cell efficiency and reliability, work has been done with formulations of silver bearing pastes for front side printing of conductive lines for these solar applications. This paper presents a comparison of functional qualities of silver bearing pastes made with a polyalkylene carbonate, cleaner burning binder and organic components. Adhesion strengths and microstructure are presented to show differences in obtainable reliability and resistive losses by using cleaner burning binder system.

9562-22, Session 6

Optimizing the energy band alignment at the CdS/Cu2ZnSnS4 heterojunction by Nickel Incorporation

Hui Ju Chen, National Cheng Kung Univ. (Taiwan)

The key issue when it comes to the CZTS based photovoltaics is the cliff-like conduction band offset (CBO), which has limited the power conversion efficiency resulted from the open circuit voltage deficit. Thus, optimizing the electronic structures at the CdS/CZTS heterojunction is necessary to achieve high-performance CZTS solar devices. This study proposes a new concept in which incorporates the appropriate Ni content into CZTS absorbers to fabricate the Cu2(Zn,Ni)SnS4 [C(Z,N)TS] absorbers, contacted with the CdS buffer to realize the ideal p-n heterojunction at the interface. Three samples of CdS/C(Z,N)TS heterojunction are investigated (different Ni content, [Ni]/[CZTS] = 0, 0.1% and 0.3%, respectively). The study is investigated by ultraviolet photoelectron spectroscopy (UPS), high resolution x-ray photoelectron spectroscopy (HRXPS), optical absorption spectroscopy and photoluminescence analysis. The Ni composition dependent bandgap energy of the C(Z,N)TS absorbers is revealed. The bandgap energy decreases from wide bandgap of 1.43 eV to narrow bandgap of 1.28 eV as the Ni content of [Ni]/[CZTS] increases from 0 to 0.3%. The valence band offset (VBO) of the CdS/C(Z,N)TS heterojunction with various Ni content have been measured by two approaches, directly method using UPS and indirectly method using HRXPS. Hence, the conduction band offset (CBO) between the CdS buffer and each C(Z,N)TS absorbers could be estimated involving the use of the VBO values together with the known bandgap energy of the C(Z,N)TS absorbers. The work exhibits the CBO at the CdS/C(Z,N)TS interface switches from original cliff type to spike type while adjusting appropriate Ni content. The ideal spike CBO inhibits interface recombination and results in the increase of Voc and PCE.

The study successfully modifies the band offsets at the CdS/C(Z,N)TS interface through the control of the Ni compositions. Note the Ni ions with the valence state of 2+ substitutes to the Zn2+ ions within the C(Z,N)TS thin films.

Conference 9563: Reliability of Photovoltaic Cells, Modules, Components, and Systems VIII

SPIE. OPTICS+ PHOTONICS OPTICS+PHOTONICS FOR SUSTAINABLE ENERGY

Sunday - Monday 9 –10 August 2015

Part of Proceedings of SPIE Vol. 9563 Reliability of Photovoltaic Cells, Modules, Components, and Systems VIII

9563-1, Session 1

Development of a resistivity standard for polymeric materials used in photovoltaic modules *(Invited Paper)*

Michael D. Kempe, David C. Miller, Dylan L. Nobles, National Renewable Energy Lab. (United States); Keichiro Sakurai, National Institute of Advanced Industrial Science and Technology (Japan); John Tucker, Keithley Instruments, Inc. (United States); Jayesh G. Bokria, Specialized Technology Resources, Inc. (United States); Tsuyoshi Shioda, Mitsui Chemicals, Inc. (Japan); Kumar Nanjundiah, The Dow Chemical Co. (United States); Toshio Yoshihara, Dai Nippon Printing Co., Ltd. (Japan); Jeff Birchmier, DNP America, LLC (United States); Oihana Zubillaga, TECNALIA (Spain); John H. Wohlgemuth, National Renewable Energy Lab. (United States)

Photovoltaic modules, which operate at high voltages and elevated temperatures, are known to degrade because of stray current going to or from ground. These degradation processes involve electrochemical degradation and/or charge build-up in thin layers. For these mechanisms, the use of polymeric materials with a high resistivity is known to reduce the rate of aging. Because of this, materials suppliers are placing increased importance on the bulk resistivity, but there is not yet an accepted method for this measurement. The measurement time has been shown to greatly affect the apparent resistivity, with an increase as great as 100X for different measurement times. We have performed a number of exploratory and round-robin tests to establish a representative and reproducible method for determining the bulk resistivity of polymeric materials, including encapsulation, backsheet, edge seals, and adhesives. The standard has developed to use measurements alternating between an “on” and “off” voltage state with a weighted averaging function and cycle times of an hour.

9563-2, Session 1

Application of new measurement technologies to backsheet durability testing to improve correlation of accelerated exposures to fielded modules *(Invited Paper)*

Thomas C. Felder, William J. Gambogi Jr., Katherine M. Stika, Alexander Z. Bradley, Lucas Amspacher, Bao-Ling Yu, Babak Hamzavytehrany, R. Scott Peacock, DuPont (United States); Hongjie Hu, DuPont (China) Research & Development and Management Co., Ltd. (China); Lucie A. G. Garreau-Illes, DuPont International Operations Sarl (Switzerland)

We have previously reported good correlation of FTIR spectra between accelerated tests and field measurements. The availability of portable FTIR spectrometers has made measurement in the field convenient and reliable.

Recently, nano-indentation has shown promise to correlate changes in backsheet mechanical properties. A precisely shaped stylus is pressed into a sample, load vs displacement recorded and mechanical properties of interest calculated in a nondestructive test. Finally, we will discuss optical profilometery. In this technique a white light interferogram of a surface is Fourier transformed to produce a three-dimensional image. Height differences from 1 nm to 5 mm can be detected over an area of a few cm. This technique can be used to determine crack and defect dimensions. Results will be presented correlating accelerated tests with fielded modules covering spectroscopic, mechanical, and morphological changes.

9563-3, Session 1

Cracking and delamination behaviours of photovoltaic backsheet after accelerated laboratory weathering

Chiao-Chi Lin, Yadong Lyu, Donald L. Hunston, Jae Hyun Kim, Kai-Tak Wan, Deborah L. Stanley, Xiaohong Gu, National Institute of Standards and Technology (United States)

The channel crack and delamination phenomena that occurred during tensile tests were utilized to study adhesion properties of a multilayered backsheet. A model sample of commercial PPE backsheet, namely polyethylene terephthalate/polyethylene terephthalate/ethylene vinyl acetate (PET/PET/EVA), was aged on the NIST SPHERE (Simulated Photodegradation via High Energy Radiant Exposure) with the UV irradiance at 170 W/m2 (300 nm to 400 nm) under accelerated weathering conditions of 85 °C and two relative humidity (R.H.) levels of 5% and 60%. A complementary aging experiment on NIST SPHERE without UV was also carried out as a control. Film stresses were analyzed experimentally based on an exact closed-form solution of multilayer bending. An asymptotic solution was used to solve the stress singularity of interfacial crack formation and therefore, the critical debond energy of the backsheet was investigated before and after aging. Furthermore, the effect of residual stress caused by thermal cycling on backsheet delamination was investigated by substituting thermal mismatch for elastic mismatch in the film stress analysis of the multilayer material.

9563-4, Session 1

Depth profiling of chemical and mechanical degradation for PV backsheets after UV exposure

Xiaohong Gu, Chiao-Chi Lin, Peter J. Krommenhoek, Stephanie S. Watson, National Institute of Standards and Technology (United States)

Polymeric backsheets protect the photovoltaic modules from damage of moisture and ultraviolet (UV) while providing electrical insulation. Due to the complication of multilayer structures, the properties of the innerlayers of the backsheets, including their interfaces, during weathering are not well known. In this study, a commercial type of PPE (polyethylene terephthalate (PET)/PET/ethylene vinyl acetate (EVA)) backsheet films was selected as a model system for a depth profiling study of chemical and mechanical properties of a backsheet film during UV exposure. Cryo-microtomy was used to obtain cross-sectional PPE samples. The NIST SPHERE (Simulated Photodegradation via High Energy Radiant Exposure) was used for the accelerated laboratory exposure of the materials with UV at 85°C and two relative humidities (RH) of 5 % (dry) and 60 % (wet). Chemical and mechanical depth profiling of the aged and unaged samples was conducted by Raman microscopic mapping and nanoindentation. The results indicate that the PPE backsheet films are comprised of five main layers, including pigmented-PET, core PET, inner EVA, pigmented-EVA and outer EVA, along with their interfacial regions and two adhesive layers. Both UV and moisture are key environmental factors for backsheet degradation. It is also found that the deterioration of adhesion layers and the residual internal stress resulted from non-uniform degradation of the multilayer can lead to the

delamination of interlayers. Besides, the relationship between the chemical and mechanical degradation is discussed.

9563-5, Session 2

UV-DH-TC and UV-DML-HF-DH sequential tests for PV modules *(Invited Paper)*

Takuya Doi, National Institute of Advanced Industrial Science and Technology (Japan); Hideyuki Morita, Takao Amioka, Toray Industries, Inc. (Japan); Atsushi Masuda, National Institute of Advanced Industrial Science and Technology (Japan)

As a test for confirming a long time reliability of PV modules, a sequential test including the stress which gives the effect of expansion and contraction (thermal cycling test, dynamic mechanical load test, etc.) is considered necessary. Therefore, we have been conducting the UV-damp heat-thermal cycling (UV-DH-TC) sequential test and the UV-dynamic mechanical load-humidity freeze-DH (UV-DML-HF-DH) sequential test using 4 cells mini-module. The purpose of this study is to clarify the relationship between degradation and UV exposure testing, and to acquire basic data which contribute to the decision of the appropriate testing condition.

Light source is xenon lamp with intensity of UV 90 W/m2 at 300-400 nm, chamber temperature 65 degrees Celsius, no humidity control (2 to 10 %RH). Major materials of samples are as follows; multicrystalline silicon solar cell (156 x 156 mm), EVA (fast cure type), backsheet (polyolefin-PET), tempered and embossed glass (400 x 400 mm, t=3.2 mm).

The results of UV 1314h-DH 500h-TC 100c-DH 500h-TC 100c sequential test; the drop in Pmax was little (<5%) until first DH 500h-TC 100c, afterward it increased dramatically in the following sequence, and it was finally 22 to 24%. The possibility of accelerating the degradation of the series resistance increase mode by combining UV exposure test with the DH test, was suggested.

As for UV-DML-HF-DH sequential test, after UV exposure (as for a parameter, 500, 1000, 1500, 2000h), the following sequence of DML 1000c-HF 10c-DH 1000h has been going now. In addition, this result will be also reported.

9563-6, Session 2

Effects of current injection during damp heat tests on thin film photovoltaic modules *(Invited Paper)*

Keiichiro Sakurai, National Institute of Advanced Industrial Science and Technology (Japan) and Photovoltaic Power Generation Technology Research Association (Japan); Akihiro Takano, Photovoltaic Power Generation Technology Research Association (Japan); Masaaki Yamamichi, National Institute of Advanced Industrial Science and Technology (Japan) and Photovoltaic Power Generation Technology Research Association (Japan); Hiroko Saito, Masayoshi Takani, Photovoltaic Power Generation Technology Research Association (Japan)

It have been reported that some degradations observed in field on some flexible thin film photovoltaic (PV) modules can be reproduced better with current injected damp heat (CDH) tests [1]. If this is true for other types of flexible products, it may be worth amending the current IEC standards for testing thin film modules. To investigate the needs for an amended test standard, we have investigated the effects of current injection during conventional damp heat (DH) tests or dry-heat tests, on multiple kinds of thin film flexible modules. So far, we have tested thin film silicon flexible modules and CIGS flexible modules. At least one type of CIGS flexible modules sold in the market showed a clear difference in EL images Concurrently, I-V characteristics may degrading faster with current injection, though the data shows a large dispersion and requires confirmation. Results of destructive analysis by TEM, EDX, SCM, FT-IR and ICP will be presented. Further investigations on other types of thin film modules may also follow as well.

9563-7, Session 2

Experimental and computational investigation of microcrack behavior under combined environments in monocrystalline Si

Wei-Jie Huang, Stefan Bringuier, Kelly Simmons-Potter, Krishna Muralidharan, Barrett G. Potter Jr., The Univ. of Arizona (United States)

An investigation of microindenter-induced crack evolution with independent variation of both temperature and relative humidity has been pursued. Environmental temperatures from 25 to 60 C and atmospheric water contents from 5 to 30 g/m3 were produced over periods of up to 20 hours. Under static tensile strain conditions, a clear increase in sub-critical crack elongation with increasing atmospheric water content was observed. Moreover, elevated temperature is found to enhance this water sensitivity, supporting an interpretation of a thermally activated transport and reaction mechanism contributing to microcrack development under these conditions. To provide further insight into the potential physical and chemical conditions at the microcrack tip, micro-Raman measurements were performed. Preliminary results, now under investigation, indicate a spatially dependent variation in the frequency of the 520 cm-1 vibrational resonance in the region of the indenter and the crack tip that are associated with local stress state.

Simultaneously, to characterize atomic-scale mechanisms that govern microcrack growth, the experimental effort is paired with molecular dynamics (MD) investigations of microcrack evolution in single crystal Si. An examination of the MD results shows that the crack-tip dynamics is intimately related to the crack orientation with respect to the principal crystallographic axis, which in turn, determines the elastic strain energy release rate and the stress-strain response. Further, MD-derived mechanical parameters serve as inputs for a coarser-grained peridynamics model for crack propagation, enabling a closer correspondence to the experimental effort.

9563-8, Session 2

Environmental aging in polycrystalline-Si photovoltaic modules: Comparison of chamber-based accelerated degradation studies with field-test data

Kelly Simmons-Potter, Teh Lai, Ryan P. Biggie, Adria Brooks, Barrett G. Potter Jr., The Univ. of Arizona (United States)

Lifecycle degradation testing of photovoltaic (PV) modules in accelerated-degradation chambers can enable the prediction both of PV performance lifetimes and of return-on-investment for installations of PV systems. With degradation results strongly dependent on chamber test parameters, the validity of such studies relative to fielded, installed PV systems must be determined. In the present work, accelerated aging of a Trina Solar 250 W polycrystalline silicon module is compared to real-time performance degradation in a similar, fielded, PV technology that has been operating since October 2013. Investigation of environmental aging effects are performed in a full-scale environmental chamber equipped with single-sun irradiance capability providing illumination uniformity of 98% over a 2 x 1.6 m area. Time-dependent, photovoltaic performance (J-V) is evaluated over a recurring, compressed night-day cycle providing representative local daily solar insolation for the southwestern United States, followed by dark (night) cycling. This cycle is synchronized with thermal and humidity

environmental variations that are designed to mimic, as closely as possible, test-yard conditions for the fielded system. Early results confirm the impact of environmental conditions on the module long-term performance. While the effects of temperature de-rating can be clearly seen in the data, removal of these effects enables the clear interpretation of module efficiency degradation with time and environmental exposure. Analysis of PV module efficiency degradation for the chamber-tested system shows good comparison to the field-tested system with <1% degradation following an equivalent year of testing.

9563-9, Session 3

PID: From material properties to outdoor performance and quality control counter measures *(Invited Paper)*

Juliane Berghold, Simon Koch, PI Berlin AG (Germany); Sebastian Pingel, PI Solar Technology GmbH (Germany); Paul Grunow, PI Berlin AG (Germany)

PID is a topic with major interest and it is increasingly evident in field (Figure 1).

Figure 1: PID affected power plants with involvement of PI Berlin

Although the main root causes and referring counter measures for PID are known, a significant part of the industrial modules are still found to be PID sensitive in PID testing.

This paper is discussing field occurrence of PID with respect to environmental conditions and material properties.

One aspect for the avoidance of PID is the encapsulation material. Quality control measures were developed for the verification, whether the encapsulant (in industrial modules) is according to the 'certified' BOM.

Examples are given for the correlation of PID lab tests of a (commercial) BOM with real outdoor degradation.

Furthermore, result from outdoor experiments (Figure 2) are presented for samples at different locations (e.g. Berlin, Cyprus) with different climates and referring parameters (radiation, temperature, surface conductivity etc.) and compared with real PID field findings in power plants.

Figure 2: PID degradation (monitored by Rsh (blue, red)) for samples in Berlin and Cyprus.

Radiation (yellow) and surface conductivity (green).

Simulated potential distrbutions (Figure 3) of a solar module are presented for different conditions and materials and discussed in terms of real outdoor findings.

Figure 3: Potential distribution for different conditions (left: 'wet' versus 'dry') and with different encapsulation materials (right: ‚high resistivity' versus ‚low resistivity).

PID lab test result at different conditions are presented and comapred to PID field findings at different climates and conditions.

Module M, ?P=-75% Module N, ?P=-55% Module O, ?P=-46%

9563-10, Session 3

Survey of potential-induced degradation in thin film modules *(Invited Paper)*

Peter Hacke, Kent Terwilliger, Stephen H. Glick, Greg Perrin, Sarah R. Kurtz, National Renewable Energy Lab. (United States)

Two each CdTe and CIGS type modules were tested for degradation to system voltage stress with positive and negative 1000 V bias in an 85°C, 85% relative humidity damp heat environment. Both CdTe (currently not in production) module types exhibited degradation of about 20% power in 500 h under negative bias, although I-V curve data indicated one type was affected more prominently by series resistance losses, the other by recombination losses. One CdTe module type showed signatures of transparent conductive oxide delamination from the glass after about 750 h of stress testing. Performance of CIGS modules differed depending on the generation of technology. Under negative bias, the older module design showed an initial 12% (relative) improvement, possibly because of the influx of sodium ions that has been reported to benefit the electrical properties, followed by severe degradation with continued stress testing. The newer design CIGS module exhibited the best stability of the four thin film types tested with less than 5% (relative) power drop after 1200 h of test, and had around one order of magnitude lower leakage current from the biased active absorber layer to ground as well. Relative rates of leakage current to ground between chamber tests and modules placed outdoors under system voltage stress will be compared to extrapolate anticipated coulombs accumulated because of leakage over the lifetime of the module.

9563-11, Session 3

A modeling framework for potential induced degradation and soiling in PV modules

Peter Bermel, Reza Asadpour, Muhammad A. Alam, Purdue Univ. (United States)

Two major sources of performance degradation for glass-encapsulated PV modules are potential-induced degradation (PID) and soiling-induced efficiency loss, due to dust accumulation, precipitation, and abrasion. Recent studies have shown that thin-film modules operating in damp heat at -600 V are vulnerable to large amounts of degradation, potentially exceeding more than half the original power output. Similarly, the deterioration of glass transmission under adverse soiling conditions has been shown to reduce short circuit currents up to 40%. To improve module reliability and restore power production in the presence of PID and soiling, a fundamental rethinking of accelerated testing is needed. This in turn will require an improved understanding of technology choices made early in development that impact PID and soiling much later.

In this talk, we will present an integrated approach of modeling, characterization, and validation to address these problems. A hierarchical modeling framework will allows us to clarify the mechanisms of PID and soiling. We will employ a physics-based compact model of the cell, topology of electrode interconnection, geometry of the packaging stack, and operating conditions to predict the current, voltage, and temperature distributions in PV modules correlated with the acceleration of specific degradation modes. A self-consistent solution will capture the essential complexity of the technology-specific acceleration of TFPV-PID and soiling as a function of illumination, ambient temperature, relative humidity, and dust properties. This will yield data suitable for direct comparison with indoor and outdoor experiments, and could play a significant role in developing novel accelerated lifetime tests.

9563-12, Session 4

In-situ monitoring of moisture ingress in PV modules *(Invited Paper)*

Laure-Emmanuelle Perret-Aebi, Federico Galliano, Ctr. Suisse d'Electronique et de Microtechnique SA (Switzerland); Fanny Sculati-Meillaud, Eleonora Annigoni, Ecole Polytechnique Fédérale de Lausanne (Switzerland); Heng-Yu Li, Ctr. Suisse d'Electronique et de Microtechnique SA (Switzerland); Marko Jankovec, Univ. of Ljubljana (Slovenia); Christophe Ballif, Ctr. Suisse d'Electronique et de Microtechnique SA (Switzerland)

One of the key factors for photovoltaic (PV) installations capable to produce energy for more than 25 years with limited degradation is the resistance of PV modules to varying outdoor conditions. Moisture, temperature cycling,

UV irradiation, static and dynamic mechanical loads represent the main environmental factors that affect the module reliability and their effects often superpose in an interdependent way.

Moisture ingress is in particular affecting the performance degradation and can be strongly affected by the choice of PV encapsulant, PV module configuration and exposure location. The moisture ingress behaviour of a PV module can be indirectly predicted by means of Finite Element Modelling (FEM) diffusion modelling, provided that the properties of moisture diffusion and solubility are precisely known for the given materials. However a robust and reliable direct monitoring of the moisture ingress in PV modules is still lacking.

In this work we will present an "in-situ" monitoring technique of relative humidity (RH) by means of miniaturized humidity/temperature sensors embedded in the PV encapsulant. Based on a digital data acquisition the system provides an extremely reliable and low-noise signal of RH and T.

In the experiments the technique has been successfully used on both highly permeable (Glass/Backsheet) and low permeable (Glass/Glass) PV module configurations and using EVA as encapsulant. By parallel monitoring up to 10 sensors spatially distributed in Glass/Glass modules we could show that in steady conditions of T and RH (Damp Heat 85°C and 85 % RH) the moisture ingress in the PV module follows the expected Fickian penetration profile. The diffusion coefficient of moisture in EVA as extrapolated from these tests is within close agreement with the value obtained from permeation tests on the same encapsulant material.

The monitoring of Glass/Backsheet PV modules allowed following the rapid ingress of moisture through the backsheet into the encapsulant. In DH conditions and using a commercial PET based backsheet the encapsulant is completely water saturated after approximately 3 days. The Water Vapor Transmission Rate (WVTR) of the backsheet could be extracted and it was found to be in the same order of magnitude with that obtained from permeation tests.

Finally preliminary results from outdoor monitoring will be showed where different humidity sensors will be used at the same time as a localized weather station at the back of the module and as in situ moisture monitoring embedded in the encapsulant. The measured are compared to the prediction obtained from FEM modelling.

9563-13, Session 4

Investigation of power values of PV rooftop systems based on heat gain reduction *(Invited Paper)*

Tanokkorn Chenvidhya, King Mongkut's Univ. of Technology Thonburi (Thailand); Manit Seapan, King Mongkut's Univ. of Technology Thonburi (Thailand); Panom Parinya, King Mongkut's Univ. of Technology Thonburi (Thailand); Buntoon Wiengmoon, Naresuan Univ. (Thailand); Dhirayut Chenvidhya, Roongrojana Songprakorp, Chamnan Limsakul, Yaowanee Sangpongsanont, King Mongkut's Univ. of Technology Thonburi (Thailand)

PV rooftop system can generally be installed to produce electricity for the domestic house, office, small enterprise as well as factory. Such a system has direct useful for reducing peak load, meanwhile it also provides shaded area on the roof and hence the heat gain into the building is reduced. This study aims to investigate the shading effect on reduction of heat transfer into the building. The 49 kWp of PV rooftop system has been installed on the deck of the office building located in the middle of Thailand where the latitude of 14 ° above the equator. The estimation of heat gain into the building due to the solar irradiation throughout a day for one year has been carried out, before and after the installation of the PV rooftop systen. Then the Newton's law of cooling is applied to calculate the heat gain. The calculation and the measurement of the heat reduction is compared. Finally, the indirect benefit of the PV rooftop system installed is evaluated in terms of power value.

9563-14, Session 4

Partial illumination stress test for thin-film photovoltaic modules

Timothy J. Silverman, Michael G. Deceglie, Chris Deline, Sarah R. Kurtz, National Renewable Energy Lab. (United States)

PV cells can be permanently damaged by exposure to reverse-bias conditions, which can lead to reverse breakdown and the associated very high current density and high operating temperature. This can occur in monolithic thin-film PV modules under simple conditions of partial illumination, when cells that are not fully illuminated may be forced to operate in reverse bias due to mismatch with the illuminated cells.

The IEC standard qualification test for thin-film PV modules includes a hot-spot test that identifies major visual defects, which may pose a safety concern, resulting from partial illumination. But a test is needed to identify serious, permanent loss in performance resulting from partial illumination that may occur in the field.

In this work, we propose a partial illumination stress test for thin-film PV modules that quantifies permanent performance loss. We designed the test with the aid of a computer model that predicts the local voltage, current and temperature stress that result from partial illumination. The model predicts the module-scale interactions among the illumination pattern, the electrical properties of the photovoltaic material and the thermal properties of the module package. The test reproduces shading and loading conditions that may occur in the field. It accounts for reversible light-induced performance changes and for additional stress that may be introduced by light-enhanced reverse breakdown. We present simulated and experimental results from the application of the proposed test.

9563-15, Session 4

PV industry growth and module reliability in Thailand

Dhirayut Chenvidhya, King Mongkut's Univ. of Technology Thonburi (Thailand); Manit Seapan, King Mongkut's Univ. of Technology Thonburi (Thailand); Yaowanee Sangpongsanont, Tanokkorn Chenvidhya, Chamnan Limsakul, Roongrojana Songprakorp, King Mongkut's Univ. of Technology Thonburi (Thailand)

The cumulative PV installations in Thailand are now over 1.2 GWp. This is a result from implementation of the National Renewable Energy Programs and Targets. In the latest Alternative Energy Development Plan (AEDP), the PV electricity production target has increased from 2 GWp to 3 GWp. According to the rapid growth, PV modules have been tested over one thousand modules per annum since 2012. The test purposes include type approval test according to TIS standards, acceptance test and testing for local product development. For type test, the failed test modules were mostly found in a damp heat test. For annual performance evaluation test, power degradation and delamination were found in the modules obtained from various plants. For c-Si PV modules, the degradation of power were in range of 0-4% from its nameplate after 0-5 year operation in the field. For thin-film modules, the degradation and delamination were found in range of 0-13% (about 5% in average) from its nameplate of the modules operated less than 5 years. However, the power degradation of the modules which have been operated at our reference site on campus around 12 years was in range of 10-15% relating to their nameplates.

9563-16, Session 5

The impact of atmospheric species on CIGS solar cells *(Invited Paper)*

Mirjam Theelen, TNO (Netherlands) and Technische Univ.

Delft (Netherlands); Christopher Foster, Zeger Vroon, TNO (Netherlands); Nicolas Barreau, Institut des Matériaux Jean Rouxel (France); Miro Zeman, TNO (Netherlands) and Technische Univ. Delft (Netherlands)

CIGS solar cells were exposed to liquid water purged with the atmospheric gases carbon dioxide (CO2), oxygen (O2), nitrogen (N2) and air in order to investigate their chemical degradation behavior. The samples were analysed by electrical, compositional and optical measurements before, during and after exposure in order to follow the degradation behavior of these solar cells in time.

The solar cells showed a rapid decrease in conversion efficiency when exposed to water purged with a combination of CO2 and N2 as well as to water purged with air, while their efficiency was slowly reduced in unpurged water and water purged with N2 or O2. Cross-section SEM showed that the exposure of samples to H2O with large concentrations of CO2 led to the dissolution of the ZnO:Al layer, likely starting from the grain boundaries. This resulted in an increased series resistance, which is likely related to an increase in resistivity of the ZnO:Al layer. It also led to a very rapid decrease of the short circuit current of these samples. Therefore, the conversion efficiency was rapidly lost.

9563-17, Session 5

Activities of the PVQAT Thin Film Module Reliability Group 8

Neelkanth G. Dhere, Univ. of Central Florida (United States)

Photovoltaic module qualifications tests such as IEC 61215 and 61646 help in minimizing infant mortality. However, they do not guarantee useful lifetime over the warranty period. Highly accelerated stress testing (HAST) can be useful in exposing design and component weaknesses and consequently increasing the margin of the design. However, they do not duplicate the conditions experienced by the module and hence cannot be used for assuring the desired useful lifetime. Other attempts were concentrated on extending the existing tests such as damp heat test of 1000 hours at 85 0C and 85% RH. However, even though extending the test to 1250 hours may detect flaws that may occur in during field deployment, extending the test to 2000 and 3000 hours may cause failures that are not observed in the field. Therefore, the PV Module Quality Assurance Task Force (PVQAT) is trying to formulate accelerated tests that will be useful towards achieving the ultimate goal of assuring useful lifetime over the warranty period. Examples of accelerated stress tests and the failure modes that can be detected by them in crystalline silicon modules are as follows: damp heat test: corrosion, delamination, junction box adhesion; humidity freeze: delamination, junction box adhesion, insufficiently cured encapsulant; thermal cycles: broken interconnect, broken cells, electrical bond failure, junction box adhesion, potential for arcing. There are 12 groups working under the PVQAT. Of these the Group 8 deals with the Thin Film Module Reliability. It works on the following degradation issues that have been identified for Thin Film PV: corrosion including system voltage induced degradation, semiconductor junction diffusion, cell-to-cell; cell-to-outside interconnections and delamination (structural – macro & micro). The activities of Thin Film Module Reliability Group 8 will be presented.

9563-18, Session 5

Thin film PV standing tall side-by-side with mx-Si, also in terms of reliability

Neelkanth G. Dhere, Univ. of Central Florida (United States)

The UniSolar triple junction a-Si:H always showed exceptionally good reliability and durability. Early generation CIGS and CdTe PV modules had a different qualification standard 61646 as compared to 61215 for c-Si PV modules. This with small vulnerability in harsh climates was used to create doubts about their reliability. Recently CdTe and CIGS glass-to-glass modules have passed the rigorous accelerated tests. Moreover, the thin film and c-Si PV modules would soon undergo a unified qualification test protocol. Thus there is basis to rate thin film PV modules as lacking in terms of reliability. CdTe PV modules have shown the lowest production cost without subsidies. CIGS and CdTe cell and module have been showing efficiencies equal or greater than those of mx-Si PV modules. Now it can be stated without any hesitation that also in terms of the reliability and durability all the thin film PV modules stand tall and compare favorably mx-Si. Now they should be judged on the basis their suitability for the specific application and market place will decide their ranking.

9563-19, Session 5

Numerical simulation of wind flow over a photovoltaic solar panel using RANS equations

Andre L. Rezende, Instituto Militar de Engenharia (Brazil); Neelkanth G. Dhere, Univ. of Central Florida (United States)

The aim of this study is the numerical simulation of wind flow over solar photovoltaic panels. At present there are 113 schools in Florida that use similar 10-kW photovoltaic (PV) solar energy systems installeds on their campus. The PV electricity is fed to the grid and reduces the consumption of grid electericity of the schools. Moreover, these schools serve as disaster relief shelters. During hurricanes or other disasters the grid electricity to the shelters may be cut for few weeks. The PV electricity can then serve to provide the minimum critical necessities during such periods. Because of strong winds and hurricanes in this region, it is essential to study the effect of flow of wind on photovoltaic panels. Such study can also be useful to design efficient protectors and supports to guard the panels.

Typicals flows phenomena such as vortex shedding and boundary layer separation may influence the distribution of wind load on PV panels. Because of the similar PV system design and construction, the geometry of the solar panel installations and wind conditions would be similar in the PV systems in 113 Florida schools. The wind speed in critical conditions can reach 50 m/s.

This work consists of a steady state and incompressible flow numerical simulation through the Reynolds Averaged Navier-Stokes equations (RANS). The turbulence closure model uses the shear stress transport (SST) k-w.

The main results of the simulations are the pressure and velocity fields that are involved in loads that panels are being subjected to.

9563-20, Session 5

Analysis of PV modules based on thin films solar cells by dark measurements technique

Kamel Agroui, Unite de Developpement de la Technologie du Silicium (Algeria); Michelle Pelegrino, Flaminio Giovanni, ENEA (Italy)

A number of analytical and characterization methods are conventionally employed to measure and determine the PV module performances. For example, current-voltage (I-V), quantum efficiency (QE), photoluminescence (PL) and electroluminescence (EL) measurements are used to allow a direct evaluation of the quality of the solar cells or mini-modules. These methods are in general complementary.

In comparison, impedance spectroscopy (IS) under dark measurements is well known to be highly suitable for analyzing a variety of R-C circuits corresponding to a large number of physical materials and devices. Specifically, IS measurements can readily allow a quantitative evaluation of the electrical property of a solar cell's p-n junction, which is typically represented by an equivalent circuit of a parallel resistor and capacitor (R-C circuit model), and its series resistance. Briefly, in a simplest form of the IS measurements, a small amplitude sinusoidal AC signal is applied to

the PV module over a range of frequency. The PV module responses can be identified by mapping the real and imaginary parts of their complex impedance as a function of the frequency of the applied external electric field.

The goal of this paper is to estimate the PV module performances based on 1J:a-Si and 3J:a-Si amorphous silicon solar cells. The possibility to introduce the IS measurements to more understand the amorphous PV module behavior, as a complimentary non-destructive analysis, will be examined. The frequency and voltage dependent characteristics of PV module are determined by IS technique and frequency response analysis based on sinusoidal and periodic signals.

9563-21, Session 6

Rapid field measurement of cells performance within PV modules *(Invited Paper)*

Alessandra Colli, Klaus Attenkofer, Brookhaven National Lab. (United States)

To develop an alternative energy economy in which solar energy plays a major role, the risks of system failure have to be understood and quantitative models developed to estimate lifetime and efficiency. The lack of these models is caused by the complexity of the underlying processes in actual operating environments, and the absence of tools which allow the fundamental PV cell parameters to be determined, such as shunt resistivity, connection resistivity, and cell capacity, in an inexpensive, non-intrusive, and non-destructive way. The presentation focuses on a method and tool to collect the essential electric variables of PV cells within a module with no destructive approach. The achievable areal resolution of about 15 mm2 and the modular building concept allows optimizing the system to all commercially relevant solar panel designs. Such tool is expected to provide the information useful to fill the existing gap between applied PV system engineering and PV material physics and analysis, ultimately providing device lifetime information useful to improve the system design and the manufacturing process of PV modules and cells. It can be used to determine: (i) the equivalent electrical parameters of the PV cell and module circuit, linking to material analysis needs, (ii) the degradation pathways, (iii) the lifetime expectations of PV cells module, (iv) the quality status (performance and reliability) of aging installations to meet the energy production expectations and set the financial value of the installation, and (v) the effects of the installation design (e.g. string positioning and grounding system) on degradation.

9563-22, Session 6

PV system reliability program at Sandia National Labs: From material-level to system-level analysis *(Invited Paper)*

Olga Lavrova, Sandia National Labs. (United States)

No Abstract Available

9563-23, Session 6

When PV modules are becoming real building elements: White solar module, a revolution for BIPV

Laure-Emmanuelle Perret-Aebi, Jordi Escarré, Heng-Yu Li, Laurent Sansonnens, Federico Galliano, Gianluca Cattaneo, Patrick Heinstein, Sylvain Nicolay, Julien Bailat, Ctr. Suisse d'Electronique et de Microtechnique SA (Switzerland); Sébastien Eberhard, Solaxess SA (Switzerland); Christophe Ballif, Ctr. Suisse d'Electronique et de Microtechnique SA (Switzerland)

The use of photovoltaic (PV) is not anymore an option but a real need in the construction of nearly zero energy buildings. To date, the lack of PV products specifically designed for building integration, considering aesthetics and architectural aspects, is one important limiting factor allowing a massive deployment of PV in the built environment. Architects are continuously asking for new solutions to customize the colour of PV elements to better integrate them into the building skin. Among these colours, white is especially attractive as it is widely used in architecture for its elegance, versatility and fresh look. Until now, white solar modules were not considered to be an option and even never been though to be a technological possibility.

Nonetheless, CSEM recently developed a new technology to make white solar modules a reality. Furthermore, the new Swiss company called Solaxess is now working on the industrialisation of this very innovative technology and the first products are expecting to be on the market at the end of 2015. The technology is based on the combination of two different elements: a solar cell able to convert solar infrared light into electricity and a selective filter which reflects and diffuse the whole visible spectrum.

Any PV technology based on crystalline silicon can be used as they have a good response in the infrared. Approximately 55% of the current generated under standard test conditions comes from the infrared leading to conversion efficiencies above 11%.

We will demonstrate, that thanks to this very innovative technology PV modules can become attractive and real active building elements and therefore meets the requirements of any future energy management through advanced building skins.

9563-24, Session 6

Photovoltaic Reliability Group activities in USA and Brazil

Neelkanth G. Dhere, Univ. of Central Florida (United States); Leila R. O. Cruz, Instituto Militar de Engenharia (Brazil)

Recently prices of photovoltaic (PV) systems have been reduced considerably and may continue to be reduced making them attractive. If these systems provide electricity over the stipulated warranty period, it would be possible attain socket parity within the next few years. Current photovoltaic module qualifications tests help in minimizing infant mortality but do not guarantee useful lifetime over the warranty period. The PV Module Quality Assurance Task Force (PVQAT) is trying to formulate accelerated tests that will be useful towards achieving the ultimate goal of assuring useful lifetime over the warranty period as well as to assure manufacturing quality. Unfortunately, assuring the manufacturing quality may require 24/7 presence. Alternatively, collecting data on the performance of fielded systems would assist in assuring manufacturing quality. Here PV systems installed by home-owners and small businesses can constitute as an important untapped source of data. The volunteer group, PV – Reliable, Safe and Sustainable Quality! (PVRessQ!) is providing valuable service to small PV system owners. Photovoltaic Reliability Group (PVRG) is initiating activities in USA and Brazil to assist home owners and small businesses in monitoring photovoltaic (PV) module performance and enforcing warranty. It will work in collaboration with small PV system owners, consumer protection agencies. Brazil is endowed with excellent solar irradiance making it attractive for installation of PV systems. Participating owners of small PV systems would instruct inverter manufacturers to copy the daily e-mails to PVRG and as necessary, will authorize the PVRG to carry out review of PV systems. The presentation will consist of overall activities of PVRG in USA and Brazil.

9563-203,

The importance of reliability to the SunShot Initiative

Rebecca Jones-Albertus, U.S. Dept. of Energy (United States)

The U.S. Department of Energy's SunShot Initiative was launched in 2011 to make subsidy-free solar electricity cost competitive with conventional energy sources by the end of the decade. Research in reliability can play a major role in realizing the SunShot goal of $0.06/kWh. By improving photovoltaic module lifetime and reducing degradation rates, a system's lifetime energy output is increased. Increasing confidence in photovoltaic performance prediction can lower perceived investment risk and thus the cost of capital. Accordingly, in 2015, SunShot expects to award more than $40 million through its SunShot National Laboratory Multiyear Partnership (SuNLaMP) and Physics of Reliability: Evaluating Design Insights for Component Technologies in Solar (PREDICTS) 2 funding programs, for research into reliability topics such as determining acceleration factors, modeling degradation rates and failure mechanisms, improving predictive performance models, and developing new test methods and instrumentation.

9563-25, Session PMon

Analysis of aluminum nano-grating assisted light reflection reduction in metal-semiconductor-metal photodetectors

Xiaohu Han, Yahui Su, Huayong Zhang, Anhui Univ. (China); Xiaohu Han, Anhui Univ (China)

We report homogeneous and high aspect ratio nanogratings fabricated on crystalline GaAs surface exploiting femtosecond laser ablation. An optimum nano-grating height and period for the Homogeneous Nanograting (HNGs) were obtained by Finite-difference Time Domain (FDTD) simulation.The results show that the reflection loss of homogeneous shaped nano-grating structure ,which has a 250 nm grating period and a 630 nm height , is about 34% less than that of flat type GaAs substrates. Then a simple two-step femtosecond ablation process was used to control the nanoscale energy deposition that should be developed through the excitation of Surface Plasmon Polaritons (SPPs) during the fs-laser surface interaction. It is found that the height and shape of the HNGs, can be controlled by changing single pulse energy F and the superimposed shot number N of fs-laser pulses. With increasing the N of low-fluence fs-laser pulses, the periodic nanostructure develops through the bonding structure change of GaAs. Depending upon the experimental parameters nano-grating sizes varied in the range of 150~320nm.The experimental results indicate that the proposed approach can achieve homogeneous and high aspect ratio nanogratings with lower reflection compared to the polished GaAs surface.These nanogratings fabricated in GaAs surface may find potential applications in Photovoltaic Cells, optical recording, and other micro-optical devices.

9563-26, Session PMon

FTIR spectroscopy of silicon carbide thin films prepared by PECVD technology for solar cell application

Angela Kleinová, Polymer Institute (Slovakia)

The plasma CVD reactor with parallel plate electrodes was used for plasma enhanced chemical vapor deposition (PECVD) of silicon carbide films on Si substrates. Technological parameters for the preparation of samples were: substrate temperature was 300 oC and the gas mixture composition for the sample SA1 was (SiH4-7 ml/min., CH4-40 ml/min., Ar-10 ml/min) and for the sample SA2 (SiH4-4 ml/min., CH4-20 ml/min., Ar-10 ml/min., H2-100 ml/min.). For both samples the RF power was 150 W and the pressure was set to 40 Pa. The concentration of the elements in films was determined by Rutherford backscattering spectrometry (RBS) and elastic recoil detection (ERD) analytical method simultaneously. The chemical compositions of the samples were analyzed by Fourier transform infrared spectroscopy (FTIR). RBS and ERD results showed that the films contain silicon, carbon, hydrogen and small amount of oxygen. FTIR results confirmed the presence of Si-C, Si-H, C-H, and Si-O bonds. From the FTIR spectra the main following vibration frequencies were determined: the band at 2800 to 3000 cm-1 is attributed to stretching vibration of the CHn group in both the sp2 (2880 cm-1) and sp3 (2920 cm-1) configurations. The band at 2100 cm-1 is due to SiHm stretching vibrations. The band at 780 cm-1 can be assigned to Si-C stretching vibration. Main features of FTIR spectra were Gaussian fitted and detailed analyses of chemical bonding in SiC films was performed. Differences between two types of SiC films were discussed with the aim to use these films in the heterojunction solar cell technology.

9563-27, Session PMon

Raman spectroscopy study of SiC thin films prepared by PECVD for solar cell working in hard environment

Vlasta Sasinkova, Institute of Chemistry (Slovakia)

Amorphous silicon carbide is excellent alternative passivation layer material for silicon solar cells especially working in hard and space environment.

Amorphous silicon carbide films were deposited by PECVD technology using SiH4, CH4, H2 and N2 gas as precursors. Two types of samples were prepared: SV1- amorphous silicon carbide a-SiC:H thin film on Si substrate, SV2- N doped silicon carbide a-SiC(N):H on Si substrate. The concentration of elements in the films was determined by RBS and ERD analytical method. Raman spectroscopy study of the SiC films were performed by using a Raman microscope with 532 nm laser. Irradiation of samples with neutrons to a total fluencies A(7.9x1014 cm-2), B(5x1015 cm-2) and C(3.4x1016 cm-2) was performed. The films contain silicon, carbon, hydrogen and nitrogen. Raman spectra, especially the intensity of the lattice vibration at 520 cm-1, originates from the silicon substrate. The Raman band between 930 cm-1 and 990 cm-1 is created by acoustical and optical phonon modes of cubic or one of the hexagonal polytypes of SiC. The peak broadening is related to the damping of phonon modes due to the short range ordering of SiC crystallites and the effects of surroundings having Si, as well as C-clusters. The Raman band between 1300 cm-1 and 1700 cm-1 is assigned to diamond like carbon. Raman spectroscopy results of SiC showed decreasing of Raman band feature intensity after neutron irradiation and slightly decreased with increased neutron fluencies. Properties and differences between two types of films before and after neutron irradiation are discussed.

9563-28, Session PMon

Critical analysis on degradation mechanism of dye sensitized solar cells

Mukhzeer Mohamad Shahimin, Suriati Suhaimi, Mohamad Halim Abdul Wahid, Vithyacharan Retnasamy, Nor Azura Malini B. Ahmad Hambali, Univ. Malaysia Perlis (Malaysia); Ali Hussain Reshak, Univ. of West Bohemia (Czech Republic)

This paper reports on a précis of degradation mechanism for dye sensitized solar cell (DSSCs). The review indicates progress in the understanding of degradation mechanism, in particular the large improvement in the analysis of the materials used in DSSCs. The paper discussed on the stability issues of the dye, advancement of the photoelectrode film lifetime, changes in the electrolyte components and degradation analysis of the counter electrode. The photo electrochemical parameters were evaluated in view of the possible degradation routes. The new research trend together with the previous research has been highlighted to examine the key challenges faced for better performances solar cells and directly influenced the stability and reliability of DSSCs.

9563-30, Session PMon

Non-destructive luminescence polarization study related to recombination mechanisms and silicon material properties

Radek Stojan, Jirí Vanek, Brno Univ. of Technology (Czech Republic)

For non-destructive luminescence characterization of silicon solar cells is frequently used to standard electroluminescence (EL) diagnostic method. It's known that the EL spectrum from silicon wafer is out of visible range of the electromagnetic spectrum. The presented paper work is focused on room-temperature EL spectra and modify characteristics of polarization emission related to scientific innovation of standard luminescence diagnostic methods. In this paper will be image processing for qualitative analysis of solar cells in schematic diagnostic flow. Extended image processing allows further information to be obtained from EL images. Those details allow efficient interpretation of the results.

The polarization of the luminescence center radiation (ie. electromagnetic waves) can be viewed from the perspective of quantum mechanics. As is well known, luminescence is a radiant recombination of electrical charge in a semiconductor materials. Luminescence center incurred during this recombination can be described and approximated as quantum oscillator. Therefore we can say that the intensity of the emitted photons (which is a defining characteristic of polarization diagnostic method) is related to recombination mechanisms, material properties, optical properties and so junction voltage.

Theoretical describe of polarization emission related to change of intensity lead to additional understand of properties of defects in silicon solar cells. In this idea is potential for advance diagnostic element for better characterization of large defect in silicon structures.

9563-31, Session PMon

Characterizing different defects in multycrystalline silicon solar cells via modern imaging methods

Shishu Lou, Huishi Zhu, Peide Han, Institute of Semiconductors (China)

Defects in multicrystalline silicon solar cells such as impurities, gain boundaries, dislocations and metallic impurities have great influence to the final conversion efficiency of devices. Moreover, different kinds of defects and defects at different depth layers in multicrystalline silicon solar cell play different roles to the final performance of devices. This paper proposes a fast technique via electroluminescence imaging method and photoluminescence imaging method to distinguish different types and depths defects. Different types of defects have various influences to the distribution of extra minority carriers which would result in the distinctions in the final luminescence intensities. Therefore, we can recognize these defects via a group of PL and EL images in a few seconds. Also, we found that defects at different depths show a closely relationship with electrical breakdown which would lead to the differences on the final electroluminescence properties. The EL images under different forward-biased and reversed-biased voltages give a clear separation of defects near the front surface, around p-n junction and in bulk material. Light beam induced current (LBIC) imaging is used to verify the methods we proposed. These modern imaging methods could become popular methods in photovoltaic testing field, and we hope our research could give some help in the study of silicon based devices.

9564-29, Session PMon

Studies on thermally induced third-order nonlinearity and optical power limiting of Aniline blue diammonium salt investigated using CW He-Ne laser at 633nm excitation

Poornesh P., Pramodini S., Manipal Univ. (India)

We present the results of thermally induced third-order optical nonlinearity and optical limiting performance of an organic dye Aniline blue diammonium salt. Single beam Z-scan technique was used to determine the sign and magnitude of the absorptive and refractive nonlinearities. Continuous wave (CW) He-Ne laser operating at 633nm was used as source of excitation. The nonlinear refractive index n2, the nonlinear absorption coefficient ?eff and the third-order optical susceptibility ?(3) were found to be of the order 10-5esu, 10-3 cm/W and 10-7esu respectively. The observed large third-optical nonlinearity in the dye is due to the presence high ϖ-electron density in the backbone of the molecular structure. Self-diffraction rings pattern were observed in the dye and it is due to the refractive index change and thermal lensing. The dye exhibits good optical power limiting characteristics at the experimental wavelength 633nm. Optical power limiting and clamping studies were carried out at various input power levels. Optical clamping of about ~ 3mw and limiting threshold of 5-mw was observed. The nonlinear optical studies indicate that the dye investigated here materialize as a promising candidate for nonlinear optical devices applications such optical power limiters.

Synthesis, growth, characterization and molecular hyperpolarizabilities of a novel NLO organic material

Ashwatha Narayana Prabhu, Vyasa Upadhyaya, Manipal Univ. (India)

A novel superior characteristic nonlinear optical (NLO) organic material, 1-(5-chlorothiophen-2-yl)-3-(2,3-dimethoxyphenyl)prop-2-en-1-one [CTDMP], has been synthesized and grown as a good-quality single crystal by the slow evaporation solution growth technique. The grown crystals were characterized by FT-IR, single-crystal X-ray diffraction (XRD), differential scanning calorimetry and UV–Visible spectroscopy. Single beam Z-scan technique was employed to study the third order NLO properties of the material. The nonlinear refractive index is found to be of the order of 10-11 cm2 W-1. The magnitude of third order susceptibility is of the order of 10-13 esu. The observed increase in the third order nonlinearity in these molecules clearly indicates the electronic origin. The compounds exhibit good optical limiting at 532 nm, is due to the substituted strong electron donor. The mechanical property of the grown crystals was studied using Vicker's micro hardness tester and the load dependence hardness was observed. CTDMP belongs to the monoclinic crystal system with space group P21/c. The morphology of CTDMP single crystal was indexed using the XRD data as input to the morphology indexing computer program (WinXMorph). To support the observed variation in the experimental NLO property the static second and third order NLO hyperpolarizabilities of the chalcone derivative was computed using semiempirical MOPAC 2012 computer program.

Growth and characterization of a new nonlinear optical organic crystal: 2,4,6-Trimethylacetanilide

Vyasa Upadhyaya, Manipal Univ. (India); Sharada G. Prabhu, NMAM Institute of Technology (India)

A new nonlinear optical organic material, 2,4,6-trimethylacetanilide (246TMAA), also known as N-[2,4,6-trimethylphenyl]acetamide, has been synthesized and grown as a single crystal by the slow evaporation technique by organic solvents. The grown crystals have been characterized by morphology study. The crystals are prismatic. Surface examination shows granular dendritic pattern in optical micrograph. The Scanning Electron Micrograph shows the layered growth of the crystal. The Differential Scanning Calorimeter plot shows no phase change until melting point (219°C). The density of the crystals is 1.1g/cc and the crystals are soft. The crystals are transparent in the visible region and in the ultra-violet region till 280 nm. 246TMAA crystallizes with 2 molecules in a monoclinic unit cell in the non-centrosymmetric point group m, space group Pn [1]. Refractive indices of this optically biaxial crystal along the three crystallo-physical axes have been measured at 633 nm. The optical second harmonic generation efficiency of the crystal at 1064 nm is about half that of the urea crystal, measured by powder method using Nd:YAG laser. The results show that the 246TMAA crystal can efficiently be used for up-conversion of infrared radiation into visible green light. [1] V. Upadhyaya et al, Acta. Cryst. E58 (2002) o997.

Photorefractive polymer device with improved sensitizing property

Tam V. Nguyen, Ha N. Giang, Kenji Kinashi, Wataru Sakai, Naoto Tsutsumi, Kyoto Institute of Technology (Japan)

Recently, a photoconductive polymer of poly(4-(diphenylamino)benzyl acrylate) (PDAA) has been utilized for fast response photorefractive (PR) application because of a fast hole mobility. In most of previous studies, phenyl-C61-butyric acid methyl ester (PCBM) was used as the only sensitizer. In this study, a high-performance charge generator perylene bisimide (PBI) is additionally added into the composite. By using new charge generator, the sensitivity of PR material at a preferred wavelength and the PR speed can be enhanced simultaneously. PBI derivaties owing to a large core of ϖ-conjugated rings have been proven to provide a high electron affinity and a charge carrier mobility. These features are promising to improve PR properties. To the best of our knowledge, it is the first time

for using a combine of PCBM and PBI to improve the performance of PDAA-based composites. 2-(4-(azepan-1-yl)benzylidene)malononitrile (7DCST) is used as a nonlinear optical chromophore. (4-diphenylamino)phenyl) methanol (TPAOH) is used as a plasticizer. Green laser with the wavelength of 532 nm is used because PBI has a strong absorption. Moreover, according to the previous study by another group, 7DCST also acts as a sensitizer at this wavelength. Surprisingly, a high diffraction efficiency of 76 % and a fast response time of 8 ms were obtained in the present composite (PDAA/7DCST/TPAOH/PBI/PCBM - 45/30/25/0.2/0.4 wt %) under the electric field of 55 V/?m. The introduction of PBI is a promising approach for photorefractive composite owning the video rate response.

9564-34, Session PMon

Effect of metal films on the photostabilities of emissive organic layers as probed by fluorescence microscopy

Sikandar Abbas, Linda A. Peteanu, Carnegie Mellon Univ. (United States)

Electroluminescent (EL) and photovoltaic (PV) devices utilizing conjugated polymers are comprised of an organic layer and metal film electrode deposited on a glass substrate. Photo-damage of emissive organic layers is one factor that decreases the overall efficiency and longevity of EL devices. Therefore, improvements in organic light emitting devices (OLEDs) and solar cells require a deep understanding of photo-chemistry at metal - polymer interface and new methods to fabricate photo-stable devices. Here, the effects of metal film substrates on the emission properties of organic layers are investigated using total internal reflection (TIRF) fluorescence microscopy. MEH - PPV was spin casted over gold (Au) films of varying thickness (2 nm to 8 nm). While 8 nm gold films completely quench the MEH-PPV fluorescence, thinner gold films (~ 2 nm) cause minimal quenching. More surprisingly, the MEH-PPV layer exhibits a remarkable increase in photostabiity when deposited on thin gold films relative to that on glass even in the presence of molecular oxygen and under laser illumination. This is likely to be due to an observed shortening of excited singlet state lifetime of the MEH-PPV in the presence of the metal surface. Enhancing the stability of organic thin films in this manner supports the quest for highly-efficient EL and PV devices.

Composition dependent structural, thermal, and mechanical properties of Sm2O3 doped zinc fluoroborate glasses

Sudha D. Kamath, Manipal Institute of Technology (India)

Glasses based on Sm3+ doped zinc fluoroborate have been synthesized and characterized. Formation of glass has been investigated in the 30 ZnF2-20 TeO2-(50-x) B2O3-x Sm2O3 matrix. Fast quenching is required to prevent melt crystallization and adequate heat treatment to diminish thermal stress, which results in an efficient amorphous material. The Differential Scanning Calorimeter (DSC), Scanning Electron Microscopy (SEM), Energy Dispersive X-ray Analysis (EDAX), stability, density and refractive index have been recorded, calculated, measured and analyzed for the glass samples with different concentrations of Sm3+ ranging between 0 to 3 moL%. Density increases as dopant concentration increases and glass transition temperature Tg ranges between 395 and 420°C. The increase of molar volume with Sm2O3 content indicates that the extension of glass network is due to the increase of the number of NBOs. The results found in this investigation showed that the refractive index of glass does not only depend on the density but also depends on the electronic polarizability of the glass. The increasing stability of the glass samples shows that they are thermally resistant. The presence of NBOs in the glass network is also approved by the decrease in glass transition Temperature (Tg). The variation of the properties with different composition of dopant plays a dominant role in determining a good host material in the field of optics and photonics.

9564-1, Session 1

Coupling J-aggregate excitons with confined photons in a strongly-coupled planar microcavity *(Invited Paper)*

David G. Lidzey, The Univ. of Sheffield (United Kingdom)

By placing an organic semiconductor material having a relatively narrow electronic transition into an optical microcavity, it is possible to 'mix' excitons with confined cavity photons, forming states termed 'cavity polaritons'. Here, I discuss the formation of polariton states in microcavities containing J-aggregates of two different molecular dyes (cyanine dyes), whose J-band electronic transitions are both coupled to the same cavity photon mode. Under such conditions, three polariton branches are formed, with the "middle" polariton branch composed of an admixture of the cavity photon and the two different exciton states. I show using both photoluminescence excitation spectroscopy and photoluminescence emission measurements that such "hybrid" polariton states effectively act as an energy transfer pathway, allowing energy to be transferred between the different exciton states. A model is presented that describes exciton scattering into polariton states, and the subsequent decay and energetic relaxation of polaritons. I argue that the transfer of middle-branch polaritons to the lower-lying excitonic states is an efficient process, that occurs in time-scale of less than 10 fs. I then discuss structures in which a single J-aggregated cyanine dye is placed into a microcavity in which the extended cavity path-length results in the formation of a series of closely spaced cavity photon modes. It is shown that excitons in the cavity can simultaneously undergo strong coupling with at least four cavity photon-modes, effectively forming a ladder of polariton states, with a significant polariton population found in 3 adjacent polariton branches.

9564-2, Session 1

Control of light-matter interaction using organic-inorganic hybrid excitons *(Invited Paper)*

Vinod M. Menon, The City College of New York (United States)

In this talk we will discuss our recent work on the formation of organic-inorganic hybrid excitons in microcavities as well as the nonlinear optical response of hybrid excitonic systems. Using thin film 3,4,7,8-napthalenetetracarboxylic dianhydride (NTCDA) and ZnO nanocrystals/nanowires we demonstrate enhanced Rabi splitting of hybrid polaritons and improved third order nonlinear optical response. In the former case, the hybrid materials are embedded in an optical microcavity.

9564-3, Session 1

Measuring optical anisotropies in organic semiconductors

Steven J. Brown, Ruth A. Schlitz, Niva A. Ran, Xiaofeng Liu, John A. Love, Christropher J. Takacs, Michael L. Chabinyc, Thuc-Quyen Nguyen, Guillermo C. Bazan, Jon A. Schuller, Univ. of California, Santa Barbara (United States)

Having a firm grasp of the optical properties of the active material is critical when designing optoelectronic devices. While proven optical characterization techniques exist for isotropic, highly crystalline inorganic materials, optical characterization of anisotropic, mesoscopically ordered organic materials is still nascent. Two critical questions need to be answered for efficient device engineering: What are the active material's optical properties, and how do those optical properties relate to film morphology and processing?

In this work we present recently developed momentum-space spectroscopy techniques that are uniquely suited to studying anisotropic optical

properties in thin films. Instead of using traditional "real-space" optical design, Fourier-space optics are used to control and measure light in "momentum-space". These momentum-resolved (or equivalently, angle-resolved) techniques have far superior sensitivities to out-of-plane optical properties than traditional techniques and obviate the complicated model-dependent fitting used in e.g. ellipsometry. Using momentum-resolved luminescence and absorption measurements we study polymer (P(NDI2OD-T2)) and small molecule (p-SIDT(FBTTh2)2) films with variable morphologies which depend on processing—thereby connecting structural and optical properties. The information gleaned from these spectroscopies will increase our fundamental understanding of organic materials and allow us to engineer devices and photonic architectures that maximize light-coupling efficiency in the presence of strong optical anisotropies.

9564-4, Session 1

Engineering the photophysical properties of organic semiconductors using plasmonic nanostructures *(Invited Paper)*

Jean-Charles Ribierre, Kyushu Univ. (Japan) and Japan Science and Technology Agency (JST), ERATO, Adachi Molecular Exciton Engineering Project (Japan) and CNRS-Ewha International Research Ctr., Ewha Womans Univ. (Korea, Republic of); Anthony D'Aléo, Aix Marseille Univ., CNRS, CINaM (France); Fabrice Mathevet, Univ. Pierre et Marie Curie (France); Chihaya Adachi, Kyushu Univ. (Japan) and Japan Science and Technology Agency (JST), ERATO, Adachi Molecular Exciton Engineering Project (Japan); Pascal André, Jeong Weon Wu, CNRS-Ewha International Research Ctr., Ewha Womans Univ. (Korea, Republic of)

In this talk, we report on the engineering of the photophysical properties of organic thin films using carefully designed plasmonic nano-structures. A battery of experimental techniques including steady-state absorption and photoluminescence spectra, time-resolved photoluminescence and femtosecond transient absorption measurements are used to investigate, in both solution and thin film, the photophysical properties of a discotic liquid-crystalline donor-acceptor dyad based on triphenylene and perylene diimide units linked by a flexible non-conjugated bridge. The characterization of the photophysical properties of the dyad film shows that photo-induced charge transfer occurs between the donor and acceptor moieties. I will then demonstrate that the dynamics of the formation of the charge transfer state and its recombination could be tuned with the use of plasmonic nano-structures. The mechanism of this process will be discussed in the frame of the Marcus theory. The influence of plasmonic nano-structures on the light-emitting properties of different organic molecules in thin films is also investigated using steady-state and time-resolved photoluminescence measurements. Overall, the results will provide new guidelines to manipulate the molecular excitonic processes taking place in organic semiconducting thin films using plasmonic nano-structures.

9564-5, Session 1

Ag nanoparticles on a cellulose nanocrystal scaffold for applications in organic photovoltaics *(Invited Paper)*

Nathan J. Dawson, Case Western Reserve Univ. (United States); Stephen Spinella, Anthony Maiorana, Rensselaer Polytechnic Institute (United States); Kenneth D. Singer, Case Western Reserve Univ. (United States); Richard A. Gross, Rensselaer Polytechnic Institute (United States)

We report on Ag nanoparticles attached to a cellulose nanocrystal (CNC) scaffold which forms a nanoparticle-on-nanoparticle structure. The morphology of the cellulose scaffolds as well as the coverage and particle size are optimized. The applications to organic photovoltaics (OPV) are illustrated using a Poly(3-hexylthiophene-2,5-diyl) and [6,6]-Phenyl C60 butyric acid methyl ester (P3HT:PCBM) bulk heterojunction solar cell.

Either a poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS) or a graphene oxide (GO) electron blocking layer is spincoated onto the indium-tin-oxide (ITO). The hole blocking layer is a thermally evaporated LiF layer with and without a bathocuproine (BCP) layer between the P3HT:PCBM/LiF interface. The architecture of the most common OPV used in this study was layered as ITO/GO/P3HT:PCBM/BCP/LiF/Al.

We study the effects of the Ag-CNCs introduced at both the front and rear interfaces of the bulk heterojunction with different blocking layers. The photoconversion efficiency of the solar cells is found to increase in some cases, which depends on the Ag-CNC concentration and layering conditions.

9564-6, Session 2

Universal scaling in nonlinear optical molecules *(Invited Paper)*

Javier Perez-Moreno, Skidmore College (United States)

In organic molecules, the strength of the linear and nonlinear optical response scales depends on the size of the structure. Power-laws that correlate the length of a structure and its nonlinear structure have been proposed by different researchers. These power-laws are described as function of the number of repeating units, and are derived from the experimental characterization of one set of homologue compounds. Typically, every set of homologues has been reported to obey a different power-law. We show how the sum rules allow to derive universal scaling power-laws that apply to all structures and are in agreement with the experimental data. Using the concept of universal scaling, we propose a classification of the scaling behavior that can be used to determine what are the best molecular paradigms for future nonlinear optical applications.

9564-7, Session 2

Design rules for quasi-linear nonlinear optical structures

Richard Lytel, Sean M. Mossman, Mark G. Kuzyk, Washington State Univ. (United States)

The maximization of the intrinsic optical nonlinearities of quantum structures for ultrafast applications requires a spectrum scaling as the square of the energy eigenstate number or faster. This is a necessary condition for an intrinsic response approaching the fundamental limits. A second condition is a design generating eigenfunctions whose ground and lowest excited state probability densities are spatially separated to produce large differences in dipole moments while maintaining a reasonable spatial overlap to produce large off?diagonal transition moments. A structure whose design meets both conditions will necessarily have large first or second hyperpolarizabilities. These two conditions are fundamental heuristics for the design of any nonlinear optical structure.

In this paper, we focus on topologies with a main linear chain and one or more side groups. We use quantum graph models to show how the judicious placement of a side group along a main chain structure can produce exactly the right phase shift in the eigenfunction along the main chain such that the required spatial separations of probability density between the lowest eigenstates along the chain are achieved. We show that if a single side group is correctly placed, additional side groups provide essentially no added increase in the nonlinearity and are not necessary. The length of the side group, as well as its position, must be meticulously selected to ensure that a large phase shift along the chain is introduced while minimizing the charge density diverted to the side group. We discuss the significance of these results for molecular design.

9564-8, Session 2

Development and characterization of thermally stable electro-optic polymers and devices *(Invited Paper)*

Akira Otomo, Isao Aoki, Chiyumi Yamada, Toshiki Yamada, National Institute of Information and Communications Technology (Japan)

Electro-optic (EO) polymers are key materials for next generation optical communications not only in wide area network but also in local area and storage area network because EO polymer modulator can be operated at fast speed more than 100 GHz with low energy consumption and can be miniaturized in combination with silicon photonics. In practical applications, thermal stability is one of the important issues to be considered for developing EO polymers. Since EO activity of the polymer is proportional to dipole orientation factor of the EO moieties, electric field assisted poling around glass transition temperature (Tg) of the polymer is necessary. However, the poled order of the molecules relaxes gradually at finite temperature, and then EO activity decreases after long period of time. We have successfully developed thermally stable EO polymers that have high-Tg up to 180 °C. They show excellent thermal stability with the Telcordia thermal test. Thermal stability is also characterized by thermally stimulated depolarization current (TSDC) measurement. Analyzing the TSDC, we can estimate the activation energy and relaxation time of polarization at any temperature. We will discuss thermal stability of the high-Tg EO polymers and devices.

9564-9, Session 3

Optical and magnetic probes of hot singlet exciton fission in pi-conjugated polymers for photovoltaic applications *(Invited Paper)*

Zeev V. Vardeny, Yaxin Zhai, Ella Olejnik, The Univ. of Utah (United States)

We used steady state and ps transient photoinduced absorption (PA), excitation dependence (EXPA(?)) spectrum of the triplet exciton PA band, and its magneto-PA (MPA(B)) response to investigate singlet fission (SF) of hot-excitons into two separated triplet excitons, in luminescent ϖ-conjugated polymers. From the high energy step in the triplet EXPA(?) spectrum of poly(dioctyloxy)-phenylenevinylene (DOO-PPV) films, we identified a hot-exciton SF (HE-SF) process having threshold energy at E≈2ET (=2.8 eV, where ET is the energy of the lowest lying triplet exciton); which is about 0.8 eV above the lowest singlet exciton energy. The ps transient PA with 3.1 eV pump excitation shows that in DOO-PPV film triplet excitons are generated at short time; this is missing in DOO-PPV solution. The HE-SF process was confirmed by the triplet MPA(B) response for excitation at E>2ET, which shows typical SF response. The HE-SF process is missing in DOO-PPV solution, showing that it is predominantly interchain. Our work shows that the SF process in ϖ-conjugated polymers is a much more general process than thought previously.

9564-10, Session 3

Interfacial structure and dynamics at organic / metal interfaces *(Invited Paper)*

Oliver L. A. Monti, The Univ. of Arizona (United States)

The electronic structure of organic semiconductor interfaces presents a complex problem that is challenging for both theory and experiment. I will present recent results on unraveling factors that influence the electronic structure and dynamics at organic / metal interfaces. Using both ground and excited state photoemission spectroscopies, and based on a detailed atomistic understanding of the thin film structure, we are able to unravel the critical aspects that influence molecule / surface coupling and its influence on interfacial dynamics. The conceptual understanding arising from this work does not only shed light on the delicate interplay of localized and delocalized states, but also has immediate impact on rational design of organic electronic devices.

9564-11, Session 3

Nonlinear coherent spectroscopy in the single molecule limit *(Invited Paper)*

Eric O. Potma, Univ. of California, Irvine (United States)

Detecting coherent anti-Stokes Raman scattering (CARS) signals from signal molecules is a longstanding experimental challenge. Driving the vibrational CARS response with surface plasmon fields has proven notoriously difficult due to strong background contributions, unfavorable heat dissipation and the phase dispersion of the plasmon modes in the ensemble. In this work we overcome previous experimental limitations and demonstrate time-resolved, vibrational CARS from molecules in the low copy number limit, down to the single molecule level. Our measurements, which are performed under ambient and non-electronic resonance conditions, establish that the coherent response from vibrational modes of individual molecules can be studied experimentally, opening up a new realm of molecular spectroscopic investigations.

9564-12, Session 3

Narrow band gap conjugated polymers for emergent optoelectronic technologies *(Invited Paper)*

Jason D. Azoulay, Benjamin A. Zhang, The Univ. of Southern Mississippi (United States); Bryan M. Wong, Univ. of California, Riverside (United States); Matthew Y. Sfeir, Brookhaven National Lab. (United States)

Conjugated polymers effectively produce and harvest visible light and find utility in a variety of commercially relevant optoelectronic technologies offering distinct manufacturing paradigms. There is currently considerable interest in expanding the scope of these materials to afford complementary functionality in the infrared (IR) and to endow functionality relevant in emergent technologies. A critical challenge stems from the need to control the frontier orbital energetics (separation, position, and alignment), ground state electronic configurations, interchain arrangements, solid-state properties, and many other molecular features with a degree of synthetic precision that has yet to be achieved. We recently demonstrated that cross-conjugated 4H-cyclopenta[2,1-b:3,4-b?]dithiophene (CPDT) structural units, in combination with strong acceptors with progressively delocalized ϖ-systems, afford modular donor-acceptor copolymers with broad and long wavelength light absorption that spans technologically relevant wavelength (?) ranges from 0.7 < ? < 3.2 ?m (Eg < 0.5 eV). These solution-processable materials possess some of the narrowest band gaps reported to date and exhibit unique optical, electrical, spin, and magnetic activities. In this contribution, we will describe the synthesis and characterization of these materials and couple these results with first-principles electronic structure calculations to highlight how incorporation of peripheral cross-conjugated substituents to a cyclic substructure within a ϖ-conjugated system provides a much more complex, versatile, and highly valuable tool for the tuning of material properties.

9564-13, Session 4

Dynamic filtering with liquid crystals *(Invited Paper)*

Timothy J. White, Air Force Research Lab. (United States); Kyung Min Lee, Air Force Research Lab. (United States)

and Azimuth Corp. (United States); Vincent P. Tondiglia, Air Force Research Lab. (United States) and Leidos (United States)

We report on the preparation of stimuli-responsive optical materials based on cholesteric liquid crystals capable of large range tuning of the reflection wavelength as well as control over the reflection bandwidth. The exceptional optical performance of these dynamic filters is enabled by polymer stabilization and the exploitation of a ionic-based, electromechanical mechanism. In this presentation, we will elucidate the fundamental optical properties of this system and contrast it to other approaches. Further, recent structure-property-performance studies relating to the properties of the polymer network will be discusses.

9564-14, Session 4

Optical switching with sign control using a nonlinear layer structure

Pengfei Wu, Nankai Univ. (China)

All-optical functions and high confinement of optical field in structures such as waveguide and photonic crystals are fundamental issues of scientific and practical importance in the fields of photonic technology [1,2]. Nonlinear optical effects like the intensity dependency of the refractive index can be used in designed structures to all-optically control or self-confine the optical field and thus offer exciting perspectives to control the flow of light beams by purely optical means [3-4]. The unique properties of nonlinear optical structures allow us to build small, low cost and fast all-optical functionalized elements such as all-optical switch to replace currently-used complex electro-optical systems for applications in the next generation of all-optical networks.

In this study, we demonstrate an all-optical switching device with a nonlinear waveguide-like structure containing liquid-crystal nonlinear material. We observe that the light field coupling out the device cladding surface has interesting intensity-depended property which furnishes the device with an additional feature that the switching sign is controllable from positive to negative. The results are unique and may be useful for photonic applications in all-optical communication and optical sensing. The negative switching feature is also useful for power limiting applications to protect the optical sensors. In our study, the device is operated at low light intensity and the switching response time of the device is as fast as nanoseconds.

From nonlinear magneto-optics to magnetism in conducting polymers *(Invited Paper)*

André P. Persoons, Katholieke Univ. Leuven (Belgium); Palash Gangopadhyay, College of Optical Sciences, The Univ. of Arizona (United States); Philippe Dubois, Olivier Coulembier, Nicolas Delbosc, Univ. de Mons (Belgium); Thierry Verbiest, Guy Koeckelberghs, Katholieke Univ. Leuven (Belgium)

An overview is given on synthesis of ϖ-conjugated macrocycles based upon regioregular poly(3-hexyl)thiophenes. The latest macrocycles obtained, with about 30 thiophene-units, are fully conjugated with closure of the ring by an ethenyl bridge enabling also the interruption of the conjugation by simple chemical reduction. To understand the magnetic effects observed in these organic macrocycles and cyclic structures the hypothesis is forwarded that persistent currents are present in these macrocycles. Detailed calculations and simulations on the ϖ-electron distribution in macrocycles of these cyclic poly(3-hexyl)thiophenes will be presented and related to possible fluctuating or persistent currents - as previously shown to be present in mesoscopic rings of (not superconducting) metals.. SQUID measurements on these macrocycles are undertaken to investigate experimentally the presence of fluctuating magnetic moments generated by ring currents in these new molecular structures This could be the cause of giant Faraday rotation observed, as well as the ferromagnetic transition observed in regioregular poly(3-dodecyl)thiophene at cryogenic temperatures. The possible correlation between magnetic properties of macrocycles of ϖ-conjugated thiophene rings and chirality of the macrocyles will be discussed; the wide synthetic possibilites of organics allows to study experimentally these fascinating properties.

Experimental results on Faraday rotation studies from thin films of various polythiophene macrocycles with high degree of regioregularity, but with achiral and chiral alkyl sidechains will be presented. Possible correlations of the Faraday rotation and the supramolecular organization within these thin films will be discussed.

When appropriate, we will discuss some applications, e.g. various magneto-optic devices, or suggest directions for further research.

9564-16, Session 5

Thermoreversible networks for moldable photo-responsive elastomers *(Invited Paper)*

Julia A. Kornfield, California Institute of Technology (United States); Zuleikha Kurji, Washington State Univ. (United States)

Soft-solids that retain the responsive optical anisotropy of liquid crystals (LC) can be used as mechano-optical, electro-optical and electro-mechanical elements. We use self-assembly of block copolymers to create reversible LC gels and elastomers that flow at elevated temperatures and physically cross link upon cooling. In the melt, they can be spun, coated or molded. Segregation of the end-blocks forms uniform and uniformly spaced crosslinks. Matched sets of block copolymers are synthesized from a single “prepolymer.” Specifically, we begin with polymers having polystyrene (PS) end blocks and a poly(1,2-butadiene) midblock. The pendant vinyl groups along the backbone of the midblock are used to graft mesogens, converting it to a side-group LC polymer (SGLCP). In the present case, cyanobiphenyl groups are used as the nonphotoresponsive mesogens and azobenzene groups are used as photoresponsive mesogens. Here we show that matched pairs of block copolymers, with and without photo-responsive mesogens, provide model systems in which the optical density can be adjusted while holding other properties fixed (cross-link density, modulus, birefringence, isotropic-nematic transition temperature). For example, a triblock in which the SGLCP block has 95% cyanobiphenyl and 5% azo side groups is miscible with one having 100% cyanobiphenyl side groups. Simply blending the two gives a series of LC elastomers that have from 0 to 5% azo, while having all other physical properties matched. Results will be presented that show the outcomesof this approach to systematic and largely independent control of optical density and photo-mechanical sensitivity.

9564-17, Session 5

Model photo-responsive elastomers based on the self-assembly of side group liquid crystal triblock copolymers

Zuleikha Kurji, Washington State Univ. (United States) and California Institute of Technology (United States); Julia A. Kornfield, California Institute of Technology (United

States); Mark G. Kuzyk, Washington State Univ. (United States)

We report the synthesis of azobenzene-containing coil-liquid crystal-coil triblock copolymers that form uniform and highly reproducible elastomers by self-assembly. To serve as actuators to (non-invasively) steer a fiber optic, for example in deep brain stimulation, the polymers are designed to become monodomain "single liquid crystal" elastomers during the fiber-draw process and to have a large stress/strain response to stimulation with either light or heat. A fundamental scientific question that we seek to answer is how the interplay between the concentration of photoresponsive mesogens and the proximity to the nematic-isotropic transition governs the sensitivity of the material to stimuli. Specifically, a matched pair of polymers, one with ~5% azobenzene-containing side groups (~95% cyanobiphenyl side groups) and the other with 100% cyanobiphenyl side groups were synthesized from identical triblock pre-polymers (with polystyerene end blocks and 1,2-polybutadiene midblocks). These can be blended in various ratios to prepare a series of elastomers that are precisely matched in terms of the backbone length between physical crosslinks (because each polymer is derived from the same pre-polymer), while differing in % azobenzene side groups, allowing the effect of concentration of photoresponsive groups to be unambiguously determined.

9564-18, Session 5

On photomigration in azo-polymers

Zouheir Sekkat, Moroccan Foundation for Advanced Science, Innovation and Research (Morocco)

Photoisomerizable polymers, namely azo-polymers, have attracted much attention because of their tremendous importance in a large spectrum of adjacent research fields, including photochemistry, polymer science and engineering, chemical engineering, optics and nonlinear optics, and so on, Photo-induced patterns of surface deformations in azobenzene containing polymer films have attracted much attention because of possible applications in optical data storage and in nano-fabrication; and it is well known that such patterns reflect the state of the incident light polarization and the light intensity distribution. The photoinduced patterns are due to light induced mass movement of the polymer chains which, in turn, is triggered by the photoisomerization of the azo-chromophores. The polymer moves from high to low intensity regions in the direction of light polarization, and the trans-cis photoselective isomerization plays an important roles in the deformation process. There are studies to theoretically describe photoisomerization induced mass movement in polymers, and till now there is no theoretical model that fully describes the phenomenon, taking into account the combined aspects of photochemistry and photoselection and polymer science and molecular mobility. This is what will be discussed in this presentation.

9564-19, Session 5

Study on visible-light-curable polycarprolactone and poly(ethylene glycol) diacrylate for LCD-projected maskless additive manufacturing system

Yih-Lin Cheng, Hao-Lun Kao, National Taiwan Univ. of Science and Technology (Taiwan)

Photopolymers have been applied in many Additive Manufacturing (AM) systems and mostly are cured by UV light. Biodegradable photo-curable polymers are very limited and are not commercially available. DLP-projected maskless AM systems become more and more popular nowadays, but its working area is limited if the part resolution is required. For larger working envelope purpose, liquid crystal display (LCD) panel has great potentials, and LCD's resolution has been improved significantly in the past few years due to the smart phone application. Therefore, in this research, LCD panel is used to replace DLP for a maskless AM system to cure biodegradable materials, Polycarprolactone (PCL) and Poly(ethylene glycol) diacrylate (PEG-DA). Due to the characteristics of LCD panel, the material systems should be sensitive and photo-polymerized in visible-light range, particularly in RGB. In this study, various percentages of visible-light photoinitiator, Irgacure 784, in the material systems were investigated. Differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA) were utilized to characterize cured biomaterials. Because of the use of photoinitiator, the biocompatibility of the cured materials was also concerned, and hence, MTT assay tests were performed. The preliminary tests of fabrication, using the LCD-projected maskless AM system, cured grid patterns to illustrate the feasibility. The visible-light-curable PCL and PEG-DA will be able to be adopted in tissue engineering scaffold applications in the future.

9564-20, Session 5

Light manipulating vector polyphotochromatic behavior in organic polarization-sensitive materials

Irakli Chaganava, Barbara N. Kilosanidze, George Kakauridze, Institute of Cybernetics (Georgia) and Georgian Technical Univ. (Georgia)

The phenomenon of vector polyphotochromism within a wide spectral range is revealed in organic polarization-sensitive materials when material is illuminated with linearly polarized actinic light. The effect has a purely vector nature, while the transmission spectrum of the exposed material essentially changes in case of observing between crossed polarizers and the change in the spectrum unambiguously depends on the energy exposure. A significant dependence of the kinetic of the vector polyphotochromism induction on the power density of linearly polarized actinic light (445 nm) is shown for probing beam of 635 nm. It is also shown that the kinetics of the effect depends on the degree of integration of the component molecules of the material by the cohesion of both ways the electrostatic forces (by use mineral electrolytes and polyelectrolytes) and the covalent bonds (azopolymers based on different chromophores), as well as on the photosensitive layer thickness and the concentration of the chromophore. The mechanism of the phenomenon is discussed. Considering the fact that the change in the spectral characteristics occurs throughout the full visible range, this effect may be used for creating the spectrally selective dynamic polarization holographic gratings, displays based on new physical principles, and also for creating modulators and dynamic polarization spectral filters controlled by light.

9564-21, Session 6

Visible light responsive systems based on metastable-state photoacids *(Invited Paper)*

Yi Liao, Florida Institute of Technology (United States)

Proton transfer is one of the most fundamental processes in nature. Metastable-state photoacids can reversibly generate a large proton concentration under visible light with moderate intensity. which provides a general approach to control various proton transfer processes. The potential of metastable-state photoacids in controlling polymer interactions and properties, supramolecular assemblies, acid catalyzed reactions, and microbial fuel cell have been demonstrated by different groups recently. They have also been used to develop anti-bacterial materials, odorant release materials, cationic sensors and molecular switches. In this talk, the mechanism, structure design, and applications of metastable-state photoacids are introduced. Recent development of different types of metastable-state photoacids is presented. Challenges and future work are also discussed.

9564-22, Session 6

Characterization of photomechanical elastomers for device applications

Elizabeth A. Bernhardt, Joseph T. Lanska, Nathan F. Rasmussen, Chad M. Garrison, Mark G. Kuzyk, Washington State Univ. (United States); Mykhailo Y. Pevnyi, Fred Minkowski, Peter Palffy-Muhoray, Kent State Univ. (United States); Zuleikha Kurji, California Institute of Technology (United States) and Washington State Univ. (United States); Julia A. Kornfield, California Institute of Technology (United States)

Characterizing the photomechanical properties of novel materials and developing a theoretical model for their response functions is a crucial prerequisite for designing devices for medical applications. We present a rigorous determination of several properties of photomechanical elastomers to be used to control placement of a brain stimulation device.

High intensity laser stimulation induces stress in dye-doped photomechanical elastomers, causing a length change. Using principles of nonlinear optics and continuum mechanics, we develop a theoretical model quantifying how these elastomers react to laser stimulation. The model evaluates the quality of the response using a photomechanical coefficient, such that a larger coefficient means a larger stress, and hence a more highly photoresponsive material. We are able to determine the photoresponsiveness as a function of pre-strain, laser intensity, strain history, and other properties. Furthermore, we test our model with various types of elastomers, as well as different dyes and doping agents.

Utilizing commonly available components, we designed and implemented a methodology for characterizing the photomechanical properties of light-activated materials. We discuss the technical specs of our apparatus as well as its design.

We thank the National Science Foundation (EFRI-??ODISSEI:1332271) for supporting this work.

9564-23, Session 6

Fabrication and modeling of fiber Bragg grating device networks in photomechanical polymer optical fibers

Joseph T. Lanska, Mark G. Kuzyk, Washington State Univ. (United States); Dennis M. Sullivan, Univ. of Idaho (United States)

Glass fiber Bragg gratings (FBGs) have found widespread use in telecommunications and optoelectronics; however, polymer fibers have lower Young's moduli (allowing for easier stretching and wavelength tuning), larger nonlinear optical susceptibilities, and larger photomechanical effects. We report on the fabrication of FBG networks in poly(methyl methacrylate) (PMMA) polymer fibers doped with azo dyes. Our target is the development of Photomechanical Optical Devices (PODs), comprised of two FBGs in series, separated by a Fabry-Perot cavity of photomechanical material. PODs exhibit photomechanical multi-stability, with the capacity to access multiple length states for the same optical input when a mechanical shock is applied.

Using finite-difference time-domain (FDTD) numerical methods, we modeled the photomechanical response of coupled networks of Bragg gratings in a single polymer optical fiber. Our model incorporates material response time, nonlinear susceptibility, intensity-dependent mechanical strain, and coherence length. Our model correctly predicts the essential optical features of FBGs, including narrow reflectance at the Bragg wavelength, as well as the photomechanical multi-stability of nonlinear Fabry-Perot cavity-based PODs. In addition, a POD can act as memory, and its response can depend on input history.

Networks of PODs may provide a framework for smart shape-shifting materials and very fast optical computation where the decision process is distributed over the entire network. Our models inform and will accelerate targeted development of novel Bragg grating-based polymer fiber device networks for a variety of applications in optical computing and smart materials.

9564-24, Session 6

Adaptable and dynamic soft colloidal photonics

Alexander J. C. Kuehne, Dennis Go, DWI an der RWTH Aachen e.V. (Germany)

Existent photonic systems are highly integrated with the active component being completely isolated from the environment as a result of their complex format. There are almost no example for periodic photonic materials, which can interact with their environment by being sensitive to external stimuli while providing the corresponding photonic response. Due to this lack of interaction with the outside world, smart optical components, which are self-healing or adaptable, are almost impossible to achieve.

I am going to present an aqueous colloidal system, consisting of core-shell particles with a solid core and a soft shell, bearing both negatively and positively charged groups. The described soft colloids exhibit like charges over a broad range of pH, where they repel each other resulting in a pefect and defect-free photonic crystal. In the absence of a net charge the colloids acquire the arrangement of an amorphous photonic glass.

We showcase the applicability of our colloidal system for photonic applications by temporal programming of the photonic system and dynamic switching between ordered and amorphous particle arrangements. We can decrease the pH slowly allowing the particles to transit from negative through neutral to positive, and have them arrange accordingly from crystalline to amorphous and back to crystalline. Thus, we achieve a pre-programmable and autonomous dynamic modulation of the crystallinity of the colloidal arrays and their photonic response.

9564-25, Session 7

Advances in photorefractive polymers and applications *(Invited Paper)*

Pierre-Alexandre J. Blanche, Brittany Lynn, Robert A. Norwood, Nasser N. Peyghambarian, College of Optical Sciences, The Univ. of Arizona (United States)

Photorefractive (PR) polymers change their index of refraction upon illumination through a series of electronic phenomena that makes these materials one of the most complex organic systems known. The refractive index change is dynamic and fully reversible, making PR materials very interesting for a large variety of applications.

In this talk I will introduce the PR effect in polymers and the different mechanisms that ultimately lead to the index modulation. I will present some of the most recent developments in molecular dopants such as sensitizer molecules. Their function is to absorb the photons and convert them into mobile charges. The mechanism involves the creation of an exciton, the charge must then go over the coulomb barrier and ultimately transfer to the photoconducting polymer. This indicates that HOMO/LUMO energy levels of these molecules should match each other and recombination rates should be as low as possible. In the past, variation of C60 molecules such as PCBM have been used, but most recently advances in functionalized reduced graphene oxide and perylene imide molecules have shown promising development.

At the other end of the PR effect is the chromophore alignment that leads to the index modulation. We used a multiphoton microscope to directly observe the chromophore orientation in the non-homogenous electric field created by coplanar electrodes. This type of electrode geometry, introduced

recently by our group, does not require the sample to be tilted with respect to the writing beams to record the hologram. This is a significant advantage for some applications such as the holographic 3D display we developed.

Electrostatic modification of ITO/ ZnSe interface in polymer-nematogen composite and its impact on photorefractive hologram

Jingwen Zhang, Jiayin Fu, Hua Zhao, Harbin Institute of Technology (China)

To meet imminent needs in real time holographic updatable display fast response photorefractive (PR) polymeric composites were designed and studied in the past years [1,2]. In further studying selected PR films made of polymer-nematogen composite: poly (N-vinylcarbazole + pentyl-cyanobiphenyl + fullerene (C60), with excellent photoconducting ZnSe thin films as interlayers, we observed 2D diffraction patterns emerging from the polymeric film when only two incident laser beams of small cross angle were used, without any additional feedback employed in the systems discussed in [3]. It was found that there were distinctly a bulk grating and a surface grating formed in the film, and that the latter was behind the 2D diffraction pattern observed and the accompanying energy transferring direction switching, both beyond the reach of conventional PR picture. The origin of the findings seems rooted in the electrostatic modification of the interface due to electric field applied on the polymeric film [4]. Surface plasmon polaritions (SPPs) were evidently excited near the interface due to blueshift of the plasma frequency of ZnSe via electrostatic modification and this proposed picture elucidates all the findings. The interface electrostatic modification and the SPP involvement deserve further investigation in similar PR systems.

Photopolymerizable polymer nanocomposites incorporated with hyperbranched polymer having ultrahigh index of refraction for holographic light manipulation

Yasuo Tomita, Hiroshi Urano, Taka-aki Fukamizu, Yasuhiro Kametani, The Univ. of Electro-Communications (Japan); Naoya Nishimura, Keisuke Odoi, Nissan Chemical Industries, Ltd. (Japan)

Holographic dry photopolymers have received much attention owing to their light-manipulating capability in diffractive optics, optical data storage and optical communications. But simultaneously satisfying requirements for large refractive index modulation and dimensional stability are difficult to achieve in conventional photopolymers owing to their limited refractive-index range and inherent polymerization shrinkage. In this work we report on the diffraction properties of volume gratings recorded in a new type of photopolymerizable polymer nanocomposites that incorporate hyperbranched polymer (HBP) acting as transporting organic nanoparticles. The HBP was prepared by the polycondensation of a diamine monomer with 2, 4, 6-trichloro-1, 3, 5-triazine in N, N-dimethylacetamide, followed by the end-capping reaction with aniline. The synthesized HBP exhibits ultrahigh index of refraction (> 1.8) since it possesses triazine and aromatic ring units. Its average size and heterogeneity are approximately 10 nm and 4.4, respectively. In order to obtain high dispersion of HBP in monomer, we mixed HBPs with solvents used for a plasticizer. This syrup was further mixed with a photoinitiator titanocene and multi-functional acrylate monomer to prepare photopolymerizable polymer nanocomposite films for holographic measurements. We used a two-beam interference setup to write an unslanted transmission volume grating at grating spacing of 1 ?m and at a wavelength of 532 nm. We show that a volume grating with the refractive index change as large as 0.02 can be recorded at the HBP concentration of 25 vol.%. The out-of-plane thickness change due to polymerization shrinkage, measured by a holographic method, can also be reduced below 2 % at the HBP concentration of 25 vol.%.

9564-28, Session 7

Photorefractive amplification of moving light signals by photoconductive ferroelectric liquid crystal blends

Takeo Sasaki, Masanori Yoshino, Tokyo Univ. of Science (Japan)

Dynamic amplification of optical signal was demonstrated using a photorefractive ferroelectric liquid crystal blend. Ter-thiophene compounds with chiral structures were chosen as the photoconductive chiral compounds, and they were mixed with an achiral smectic C liquid crystal. The mixtures exhibit the ferroelectric chiral smectic C phase. The photorefractivity of the mixtures was investigated by two-beam coupling experiments. It was found that the ferroelectric liquid crystals containing the photoconductive chiral compound exhibit a large gain coefficient of over 1200 cm-1 and a fast response time of 1 ms. Real-time dynamic amplification of an optical image signal of over 30 fps using the photorefractive ferroelectric liquid crystal was demonstrated.

9565-1, Session 1

Electrically tunable selective reflection of light by heliconical cholesteric structures *(Keynote Presentation)*

Oleg D. Lavrentovich, Jie Xiang, Sergij V. Shiyanovskii, Quan Li, Kent State Univ. (United States)

Cholesteric liquid crystals with helicoidal molecular architecture are known for their ability to selectively reflect light with the wavelength that is determined by the periodicity of molecular orientations. Resulting interference colors are highly saturated, they add like colored lights and produce a color gamut greater than that obtained with inks, dyes, and pigments. The periodicity of the helical structure and thus the wavelength of the reflected light can be controlled by chemical composition and sometimes by temperature, but tuning with the electric field has been so far elusive. Here we demonstrate that by using a cholesteric with oblique helicoidal (heliconical) structure, as opposed to the classic "right-angle" helicoid, one can vary the wavelength of selectively reflected light in a broad spectral range, by simply adjusting the electric field applied parallel to the helicoidal axis. The effect can enable many applications that require dynamically controlled transmission and reflection of light, from energy-saving smart windows to tunable organic lasers, and transparent "see-through" displays. Since the material is non-absorbing and transparent everywhere except the electrically preselected reflection band, the effect can be used in creating multilayered structures with a dynamic additive mixture of colors.

9565-2, Session 1

Light-driven motion of micro-particles by means of photoisomerization of azobenzene groups as molecular motor on a liquid crystalline film *(Invited Paper)*

Seiji Kurihara, Yutaka Kuwahara, Sunnam Kim, Tomonari Ogata, Kumamoto Univ. (Japan)

Light-driven micro-particles (MPs) were prepared by modification of photo-responsive azobenzene(Azo) groups as molecular motors. In a nematic liquid crystal, 5CB, we have achieved remote control of the Azo-modified MPs (Azo/MPs), which constructed with glass spheres (GSs) or rod-like glass particles (GRs) as MPs, by light stimuli. As results of photo-induced isomerization from UV-visible extinction spectroscopy and from phase evaluation under microscope observation, the motion behavior suggest to be correlated with the generation of micro-sized isotropic phase (I-phase) regions, which could be caused by disorganization of the 5CB molecules in the nematic phase (N-phase) due to photo-induced continuous isomerization of Azo groups.

9565-3, Session 1

Liquid crystal based adaptive holography for optical sensing applications *(Invited Paper)*

Arnaud Peigné, Thales Underwater Systems (France); Umberto Bortolozzo, INLN, Univ. de Nice Sophia Antipolis, CNRS (France); Stéphanie Molin, Daniel Dolfi, Thales Research & Technology (France); Jean-Pierre Huignard, Jphopto (France); Stefania Residori, INLN, Univ. de Nice Sophia Antipolis, CNRS (France)

Self-adaptive holography allows measuring small optical phase modulations even in noisy environments and with strongly distorted optical wavefronts. We report examples of adaptive holographic systems based on liquid crystals, such as optically addressed liquid crystal spatial light modulator [1] and digital holography with an LCOS spatial light modulator [2]. Thanks to a beam-coupling process, a refractive index grating is written in the LC medium by a reference and signal beam. The induced hologram follows dynamically the low frequency variations undergone by the signal beam, with the frequency bandwidth B of the adaptive adjustment related to the response time of the medium. Indeed, at low frequency (< B) the phase information stored in the hologram is cancelled by the self-diffraction because of the automatic compensation of the phase conjugate components [3]. Thanks to this property, low frequency (< B) noise is rejected while high frequency (>B) phase modulations are transmitted to the diffracted orders and can be directly measured as intensity variations at the output of the hologram.

9565-4, Session 1

Photodeformation of azobenzene containing liquid crystalline polymer networks *(Invited Paper)*

Vladimir P. Toshchevikov, Leibniz-Institut für Polymerforschung Dresdene e.V. (Germany) and Institute of Macromolecular Compounds (Russian Federation); Tatiana Petrova, Leibniz-Institut für Polymerforschung Dresdene e.V. (Germany) and Cherepovets State Univ. (Russian Federation); Marina Saphiannikova, Leibniz-Institut für Polymerforschung Dresdene e.V. (Germany)

Azobenzene containing polymers due to their ability to deform under light irradiation have a fascinating potential for technical applications serving as artificial muscles, sensors, microrobots, actuators, etc. Further development of these materials is determined by the understanding of the mechanism of the light-induced deformation. Recently we have shown that reorientation of chromophores perpendicular to the polarization direction of the light E (caused by multiple trans-cis-trans photoisomerization) induces the mechanical stress which is large enough to deform azobenzene polymers [1, 2].

The present theoretical study is devoted to the light-induced deformation of two-component polymer networks containing azobenzene chromophores and liquid crystalline (LC) mesogens. We show that reorientation of chromophores under light irradiation leads to the reorientation of the mesogens due to LC interactions between the components and results in the light-induced deformation of the polymer network. The sign of deformation (expansion / contraction with respect to the vector E) depends on the orientation distribution of the mesogens and chromophores inside the network strands. The magnitude of deformation increases with increase of the volume fraction of chromophores and the strength of LC interactions between the components. Influence of the bent cis-isomers of the azobenzene on the light-induced deformation is discussed.

9565-5, Session 1

Studies of the underlying mechanisms for optical nonlinearities of blue phase liquid crystals

Chun-Wei Chen, National Sun Yat-Sen Univ. (Taiwan); Iam Choon Khoo, Shuo Zhao, The Pennsylvania State Univ. (United States); Tsung-Hsien Lin, National Sun Yat-Sen Univ. (Taiwan); Tsung-Jui Ho, The Pennsylvania State Univ. (United States)

We have investigated the mechanisms responsible for nonlinear optical processes occurring in azobenzene-doped blue phase liquid crystals (BPLC), which exhibit two thermodynamically stable BPs: BPI and BPII. In coherent two wave-mixing experiments, a slow (minutes) and a fast (few milliseconds) side diffractions are observed. The underlying mechanisms were disclosed by monitoring the dynamics of grating formation and relaxation as well as by some supplementary experiments. We found the photothermal indexing and dye/LC intermolecular torque leading to lattice distortion to be the dominant mechanisms for the observed nonlinear response in BPLC. Moreover, the response time of the nonlinear optical process varied with operating phase. The rise time of the thermal indexing process was in good agreement with our findings on the temperature dependence of BP refractive index: ?(ISO) > ?(BPI) > ?(BPII). The relaxation time of the torque-induced lattice distortion was analogue to its electrostriction counterpart: ?'(BPI) > ?'(BPII). In a separate experiment, lattice swelling with selective reflection of <110> direction changed from green to red was also observed. This was attributable to the isomerization-induced change in cholesteric pitch, which directly affects the lattice spacing. The phenomenon was confirmed by measuring the optical rotatory power of the BPLC.

9565-6, Session 1

Recent results on the heliconical nematic phase

Eva D. Korblova, Alyssa Scarbrough, Mark Moran, Lee Foley, Michael Tuchband, Min Shuai, Renfan Shao, Joseph E. Maclennan, Matthew A. Glaser, Noel A. Clark, David M. Walba, Univ. of Colorado at Boulder (United States)

In 2012 the basic argument for the existence of a new nematic phase exhibiting spontaneous reflection symmetry breaking, the Heliconical Nematic (HN, also known as the Twist-Bend Nematic, or NTB phase) began to get traction, and in 2013 the very tight helical pitch of the prototype HN phase was directly observed by freeze-fracture TEM by the Boulder LC group. Since then, work on this extremely novel phase has accelerated. Organic design and synthesis, including new structured exhibiting the HN phase, theoretical simulations, optical microscopy, and electron and probe microscopy experiments aimed at developing a fundamental understanding of the microscopic origins of the HN phase and emergent mesoscopic properties, will be described.

9565-7, Session 2

Tailoring complex optical fields via anisotropic microstructures *(Keynote Presentation)*

Yan-Qing Lu, Wei Hu, Guo-Xin Cui, Nanjing Univ. (China)

In recent years, complex optical fields with spatially inhomogeneous phases, polarizations and optical singularities have drawn many research interests. Many novel effects have been predicted and demonstrated for light beams with these unconventional states in both linear and nonlinear optics regimes. Although local optical phase could be controlled directly or through hologram structures in isotropic materials such as glasses, optical anisotropy is still required for manipulating polarization states and wavelengths. The anisotropy could be either intrinsic such as in crystals/liquid crystals (LCs) or the induced birefringence from dielectric or metallic structures. In this talk, we will briefly review some of our attempts in tailoring complex optical fields via anisotropic microstructures. We developed a micro-photo-patterning system that could generate complex micro-images then further guides the arbitrary local LC directors. Due to the electro-optically (EO) tunable anisotropy of LC, various reconfigurable complex optical fields such as optical vortices (OVs), multiplexed OVs, OV array, Airy beams and vector beams are obtained. Different LC modes such as homogeneous alignment nematic, hybrid alignment nematic and even blue phase LCs are adopted to optimize the static and dynamic beam characteristics depending on application circumstances. We are also trying to extend our approaches to new wavelength bands, such as mid-infrared and even THz ranges. Some preliminary results are obtained. In addition, based on our recently developed local poling techniques for ferroelectric crystals, we will also discuss and demonstrate the nonlinear complex optical field conversion in Lithium Niobate wafers with patterned ferroelectric domain structures.

9565-8, Session 2

Electrical induction and optical erasure of birefringence in the isotropic liquid phase of a dichiral azobenzene liquid-crystalline compound *(Invited Paper)*

Takahiro Yamamoto, National Institute of Advanced Industrial Science and Technology (Japan); Isa Nishiyama, DIC Corp. (Japan)

Liquid crystal is a representative soft matter, which has physical properties between those of conventional liquid and those of crystal in a temperature range above a melting point. A liquid-crystal display (LCD) employs the response of the liquid-crystal alignment to the electric field and is a key device of an information display. For common LCDs, the precise control of the initial alignment of LC molecules is needed so that a good dark state, thus a high contrast ratio, can be obtained. If the birefringence can be induced in the liquid phase by the application of electric field, it is of great use as a material for the LCD application. In this study, we will report a unique property of dichiral azobenzene liquid crystals: an electric induction of birefringence in a liquid phase of an antiferroelectric dichiral azobenzene liquid crystal. The optically isotropic texture changes into the homogenous birefringent texture by the application of the in-plane electric field above the clearing temperature of the liquid crystal. We find that one of the possible reasons of the induction of the birefringence in the isotropic phase is the electrically-induced increase of the phase transition temperature between the antiferroelectric liquid-crystalline and "liquid" phases, i.e., increase in the clearing temperature. The resulting birefringence can be disappeared by the irradiation of UV light, due to the photoinduced isomerization of the azobenzene compound, thus dual control of the birefringent structure, by the irradiation of light and/or by the application of the electric field, is achieved.

9565-9, Session 2

Low voltage driving and ultra-fast switching of SmC* on the slippery interfaces

Jun Yamamoto, Kyoto Univ. (Japan); Isa Nishiyama, DIC Corp. (Japan)

Homeotropic SmC* phase shows the fast electro-optic response against the in-plane electric field, because the molecular tilt direction (C-director) is rotated due to coupling between the spontaneous polarization and the electric field. Perfect orientation and smooth ultra-fast switching (10-100 micro sec) can be achieved. But it is problem for the flat panel application that the driving voltage of the switching is extremely high (>100V/10

micro meter) compare to the conventional nematic and the surface stabilized homogeneous SmC*. In this paper, we demonstrated that the drastic reduction of the driving voltage (<1 order ~10V/10micro meter) by introducing the slippery interface of the liquid walls under interdigitated in-plane electrodes keeping the nature of the ultra-fast switching dynamics. Slippery interfaces are artificially designed and spontaneously realized by the macroscopic phase separation due to the solvent effects on the liquid crystals. Smooth motion of the C-director is originated by the lubrication of the molecular motion on the slippery liquid interfaces. We have identified the clear change of the mechanism of the electro-optic response of SmC* related to helix motion by analyzing the motion of the Cano's wedge by polarizing microscope. We discussed about the switching dynamics of SmC* on the slippery interfaces both intra and inter helix unwinding/rewinding motions.

9565-10, Session 2

Shape programming with light: Voxelated liquid crystal elastomers *(Invited Paper)*

Timothy J. White, Air Force Research Lab. (United States); Taylor H. Ware, Air Force Research Lab. (United States) and Azimuth Corp. (United States); Michael E. McConney, Air Force Research Lab. (United States); Jeong Jae Wie, Air Force Research Lab. (United States) and Azimuth Corp. (United States); Vincent P. Tondiglia, Air Force Research Lab. (United States) and Leidos (United States)

Shape can be a functional property of devices. Shape is derived topology and is designed as evident in the planar fold lines of a cardboard box or the mechanical anisotropy of certain natural structures. Here, we report on the use of light to pattern the alignment of liquid crystal elastomers. We report on the development of a facile chemistry platform that is for the first time conducive to photoalignment. Derived from the inherent spatio-temporal control afforded to light, we report on the preparation of topologically blueprinted liquid crystal elastomers that show exceptional properties as actuators and self-folding (deploying) structures.

9565-11, Session 3

Manipulating lipid membrane architecture by liquid crystal-analog curvature elasticity *(Keynote Presentation)*

Sin-Doo Lee, Seoul National Univ. (Korea, Republic of)

Soft matters such as liquid crystals and biological molecules exhibit a variety of interesting physical phenomena as well as new applications. Recently, in mimicking biological systems that have the ability to sense, regulate, grow, react, and regenerate in a highly responsive and self-adaptive manner, the significance of the liquid crystal order in living organisms, for example, a biological membrane possessing the lamellar order, is widely recognized from the viewpoints of physics and chemistry of interfaces and membrane biophysics. Lipid bilayers, resembling cell membranes, provide primary functions for the transport of biological components of ions and molecules in various cellular activities, including vesicle budding and membrane fusion, through lateral organization of the membrane components such as proteins. In this lecture, I will describe how the liquid crystal-analog curvature elasticity of a lipid bilayer plays a critical role in developing a new platform for understanding diverse biological functions at a cellular level. The key concept is to manipulate the local curvature at an interface between a solid substrate and a model membrane. Two representative examples will be demonstrated: one of them is the topographic control of lipid rafts in a combinatorial array where the ligand-receptor binding event occurs and the other concerns the reconstitution of a ring-type lipid raft in bud-mimicking architecture within the framework of the curvature elasticity.

9565-12, Session 3

Liquid crystals under the spotlight: Light based measurements of electrical and flow properties of liquid crystals *(Invited Paper)*

Giampaolo D'Alessandro, Thomas P. Bennett, Matthew B. Proctor, Malgosia Kaczmarek, Univ. of Southampton (United Kingdom)

Many liquid crystal devices consist of a thin layer of liquid crystal sandwiched between two transparent plates, normally coated with metal and polymer layers. The first allows the application of an electric field. The second not only gives a preferred orientation to the liquid crystal, but can also play an active role in the cell dynamics. In a photorefractive cell, for example, a photoconducting layer modulates the electric field as a function of the light intensity, thus making them ideal component of optical light modulators.

The performance of such devices depends strongly on the mechanical, electrical and flow properties of their liquid crystal constituents, but also on those of the polymer layers. It is therefore essential for the development of new devices, to be able to characterize as many liquid crystal and polymer parameters as possible in the simplest way. In this paper we generalize a standard cross-polarized intensity experiment to measure cell thickness, pretilt, anchoring energy, elastic constants, rotational viscosity and some of the Leslie viscosities, and also the relative dielectric permittivity and resistivity of the liquid crystal and polymer layers as a function of voltage and light intensity. We are able to do this by using the amplitude and frequency of the applied AC voltage and the intensity and wavelength of the incident light as control parameters. The advantage of using light for all these combined measurements is that we can also create a map of the cell surface and identify areas of anomalous pretilt and anchoring energy.

9565-13, Session 3

Nematic and blue phase liquid crystals for temperature stabilization and active optical tuning of silicon photonic devices *(Invited Paper)*

Joanna N. Ptasinski, Space and Naval Warfare Systems Ctr. Pacific (United States); Iam Choon Khoo, The Pennsylvania State Univ. (United States); Yeshaiahu Fainman, Univ. of California, San Diego (United States)

We describe the underlying theories and experimental demonstrations of passive temperature stabilization of silicon photonic devices clad in nematic liquid crystal mixtures, and active optical tuning of silicon photonic resonant structures combined with dye-doped nematic and blue phase liquid crystals. We show how modifications to the resonator device geometry allow for not only enhanced tuning of the resonator response, but also aid in achieving complete athermal operations of silicon photonic circuits. [Ref.: I.C. Khoo, "DC-field-assisted grating formation and nonlinear diffractions in methyl-red dye-doped blue phase liquid crystals," Opt. Lett. 40, 60-63 (2015); J. Ptasinski, I.C. Khoo, and Y. Fainman, "Enhanced optical tuning of modified-geometry resonators clad in blue phase liquid crystals," Opt. Lett. 39, 5435-5438 (2014); J. Ptasinski, I.C. Khoo, and Y. 9565-14, Session 3

Photoalignment control for photonic and mechanical applications *(Invited Paper)*

Atsushi Shishido, Tokyo Institute of Technology (Japan)

Light-control over molecular alignment has attracted particular interest,

for potential applications such as photonic elements and photomechanical energy conversion. We introduce our recent progress on photoalignment control for optical switching and photomechanics. Dye-doped polymer-stabilized liquid crystals decreased the threshold intensity to cause photoinduced molecular reorientation.

9565-15, Session 3

Enhanced electro-optical properties of liquid crystal microlens: Low driving voltage and large dynamic operating range

Yun-Tzu Lin, National Taipei Univ. of Technology (Taiwan); Guan-Jhong Lin, National Taiwan Univ. (Taiwan); Yen-Hsing Lin, Tien-Jung Chen, National Taipei Univ. of Technology (Taiwan); Ying-Jay Yang, National Taiwan Univ. (Taiwan); Chung-Ping Chen, Jin-Jei Wu, National Taipei Univ. of Technology (Taiwan)

In this study, liquid crystal microlens with different radii of hole-pattern electrode and cell gap was simulated and discussed in detail. The fringe-field was generated by hole-pattern electrode. The top substrate is a hole-pattern electrode and the bottom is a planar ITO glass. The structure is less affecting factor and easier to discuss. A liquid crystal microlens with large dynamic focal length range at low operating voltage is demonstrated. As the voltage is increased, the phase retardation resulting from the center and edge is decreased and an effective focal length can be obtained. With different radii and cell gap, there is various range of focal length when adjusting the applied voltage. This proposed structure can benefit the electro-optical properties of liquid crystal microlens in the analysis.

9565-16, Session 3

Strengthened nonlinearity in liquid crystal panel with ZnSe aligning layers due to surface charge accumulation

Jingwen Zhang, Tingyu Xue, Hua Zhao, Harbin Institute of Technology (China)

With excellent photoconducting zinc selenide thin films as aligning layers in fabricating liquid crystal (LC) panel with pentyl-cyanobiphenyl doped with fullerene (C60), the response time in writing erasable holograms was shortened further to milliseconds [1-2]. 2D diffraction patterns were observed when two coherent laser beams were overlapped in the LC panel [3], along with intriguing findings. The energy transferring direction and strength between the two beams was found LC layer thickness, incidence face, applied voltage and polarity dependent, so was the exponential gain coefficients by employing hybrid LC panels. The surface dominant grating behind the 2D diffraction patterns was found resulting from electric field induced surface charge accumulation, which pushing the plasma response of ZnSe layer towards visible regime. The dynamics of 2D diffraction patterns and all related findings can be explained well in a proposed picture based on the excitation of surface plasmon polaritons in the interfaces. The elimination of polar aligning layer and phase grating mediation SPP excitation make this LC system promising in designing photonics devices [4].

Hysteresis on a liquid crystal and polymer composite film *(Invited Paper)*

Yi-Hsin Lin, Ming-Syuan Chen, National Chiao Tung Univ. (Taiwan); Chun-Yu Hsu, National Tsing Hua Univ. (Taiwan); Jing-Yi Wang, National Chiao Tung Univ. (Taiwan)

We have been developed and studied a liquid crystal and polymer composite film (LCPCF) whose surface properties are electrically switchable resulting from orientations of liquid crystal molecules. Many applications are also developed, such as displays, ophthalmic lenses, sperm testers, and biosensing devices of high-density lipoprotein (HDL) in human serum. In experiments, the hysteresis of LCPCF, defined as the difference between the advancing angle and the receding angle, changes with the applied electric fields which also affects the motion of droplet on LCPCF. In this paper, we investigate how LC orientation and surface morphologies affect the hysteresis of the LCPCF and then affect the motion of the droplet. The droplet on LCPCF has to overcome the hysteresis of LCPCF to move which depends on an oscillation between two sides of the contact angles of a droplet on LCPCF. When the hysteresis of the LCPCF under applied electric fields is low enough, the droplet moves without oscillation. When interfacial interaction between fluid and LC molecules is considered, the hysteresis of LCPCF changes because the LC molecules are realigned by such an interaction which turns out different droplet movement. This study can help us to understand why the droplet can move easily on LCPCF even though the surface free energy of LCPCF does not change dramatically with the applied electric fields.

9565-18, Session 4

Structural dynamics in azobenzene liquid crystal polymer films studied by microscopic and time-resolved techniques *(Invited Paper)*

Kenji Katayama, Shota Kuwahara, Tomiki Ikeda, Chuo Univ. (Japan)

In the last 20 years, various liquid crystalline (LC) polymer materials including photoresposive molecules have been developed, which have varieties of functions. They are subject to deformation, shape change, even motion, and have been applied for rewritable holograms and grating formation. In such materials, azobenzene included cross-linked liquid crystalline polymers have shown promising results, such as macroscopic bending or motion, and these films can be bent by a UV light and be returned back by a visible light. In this moiety, azobenzene connected to the mesogen is subject to photo-isomerization, causing the polymer chain contraction to induce the macroscopic transformation.

Here, we studied the photo-induced structural dynamics in a LC polymer film including azobenzene by using a time-resolved and a microscopic technique. The film was confined in a liquid crystal cell, while it is a photomobile film under a free standing condition, which is triggered by the photoisomerization of azobenezene. From the result of the time-resolved measurements, the change inside the film induced by UV irradiation was highly anisotropic polarization change, and the induced change was largest when the temperature was optimized for bending. Microscopic observation revealed that the film was consisted of ordered and disordered region with a patched structure, and the UV induced change was travelled in the ordered region on the order of seconds.

9565-19, Session 4

Thermoelectricity in liquid crystals *(Invited Paper)*

Suhana B. Mohd Said, Norbani Abdullah, Abdul Rahman

Nordin, Univ. of Malaya (Malaysia)

The thermoelectric effect, also known as the Seebeck effect, describes the conversion of a temperature gradient into electricity. A Figure of Merit (ZT) is used to describe the thermoelectric ability of a material. It is directly dependent on its Seebeck coefficient and electrical conductivity, and inversely dependent on its thermal conductivity [1]. There is usually a compromise beteween these parameters, which limit the performance of thermoelectric materials. The current achievement for ZT~2.2 falls short of the expected threshold of ZT=3 to allow its viability in commercial applications.

In recent times, advances in organic thermoelectrics been significant, improving by over 3 orders of magnitude over a period of about 10 years. Liquid crystals are newly investigated as candidate thermoelectric materials, given their low thermal conductivity, inherent ordering, and in some cases, reasonable electrical conductivity. In this work the thermoelectric behaviour of a discotic liquid crystal, is discussed. The DLC was filled into cells coated with a charge injector, and an alignment of the columnar axis perpendicular to the substrate was allowed to form. This thermoelectric behavior can be explained in terms of the carrier concentration, carrier mobility and order-disorder transition [3]. A reasonable thermoelectric power in the liquid crystal temperature regime was noted, together with hysteresis effects between the heating and the cooling curves. The following thermoelectric phenomena are unique to liquid crystals: anisotropy, hysteresis effects, and correlation between liquid crystal morphology and thermoelectric behavior, and temperature switching. In summary, thermoelectric liquid crystals may have the potential to be utilised in flexible devices, as a standalone power source.

9565-20, Session 4

A composite lens by integrating a polarization switch of ferroelectric liquid crystals with a passively anisotropic polymeric lens for ultrafast laser system

Chia-Ming Chang, Yu-Jen Wang, Hung-Shan Chen, Yi-Hsin Lin, National Chiao Tung Univ. (Taiwan); Abhishek K. Srivastava, Vladimir G. Chigrinov, Hong Kong Univ. of Science and Technology (China)

We recently have developed a bistable negative lens by integrating a polarization switch of ferroelectric liquid crystals (FLCs) with a passively anisotropic focusing element. The proposed lens not only exhibits electrically tunable bistability but also fast response time of sub-milliseconds which leads to good candidate of optical component in ultra-fast laser system for medical applications. In this paper, we redesign and demonstrate a lens with two bistable lens powers of positive and negative lens based on polarization switch of FLC. The focusing properties and electro-optical performance at wavelength of 1064nm are measured and discussed. The damage threshold of the lens and the depth of focus are measured as well. Instead of conventional lenses with mechanical movement in the medical laser system, the electrically tunable focusing lens with fast response time and high damage threshold exhibits precise adjustment. The electrically bistable lenses are also useful in the applications of portable devices, wearable devices and colored ophthalmic lenses.

9565-21, Session 4

Programable lattices of optical vortices in nematic liquid crystal *(Invited Paper)*

Marcel G. Clerc, Univ. de Chile (Chile); Stefania Residori, Umberto Bortolozzo, Institut Non Linéaire de Nice Sophia Antipolis (France) and Univ. de Nice Sophia Antipolis (France); Raouf Barboza, Estefania Vidal-Henriquez, Univ. de Chile (Chile); Gaetano Assanto, Univ. degli Studi di Roma Tre (Italy)

Using self-induced vortex-like defects in the nematic liquid crystal layer of a light valve with photo-sensible wall, we demonstrate the realization of programable optical vortices lattices with arbitrary configuration in space.

On each lattice site, every matter vortex acts as a photonic spin-to-orbital momentum coupler and an array of circularly polarized input beams is converted into an output array of vortex beams with topological charges consistent with the vortex matter lattice. The vortex arrangements are explained the basis of light-induced matter defects and topological rules.

9565-22, Session 5

Recent advances in IR liquid crystal spatial light modulators *(Keynote Presentation)*

Fenglin Peng, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States); Robert J. Twieg, Kent State Univ. (United States); Shin-Tson Wu, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

Liquid crystal (LC) is an amazing class of electro-optic media; its applications span from visible to infrared, millimeter wave, and terahertz regions. In the visible and short-wavelength infrared (SWIR) regions, most LCs are highly transparent. However, to extend the electro-optic application of LCs into MWIR and LWIR, several key technical challenges have to be overcome: (1) low absorption loss, (2) high birefringence, (3) low operation voltage, and (4) fast response time. In the MWIR and LWIR regions, several fundamental molecular vibration bands and overtones exist, which contribute to high absorption loss. The absorbed light turns to heat and then alters the birefringence locally, which in turns causes spatially non-uniform phase modulation. To suppress the optical loss, several approaches have been investigated: (1) Employing thin cell gap by choosing a high birefringence LC mixture; (2) Shifting the absorption bands outside the spectral region of interest by deuteration, fluorination, or chlorination; (3) Reducing the overtone absorption by using a short alkyl chain. In this paper, we report some recently developed chlorinated LC compounds and mixtures with low absorption loss in the SWIR and MWIR regions. To achieve fast response time, we demonstrated a polymer network liquid crystal with 2-pi phase change at MWIR and response time less than 5 ms.

9565-23, Session 5

Vortex grating diffractive waveplate

Gary F. Walsh, Brian R. Kimball, U.S. Army Natick Soldier Research, Development and Engineering Ctr. (United States); Nelson V. Tabiryan, BEAM Engineering for Advanced Measurements Co. (United States)

Diffractive waveplates (DWP) have recently demonstrated unique optical properties including the creation of high order vortex beams, circular polarization selective diffraction, and complete suppression of zero order diffraction. These devices, which are part of a larger class known as metasurfaces, consist of patterned liquid crystal orientations and have been shown to operate over a broad spectral range. We present DWP gratings that couple incident light perfectly into specific diffraction orders. The continuous non-uniform liquid crystal director patterns for these gratings are constructed from an array of axial waveplate vortex singularities. A mathematical formulation of a grating structure with prefect translation symmetry has been developed. Selection of grating orders is accomplished through design of the vortex topological charge distribution. Switching between diffractive orders can be actuated with a variable phase retarder. We present results from designed arrays showing selective excitation of specific diffraction orders. This device could be used in beam steering and switching applications.

9565-24, Session 5

Imaging in natural light with nematic liquid crystals *(Invited Paper)*

Tigran V. Galstian, Univ. Laval (Canada)

Nametic liquid crystals (NLC) are most commonly used liquid crystal (LC) materials in various light modulators [1], displays [2] and lenses [3]. However those materials have a fundamental limitation: they are polarization sensitive since the refractive index modulation here is achieved by the electric field induced reorientation of their local anisotropy axis. Thus, the standard imaging optical systems (used in consumer electronic products and dealing with natural light sources [4]) have to use double NLC structures in a cross oriented way and in rather requiring geometrical conditions.

We describe a simple but very efficient optical device that allows the dynamic focusing of unpolarized light using a single NLC layer. The operation principle of the proposed device is based on the combination of an electrically variable “single layer lens” with two fixed optical elements for light reflection and 90? polarization flip. Such an approach is made possible thanks to the close integration of thin film wave plate and mirror. Preliminary experimental studies of the obtained electrically variable mirror show very promising results.

Several standard camera geometries, using the double layer approach, and possible new geometries, using the reflective approach, will be described.

Device and material technologies for advanced flexible liquid crystal displays *(Invited Paper)*

Hideo Fujikake, Takahiro Ishinabe, Tohoku Univ. (Japan)

Device and material technologies of our recent researches are discussed for advanced high-quality and large-sized flexible liquid crystal displays. As next-generation displays, flexible displays will create innovative usages and human interfaces due to excellent storability and portability. The features of flexible displays are enhanced as display screen size increases. The flexible liquid crystal displays using plastic substrates instead of glass plates have the great advantages of ease in large-size fabrication, excellent operation reliability and low cost fabrication, in comparison with other flexible displays using organic light emitting diodes formed on plastic substrate. We have researched the molecular-aligned polymer wall spacers, made from a molecular-aligned solution layer of monomer and liquid crystal, for keeping the substrate gap constant and for not disordering liquid crystal alignment. The blue phase liquid crystal layer, which had difficulty in keeping liquid crystal alignment structure, could be stabilized by polymer walls and networks in flexible devices using plastic substrates. Even when using plastic substrates, for maintaining high contrast ratio and wide viewing angle properties, we have been also developing the optical compensation technologies for vertically-aligned and in-plain switching liquid crystal displays based on precise measurement of optical anisotropy for various plastic substrates with different formation methods. We are now researching a flexible local-dimming backlight system by using a segment-driven polymer-dispersed liquid crystal devices as a thin light-guide plate for flexible displays.

9565-26, Session 5

Bent LC molecules with a 60° central core that can form B7 and B2 phases *(Invited Paper)*

Junji Watanabe, Tokyo Institute of Technology (Japan)

We synthesized small-angle bent-core liquid-crystalline (LC) molecules based on a 1,2-bis(phenylethylene) benzene central core, containing seven aromatic rings and alkoxy tails with carbon numbers of 12, 16 and 18. This ortho-bistolane central core offers a 60o bend angle. Irrespective of this unusually small angle, these molecules can form banana smectic phases with a ferroelectric B7-antiferroelectric B2 phase sequence upon cooling as clarified from the micoscopic, X-ray and opto-electric observations. This indicates that despite of the low bend angle of 60o, these are able to be still packed into a layer with the polar bent direction parallel to the layer like ordinal banana molecules. The present result is striking since it had been believed that banana phases can only be stabilized when the bending angle is in the range from 110-140o, providing additional insight into the nature of banana-shaped molecules.

9565-27, Session 5

Nonlinear doped liquid crystals for dynamic holographic displays *(Invited Paper)*

Yikai Su, Shanghai Jiao Tong Univ. (China)

We study nonlinear performances of doped liquid crystals employing azo dye (DR1) and quantum dots. The nonlinear mechanisms include thermal effect, space-charge induced electric field, photo-isomerization, and optical-field induced molecular polarization. Our preliminary investigations reveal that these doped liquid crystals are dominated by different nonlinear mechanisms. In particular, we find that For dye-doped LC, the response time is generally robust to temperature variation but the diffraction efficiency is temperature-sensitive. Whereas, the QD-doped LC remains robust for both characteristics around room temperature. We also demonstrate dynamic holographic displays using these doped liquid crystals at a video rate of 60 Hz.

9565-28, Session 6

Reflective-emissive liquid-crystal displays constructed from AIE luminogens *(Keynote Presentation)*

Ben Zhong Tang, Dongyu Zhao, Hong Kong Univ. of Science and Technology (Hong Kong, China); Anjun Qin, Hong Kong Univ. of Science and Technology (China)

The chiral nematic liquid crystal (N*-LC) has plenty of prospective applications in LC display (LCD) owing to the selective reflection and circular dichroism. The molecules in the N*-LC are aligned forming a helically twisted structure and the specific wavelength of incident light is reflected by the periodically varying refractive index in the N*-LC plane without the aid of a polarizer or color filter. However, N*-LC do not emit light which restricts its application in the dark environment. Moreover, the view angle of N*-LC display device was severe limited due to the strong viewing angle dependence of the structure color of the one dimensional photonic crystal of a N*-LC. In order to overcome these weaknesses, we have synthesized a luminescent liquid crystalline compound consisting of a tetraphenylethene (TPE) core, TPE-PPE, as a luminogen with mesogenic moieties. TPE-PPE exhibits both the aggregate-induced emission (AIE) and thermotropic liquid crystalline characteristics. By dissolving a little amount of TPE-PPE into N*-LC host, a circular polarized emission was obtained on the unidirectional orientated LC cell. Utilizing the circular polarized luminescence property of the LC mixture, we fabricated a photoluminescent liquid crystal display

(PL-LCD) device which can work under both dark and sunlit conditions. This approach has simplified the device design, lowered the energy consumption and increased brightness and application of the LCD.

9565-29, Session 6

Computational chemistry modeling and design of photoswitchable alignment materials for optically addressable liquid crystal devices *(Invited Paper)*

Kenneth L. Marshall, Emily R. Sekera, Kyle Xiao, Univ. of Rochester (United States)

Photoalignment technology has received great interest as an alternative to buffed alignment layers for generating high-quality uniform molecular alignment in liquid crystal (LC) devices. The 1054 nm laser damage resistance of coumarin photoalignment layers (up to 60 J/cm2, 1 ns pulse) approaches that of fused silica, making these materials prime candidates for use in photoaligned LC optics for high peak power lasers. Optically-switchable azobenzene "command surfaces" have 1054-nm laser-damage thresholds comparable to coumarin materials, and have been proposed for use in an "optically driven" LC spatial beam shaper for high peak power laser applications. Spatially-varying the LC molecules between two alignment states in this device is achieved using low-energy polarized UV/visible incident light, providing the in-system write/erase flexibility of electro-optical LC spatial beam shapers while eliminating conductive coatings and electrical interconnects that reduce laser-damage threshold and increase device fragility and complexity, respectively. Beyond azobenzenes, relatively little has been done to develop photoswitchable alignment layers based on other photosensitive materials, and such development has been guided largely by an empirical approach. Applying computational chemistry methods to photoswitchable alignment materials design presents itself as a unprecedented opportunity to develop predictive capabilities that will lead to materials with low switching energies, enhanced bistability, and resistance to both write/erase fatigue and laser damage. To this end, we will describe our recent efforts to apply Density Functional Theory (DFT) computational methods in determining the effect of molecular structure and functional groups on the optical switching state energies of novel photoswitchable alignment materials composed of acrylate and methacrylate polymer backbones functionalized with azobenzene and spiropyran pendants.

9565-30, Session 6

Photonic band-gap modulation of blue phase liquid crystal *(Invited Paper)*

Tsung-Hsien Lin, National Sun Yat-Sen Univ. (Taiwan)

Blue phase liquid crystals (BPLCs) are self-assembled 3D photonic crystals exhibiting high susceptibility to external stimuli. Two methods for the photonic bandgap tuning of BPs were demonstrated in this work. Introducing a chiral azobenzene into a cholesteric liquid crystal could formulate a photoresponsive BPLC. Under violet irradiation, the azo dye experiences trans-cis isomerization, which leads to lattice swelling as well as phase transition in different stages of the process. Ultrawide reversible tuning of the BP photonic bandgap from ultraviolet to near infrared has been achieved. The tuning is reversible and nonvolatile. We will then demonstract the electric field-induced bandgap tuning in polymer-stabilized BPLCs. Under different BPLCs material preparation conditions, both red-shift and broadening of the photonic bandgaps have been achieved respectively. The stop band can be shifted over 100 nm. The bandwidth can be expanded from ~ 30 nm to ~ 250 nm covering nearly the full visible range. It is believed that the developed approaches could strongly promote the use of BPLC in photonic applications.

Asymmetrical phase difference distribution properties of a liquid-crystal micro-lens array with tetragonally-patterned electrodes

Marenori Kawamura, Kento Nakamura, Akita Univ. (Japan); Susumu Sato, LC-Lens Institute (Japan)

Liquid crystal (LC) materials have a large birefringence property and they are widely used not only for display devices but tunable optical devices. The LC device such as an LC lens with a radially-varying refractive gradient-index distribution can be realized by the LC molecular reorientation caused by an axially symmetrical electric field in the circularly hole-patterned electrode. The LC micro-lens arrays (LC-MLAs) with two-faced circularly hole-patterned electrodes have been proposed based on the orientation effects of LC molecules in inhomogeneous electric fields. By controlling the applied voltage on the LC-MLAs, their optical property such as focal length can be electrically varied. The authors also proposed an LC-MLA with two-divided and tetragonally-patterned electrodes for varying a focal length and a beam deflection angle estimated by the induced refractive index distributions.

In this study, the spatial distributions of the re-orientated LC directors in the tetragonal region of the LC-MLA are calculated by a finite difference method for analyzing the static behaviors of the LC directors. The calculated and experimental results are discussed. The phase difference distribution in the tetragonal region can be estimated and its phase profile such as asymmetrical phase difference distribution properties can be predicted fairly well by the calculation.

9565-32, Session 7

Complex topological structures of frustrated liquid crystals with potential for optics and photonics *(Keynote Presentation)*

Slobodan ?umer, Univ. of Ljubljana (Slovenia) and Jo?ef Stefan Institute (Slovenia); Miha Cancula, Simon Copar, Miha Ravnik, Univ. of Ljubljana (Slovenia)

Geometrical constrains and intrinsic chirality in nematic mesophases enable formation of stable and metastable complex defect structures. Recently selected knotted and linked disclinations have been formed using laser manipulation of nematic braids entangling colloidal particles in nematic colloids [Tkalec et al., Science 2011; Copar et al., PNAS 2015]. In unwinded chiral nematic phases stable and metastable toron and hopfion defects have been implemented by laser tweezers [Smalyukh et al., Nature Materials 2010; Chen et al., PRL2013] and in chiral nematic colloids particles dressed by solitonic deformations [Porenta et al., Sci. Rep. 2014]. Modelling studies based on the numerical minimisation of the phenomenological free energy, supported with the adapted topological theory [Copar & Zumer, PRL 2011; Copar, Phys. Rep. 2014] allow describing the observed nematic defect structures and also predicting numerous structures in confined blue phases [Fukuda & Zumer, Nature Comms 2011 and PRL 2011] and stable knotted disclinations in cholesteric droplets with homeotropic boundary [Sec et al., Nature Comms 2014]. Coupling the modeling with finite difference time domain light field computation enables understanding of light propagation and light induced restructuring in these mesophases. The method was recently demonstrated for the description of low intensity light beam changes during the propagation along disclination lines [Brasselet et al., PRL 2009; Cancula et al., PRE 2014]. Allowing also high intensity light an order restructuring is induced [Porenta et al., Soft Matter 2012; Cancula et al., 2015]. These approaches help to uncover the potential of topological structures for beyond-display optical and photonic applications.

9565-33, Session 7

Acquiring three dimensional images based on electronically controlled liquid crystal micro lens array

Hui Li, Fan Pan, Wuhan Institute of Technology (China); Kan Liu, Wuhan Institute of Physics and Mathematics (China); Yuntao Wu, Yanduo Zhang, Wuhan Institute of Technology (China); Xiaolin Xie, Huazhong Univ. of Science and Technology (China)

In this paper, we will present a novel method based on an electrically controlled liquid crystal (LC) micro lens array (MLA) to acquire three-dimensional (3D) image, which is extremely different from the other existing 3D imaging methods. This proposed method doesn't need any mechanical movements because of adapting the proposed LC-MLA as a key imaging element to compose a 3D imaging system. The 3D imaging system based on LC-MLA, which is smart, light and cheap, can be realized to solve that common problem in conventional 3D imaging systems. The LC-MLA with 128?128 elements is fabricated by the methods of photolithography and hydrochloric acid etching. Its top patterned electrode is composed of 128?128 micro-circular holes. The diameter of each micro-circular hole is 50?m, and the center-to-center distance between neighboring lenses is 150?m, and the thickness of LC layer is 20?m. The LC-MLA has 50?m hole-pattern electrodes, the operating voltage as low as 0.2Vrms, focal length range of 50?m-400?m, millisecond response time, and the optical consistency between neighbor elements of 9%. In order to present its 3D imaging feature, an interesting imaging experiment based on LC-MLA is set up. In the experiment, the two-dimensional (2D) images under different perspectives and magnifications are respectively got by tuning the external applied voltage from 0.2 to 5.0Vrms at 0.5Vrms/step, and then a ray back projection algorithm is applied to process those 2D images in order to reconstruct the 3D image of the target object. This 3D imaging system is novel for compactness and smart, so this kind of proposed imaging system is very attractive in many applications, such as 3D TVs, games, and movies.

9565-34, Session 7

Digital confocal microscopy through a multimode fiber *(Invited Paper)*

Christophe Moser, Damien Loterie, Salma Farahi, Demetri Psaltis, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Confocal microscopy is an important tool in biological imaging, because it substantially improves the contrast of images compared to wide field microscopy. The principle is based on a double filtering operation: a volume inside the sample is selectively illuminated by a focused beam, and light originating from this focal volume is selectively observed using a pinhole in the detection pathway. We propose to extend the concept to imaging with a multimode fiber for which its transmission matrix (TM) is first measured. Then, by using wavefront shaping and the knowledge of the TM, sharp focus spots are scanned at the distal end of the fiber and the light fields propagating in the reverse direction through the multimode fiber are decoded with the matrix. Then, we implement the double filtering required for confocal microscopy, but in the digital domain. We demonstrate that this leads to a significant increase in imaging contrast in spot-scanned images. A correlation-based filtering technique is also introduced, which offers similar performance for a significantly reduced computational cost.

9565-35, Session 7

The helical nanofilament phase as a host for creation of aligned, nanostructured composites *(Invited Paper)*

David M. Walba, Rebecca A. Callahan, Eva D. Korblova, Dong Chen, Yongqiang Shen, Michael Tuchband, Eric Carlson, Univ. of Colorado at Boulder (United States); Hanim Kim, KAIST (Korea, Republic of); Garry Rumbles, National Renewable Energy Lab. (United States); Sean E. Shaheen, Univ. of Colorado at Boulder (United States); Dong Ki Yoon, KAIST (Korea, Republic of); Noel A. Clark, Univ. of Colorado at Boulder (United States)

The helical nanofilament (HNF) liquid crystal phase is a member of an unusual class of thermotropic phases with lamellar structures dominated by a tendency towards developing negative Gaussian curvature of the layers. Members of this family are sometimes termed "dark conglomerates," due to their behavior in polarized light microscopy. These include a fluid phases - the high temperature dark conglomerate phase, which is a kind of sponge phase, and the low temperature dark conglomerate phase, also seemingly a sponge phase with structural details currently under investigation. The HNF phase, also a "dark conglomerate," seems to be unique in the family, since slow conformational dynamics indicate a quasi-crystalline structure within layers, but no long range positional correlations across layers. We have been exploring possible applications of the HNF phase, which is highly porous, as a host for the formation of alignable composites for photovoltaics and other organic semiconductor applications. Recent results regarding the structure of these composites, including data suggesting a remarkably elegant nanostructure for HNF-chiral nematic composites, will be discussed.

9565-36, Session 7

Liquid-crystal-based immunodetection beyond texture observations *(Invited Paper)*

Mon-Juan Lee, Chang Jung Christian Univ. (Taiwan); Chi-Hao Lin, Wei Lee, National Chiao Tung Univ. (Taiwan)

Immunodetection of cancer biomarkers is an essential procedure in early screening and diagnosis of cancer. Going beyond the optical texture observation, this work aims at the development of label-free and array-based multiplex immunodetection techniques by exploiting the high sensitivity of liquid crystal (LC) orientation toward the formation of antigen–antibody immunocomplexes. Results from our previous studies suggested that, by applying a nematic LC with large birefringence (?n = 0.33) and by UV modification of the monolayer of N,N-dimethyl-n-octadecyl-3-aminopropyltrimethoxysilyl chloride (DMOAP) as the alignment layer, the sensitivity of LC-based immunodetection is drastically enhanced. As a matter of fact, the core technology involved in our previous research still stemmed from the conventional and widely adopted method; i.e., by texture observations, which made quantitative measurements difficult.

In this invited paper, we report on our attempt to further improve the LC-based immunoassay technique through the analysis of some cancer biomarkers commonly used in clinical cancer screening, including carcinogenic antigen 125 (CA125). We propose to overcome the technical limitations in the quantitative analysis of LC-based immunodetection. By means of the induced changes in dielectric and electro-optical properties of LCs, which are expected to change in the presence of different types and concentrations of cancer biomarkers, novel quantitative techniques specific for LC-based immunodetection are developed.

9565-37, Session 7

Revealing pathologies in the liquid crystalline structures of the brain by polarimetric studies

Karen Bakhshetyan, Gurgen G. Melkonyan, Tigran V. Galstian, Armen Saghatelyan, Univ. Laval (Canada)

Natural or "self" alignment of molecular complexes in living tissue represents many similarities with liquid crystals (LC), which are anisotropic liquids. The orientational characteristics of those complexes may be related to many important functional parameters and their study may reveal important pathologies. The know-how, accumulated thanks to the study of LC materials, may thus be used to this end. One of the traditionally used methods, to characterize those materials, is the polarized light imaging (PLI) that allows for label-free analysis of anisotropic structures in the brain tissue and can be used, for example, for the analysis of myelinated fiber bundles.

In the current work, we first attempted to apply the PLI on the mouse histological brain sections to create a map of anisotropic structures using cross-polarizer transmission light. Then we implemented the PLI for comparative study of histological sections of human postmortem brain samples under normal and pathological conditions, such as Parkinson's disease (PD).

Imaging the coronal, sagittal and horizontal sections of mouse brain allowed us to create a false color-coded fiber orientation map under polarized light. In human brain datasets for both control and PD groups we measured the pixel intensities in myelin-rich subregions of internal capsule and normalized these to non-myelinated background signal from putamen and caudate nucleus. Quantification of intensities revealed a statistically significant reduction of fiber intensity of PD compared to control subjects (2.801 ± 0.303 and 3.724 ± 0.07 respectively; *p < 0.05).

Our study confirms the validity of PLI method for visualizing myelinated axonal fibers. This relatively simple technique can become a promising tool for study of neurodegenerative diseases where labeling-free imaging is an important benefit.

9565-38, Session 8

The next horizon for diffractive waveplate technology *(Keynote Presentation)*

Nelson V. Tabiryan, BEAM Engineering for Advanced Measurements Co. (United States); Diane Steeves, Brian Kimball, U.S. Army Natick Soldier Research, Development and Engineering Ctr. (United States)

Thin liquid crystal polymer films coated on a variety of substrates, glass or plastic, planar or curved, solid or flexible, can perform many of the functions of conventional optics -- deflecting, reflecting, focusing, and shaping light beams -- by appropriately patterning their optical axis orientation in the plane of the film. We will discuss this state of the art technology, its current and anticipated capabilities, and opportunities for replacing and augmenting conventional optical elements in photonics and display systems. Novel optical functions due to the full use of the unique combination of mechanical, optical and electro-optical properties of such diffractive waveplate systems will be presented.

9565-39, Session 8

One- and two-dimensional liquid crystal structures for lasing applications *(Invited Paper)*

Inge Nys, Jeroen Beeckman, Kristiaan Neyts, Univ. Gent (Belgium)

Combining liquid crystals with light emitting materials offers interesting possibilities for lighting and lasing applications. Liquid crystal lasers have great potential as small size, low-cost, widely tunable lasers. Dye-doped chiral nematic liquid crystals are often used as active laser media since a photonic bandgap for visible light is spontaneously formed. In recent years, we have investigated different cases of light emission from one- and two-dimensional liquid crystal-containing structures.

Non-chiral nematic liquid crystals have been used to make electrically tunable lasers with a slope efficiency up to 30%. The laser performance strongly depends on the thickness of the cell and the reflectivity of the substrates.

Chiral nematic liquid crystals are frequently used to make out-of-plane emitting lasers with a one-dimensional structure but they can also be used to develop in-plane emitting liquid crystal lasers with a two-dimensional structure. These lasers have the potential to achieve low threshold lasing and they are suited for integration in a lab-on-chip environment. Compared to the conventional out-of-plane emitting liquid crystal lasers, in-plane emitting lasers with a lying helix structure are more difficult to obtain experimentally and to study theoretically. We investigated different techniques to obtain an in-plane lying helix structure and we have been working on the numerical simulation of this structure. The accurate modeling of light generation in in-plane liquid crystal lasers is difficult because the structure is two-dimensional and the optical properties are anisotropic. We combine a liquid crystal simulation tool with finite-element calculations to simulate the optical modes.

9565-40, Session 8

Photopatterning of complex molecular orientation fields in liquid crystals

Qi-Huo Wei, Yubing Guo, Miao Jiang, Kent State Univ. (United States); Kai Sun, Univ. of Michigan (United States); Chenhui Peng, Kent State Univ. (United States); Oleg V. Yaroshchuk, National Academy of Sciences of Ukraine (Ukraine); Oleg D. Lavrentovich, Kent State Univ. (United States)

This talk will present a new technique for photopatterning molecular oridentational ordering in liquid crystalline materials. The technique is based on new designs of plasmonic photomasks which, when illuminated with broadband non-polarized light, can generate light with predesigned polarization patterns. Photo-active materials exposed by light with polarization patterns induce spatial-varying molecular orientations of liquid crystal molecules or mesogens with predesigned director fields. This new technique is scalable and inexpensive for large scale manufacturing, and holds a large potential for applications in various liquid crystal device manufacturing. Detailed mask designs and fabrication procedures, and their applications in defining various topological defect combinations or arrays in nematic liquid crystals will be discussed.

9565-41, Session 8

Study of liquid crystal formation of graphene oxide flakes

Ji Hyun Park, Min Jae Kim, HyeRan Jo, Kieup Lee, YoungBeom Jo, Seoul National Univ. (Korea, Republic of); Stephane Campidelli, CEA-IRAMIS (France); Jun Yamamoto, Kyoto Univ. (Japan); Youn Sang Kim, Seoul National Univ. (Korea, Republic of); Giusy Scalia, Seoul National Univ. (Korea, Republic of) and Univ. du Luxembourg (Luxembourg)

Graphene can be produced with chemical method and this process goes through the formation of an oxidative form of graphene, called graphene oxide (GO), useful for mass production of graphene, obtained by reduction. Interestingly, graphene oxide is dispersible in water due to its hydrophilic functional groups and this allows the formation of liquid crystal phases

above certain threshold concentration. GO shows a discotic nematic phase above a certain concentration threshold. Due to the diversity of GO flake average size, as a result of variations in production methods, the value of the threshold and the width of the region of coexistence of the isotropic and liquid crystal phase can strongly vary from samples to samples. We have observed the appearance of a nematic liquid crystal phase at very low concentration and a co-existence region form 0.1mg/ml to 1.0mg/ml by final GO obtained from synthesis. We have controlled the size of the flakes by ultra-sonication. With smaller flakes the transition concentration shifted towards much higher concentrations since the aspect ratio of the flakes has decreased. We report a detailed study of the size distribution of the GO flakes, together with UV-VIS spectroscopic and polarized dynamic light scattering, for understanding the liquid crystal phase formation.

9565-42, Session 8

Tunable Bragg extraction of light in photonic quasi crystals: Dispersed liquid crystalline metamaterials *(Invited Paper)*

Massimo Rippa, Rossella Capasso, Consiglio Nazionale delle Ricerche (Italy); Cesare Umeton, Univ. della Calabria (Italy); Lucia Petti, Consiglio Nazionale delle Ricerche (Italy)

Metamaterials (MTMs) and Photonic Quasi-Crystals (PQCs) have attracted the attention of the scientific community in the last few years due to their ability to control the electromagnetic (EM) field in an unusual way. The performances of such artificial materials are determined by their engineered configuration; Electromagnetic properties of PCs and PQCs can be controlled by properly designing their geometry: almost each single parameter of these structures, related to periodicity or aperiodicity, shape, material, etc., can be managed to achieve a desired propagation or extraction property. Thus, it is, in general, hard to reconfigure the MTMs or control their extraction properties without redesigning them and repeating the entire fabrication process, so that, transforming these passive optical elements into devices that can be actively controlled or, more in details, fabricating MTMs that are reconfigurable/switchable, represents a new challenge. In this communication, we report on the realization and characterization of a switchable photonic device, working in the visible range, based on nanostructured PQCs, layered with a photo-responsive LC. Both experimental characterization and numerical simulations show that extraction spectra can be controlled by applying an external voltage or by means of a laser light. In our opinion, these results represent a breakthrough in the realization of innovative MTMS based active photonic devices.

Analysis of selective reflection spectrum in cholesteric liquid crystal cells for solar-ray controller

Akifumi Ogiwara, Kobe City College of Technology (Japan); Hiroshi Kakiuchida, National Institute of Advanced Industrial Science and Technology (Japan)

If a nematic liquid crystal is doped with a concentration of chiral materials, then cholesteric liquid crystal (CLC) is formed with a certain helical pitch in a chiral nematic phase. Because the CLC cells have attracted features such as periodic helical structure, wavelength selective reflection of circularly polarized light, and tunable reflection wavelength, they have been widely used for modern electro-optic applications. The pitch length of the helix corresponding to a molecular rotation is determined by the concentration of the chiral dopant, decreasing with increasing the fraction of the chiral dopant. The central wavelength and bandwidth of selective reflection spectrum in CLC cells is characterized by the chiral dopant molecules and the polymer network structure formed by photopolymerization. The bandwidth of the selective reflection spectrum in CLC cells is affected by doping liquid crystal (LC) diacrylate monomers which define a macroscopic helical twisting power in photopolymerization.

We investigated the effects of modulation of the selective reflection spectrum in CLC cells on the visible and infrared lights in spectral solar irradiance. The CLC cells are fabricated by varying the concentration of various chiral dopants and liquid crystal (LC) diacrylate monomers. The central wavelength and bandwidth of selective reflection spectrum in CLC cells are evaluated by a spectroscopic analysis. The spectral solar irradiance for air mass 1.5 and the standard luminous efficiency function for photopic vision are analyzed to estimate the performance for a solar-ray controller based on the results. The optical characteristics achieved in CLC cells are confirmed to be applicable as a novel optical device for a solar-ray controller.

LCD

Dongyu Zhao, Beijing Univ. of Aeronautics and Astronautics (China)

Twisted nematic (TN) liquid crystal devices doped with flower-type CuS nanoparticles were fabricated. The effects of CuS nanoparticles on the drive voltage, contrast ratio and response time of TN liquid crystal devices were investigated. It was found that addition of flower-type CuS nanoparticles remarkably decreased the drive voltage as well as response time and significantly increased the contrast ratio. The reason was deeply analyzed. Firstly, through doping of CuS nanoparticles, the movement of charged ions in liquid crystal is limited and the gather of charged ions on both sides of the electrodes is effectively inhibited, which reduces the shielding effect of charged ions and leads to decline of the drive voltage and the response time.

Furthermore, the orientation of liquid crystal molecules nearby is influenced by the orientation of CuS nanoparticles. They cannot form distorted arrangement ideally, and the light transmittance in the off state dropped significantly and light transmittance in the open state have elevated. Owing to the above two reasons, the contrast ratio increases strikingly. After doping 0.05% CuS nanoparticles, Vth and Vsat of TN liquid crystal cells fall to the minimum value. Moreover, contrast ratio of LCs increases distinctly. From the above discussion, the conclusion can be reached that with the doping of flower-type CuS nanoparticle, twisted nematic LCD modes have better electro-optical performances. Considerable work, hopefully, will be done in this area.

9565-45, Session PMon

Multifocal liquid-crystal-lens properties with additional ring-electrodes

Marenori Kawamura, Kensuke Tamura, Makoto Chida, Akita Univ. (Japan); Susumu Sato, LC-Lens Institute (Japan)

Many types of optical devices using nematic liquid crystal (LC) materials with a large birefringence and dielectric anisotropy have been developed. S.Sato et al. reported an optical device such as an LC lens with a circularly hole-patterned electrode for tuning a focal length without any mechanical movements. The LC lens with a wide variable range from a concave (negative) lens property to convex (positive) lens property has been reported. The low-driving-voltage LC lens was realized by using a highly resistive thin-film with the appropriate sheet resistivity.

In this study, we propose a low-driving-voltage multifocal LC lens, such as a concave lens inside a convex lens or a convex lens inside a concave lens. The multifocal LC lens is prepared using a circularly hole-patterned ITO electrode (15mm in diameter), inner electrode and additional ring electrodes inside the patterned-hole. A highly resistive transparent film on an insulating polymer film is laminated on these ITO electrodes. A polyimide (PI) alignment film is coated on the high resistance film and rubbed unidirectionally. Then, nematic LC material is sandwiched between the electrode and other transparent ITO electrode coated by a PI alignment film.

The multifocal lens properties, such as a ring-shaped concave-lens of about 3.5 mm width outside a convex-lens at a diameter of 8 mm or a convex-lens

outside a concave-lens with the same size, are attained. Each focal length of the concave lens and/or convex lens properties can be changed by applying low voltages to the electrodes.

9565-46, Session PMon

Three-dimensional imaging system by using a low-voltage-driving LC lens

Marenori Kawamura, Shunsuke Ishikuro, Akita Univ. (Japan)

There are many types of optical devices by using nematic liquid crystal (LC) materials with a large birefringence and dielectric anisotropy. S. Sato et. al. reported LC devices with functions of a variable focusing. An LC lens with a wide variable range from a concave (negative) lens property to convex (positive) lens property has been already reported. In this study, we propose a three-dimensional imaging system with a low-voltage-driving LC lens for obtaining all-focused image and depth mapping properties by processing an image digital filter from continuous focal images.

The position of the focused plane varies by adjusting the voltage applied to electrodes of the LC lens with circularly hole-patterned electrode and external transparent electrode above the threshold voltage. The continuous images are taken by changing the position of the focal plane. The sharp and clear all-focused image and the depth mapping image of the sample target as the test chart can be obtained by our proposed digital filter from continuous focal images. The acquisition times of this LC lens system without any mechanical movements must be faster than those of the conventional all-focused imaging system with mechanical movements such as a piezoelectric motor or stepping motor.

9565-47, Session PMon

Bragg diffraction for normal and obliquely circularly polarized light due a new chiral mixture

Paola Castro-Garay, Jesus Manzanares-Martinez, Adalberto Corella-Madueño, Arturo Rosas-Burgos, Marielena Clark, Josue Lizola-Leon, Lillian Gracia, Univ. de Sonora (Mexico)

We have found theoretically and experimentally the reflectance and transmittance of normal and obliquely incident circularly polarized light due to new chiral mixture that was distorted by electric field. The chiral mixture was achieved by mixtures of two nematic liquid crystals (5OCB and 5CB) and S-1-bromo-2-methylbutane. We have found a regime of circular Bragg diffraction for certain values of concentrations and thickness. Optical difraction phenomenon have received particular attention in research for optical and electrooptical applications, such as low –voltage modulators, reflective phase gratings and smart reflectors.

The chiral mixture was sandwiched between two glass substrates with indium tin oxide (ITO) electrodes. The electrodes were coated with PVA and Trichloro(octadecyl)silane for planar and homeotropic aligment layer, respectively. Two types of rubbing aligment were adopted , one was parallel and the other was antiparallel.

The chiral mixture was irradiated with circularly polarized light. When the concentration of chiral component is increased one circularly polarized component is reflected, while the other circularly polarized component is transmitted unattenuated. Visual Observation and spectroscopy measurement prove that, if the chiral component concentration is decreased, transitions from Granjean to focal conic textures are found and selective reflection disappears.

Using the configuration of an cholesteric liquid cristal we have found the solution of the boundary-value problem for the reflection and transmission of incident optical waves. The appearance of nested band gaps of both handednesses during the sorting mixed chiral process is also obtained.

9565-48, Session PMon

An optical image stabilization using a droplet manipulation on a liquid crystal and polymer composite film

Yu-Jen Wang, Chia-Ming Chang, Yu-Shih Tsou, Ming-Syuan Chen, Hung-Shan Chen, Yi-Hsin Lin, National Chiao Tung Univ. (Taiwan)

Motion blur is one of the major factors which decrease the image quality of a hand-held image system while the image system is under shakes or vibrations during exposure. Opical image stabilization (OIS) is a technique to reduce such a blurring. The basic principle of OIS is to stabilize the recorded image in a camera by varying the optical path to the sensor under shakes or vibrations during exposure. In this paper, we demonstrate an optical image stabilization (OIS) for an image system using a droplet manipulation on a liquid crystal and polymer composite film (LCPCF) which reduces the motion blur. The mechanism is based on manipulation of curvature and position of the liquid lens on LCPCF according to electrically tunable orientations of liquid crystals. The change of curvature of the liquid lens results in a tunable focus of the system; meanwhile, the change of the position of the liquid lens compensates the deviation of light when the image system is under a handshake vibration. Therefore, the image system forms a clear image with different focal length to overcome handshake vibration. Several factors related to the image performance, such as moving speed and applied voltage, were discussed. The concept in this paper can also be extended to design other optical components for modulating the direction of light.

9565-49, Session PMon

Thermodielectric effect in dual-frequency cholesteric liquid crystals

Yu Cheng Hsiao, Wei Lee, National Chiao Tung Univ. (Taiwan)

Dual-frequency nematic liquid crystals (DFNLCs) exhibit an attractive property that their dielectric anisotropy ?? changes from positive to negative with increasing frequency beyond the crossover frequency fc. Based on this feature, DFNLCs have been suggested for uses in fast-switching optical devices. Additionally, dual-frequency cholesteric liquid crystals (DFCLCs), made of mixtures of DFNLCs and chiral dopants (CDs), hold great promise for photonic applications. Conventionally, the switching from the optically stable, transparent planar (P) state to the

light-scattering focal conic (FC) state in a cholesteric liquid crystal is achieved by applying an AC voltage pulse. Unfortunately, the transition from the FC to P state cannot be directly achieved but requires an intermediate state. Recently, we have demonstrated the direct two-way switching between the P and FC states in DFCLCs, characterized by a much shorter transition time for potential applications as light shutters and color reflective displays. However, it is a pity that DFCLC devices suffer from one common problem—high operation voltage. In this work, we explore the thermodielectric physics in a DFCLC system and employ this thermodielectric effect to switch the cell from the P to the FC or H state by a lower voltage.

9565-50, Session PMon

Field induced lattice reorientation, deformation, and optical nonlinearities in blue phase liquid crystals

Iam Choon Khoo, Tsung-Jui Ho, Shuo Zhao, The Pennsylvania State Univ. (United States); Chun-Wei Chen, Tsung-Hsien Lin, National Sun Yat-Sen Univ. (Taiwan)

We have studied the transmission/reflection spectra and the nonlinear optical responses of Blue Phase liquid crystals (BPI and BPII) under the action of an external applied AC and DC fields. Significant reorientation and deformation of the photonic bandgap, and changes in the resulting transmission/reflection spectra of the samples are observed for applied field strengths on the order of a few volts/micron. For samples doped with photosensitive dyes such as methyl-red, unusually large optical nonlinearities are observed at well-defined applied DC voltage regions corresponding to the occurrence of major lattice deformation/reorientation. These nonlinearities exhibit transient as well as persistent components similar to methyl-red doped nematics; however, the observed effects are independent of the light polarization and direction of incidence [Opt. Lett. 40, 60-63 (2015)].

Conference 9566: Organic Light Emitting Materials and Devices XIX

SPIE. OPTICS+ PHOTONICS ORGANIC PHOTONICS+ ELECTRONICS

9566-1, Session 1

The development of materials and architectures for light-emitting diodes *(Invited Paper)*

Paul L. Burn, Ross Jansen-van Vuuren, Fatemah Maasoumi, Paul Meredith, Ebinazar Namdas, The Univ. of Queensland (Australia)

Innovation in materials and device architectures has played a crucial role in development of organic light-emitting diodes. Most research has concentrated either on small organic molecules or conjugated polymers. We have pursued an alternative approach to solution processable materials for LEDs based on conjugated dendrimers. Dendrimers consist of a core, conjugated dendrons (branches) and surface groups, and by suitable choice of these components, efficient solution-processed LEDs can be made. In this presentation we will discuss our recent developments on light-emitting materials and/or device architectures. A combination of synthesis, physical, photophysical measurements, and/or device fabrication and testing will be described.

9566-2, Session 1

Novel emission types in organic molecules: TADF and biluminescence *(Invited Paper)*

Sebastian Reineke, Technische Univ. Dresden (Germany)

Organic semiconductors possess two fundamental excited states, namely the singlet (S1) and triplet (T1) states, which are differentiated by their total spin, i.e. either 0 or 1, respectively. Generally, only the singlet state gives rise to emission, i.e. fluorescence. In OLEDs however, the vast share (75%) of excitons generated are triplets introducing severe losses. Here, thermally activated delayed fluorescence (TADF) has proven recently to overcome this spin problem. Biluminescence, where both singlet and triplet states contribute significantly and efficiently to the luminescence of a molecule, has only been observed in rare occasions. Once broadly available, it could be the platform of many different applications, such as ultra-broadband emitters, sensors, and energy manipulators. In this talk, I will discuss our recent efforts on the development and understanding of both TADF and biluminescent emitters. In the first part, I will summarize the development of novel blue TADF-based OLED emitters from molecular design to device implementation. In the second part, I will discuss organic materials with biluminescent properties, i.e. lumophores that act as dual state emitters and relate their special character to potential future applications in organic electronics.

9566-3, Session 1

Excimer formation and AIE effect in blue fluorescence core-side materials *(Invited Paper)*

Jongwook Park, Seungho Kim, Jaehyun Lee, Hyocheol Jung, The Catholic Univ. of Korea (Korea, Republic of); Daisuke Yokoyama, Yamagata Univ. (Japan); Chihaya Adachi, Kyushu Univ. (Japan)

We recently reported the syntheses of new multi-core chromophore materials containing anthracene and pyrene (AP dual core) that exhibit high PL and EL efficiencies. In this study, highly efficient blue emitting materials consisting of triple core derivatives with side group based on anthracene and pyrene moieties were designed and synthesized. Of the synthesized compounds, 1,6 DAP-TP was found to exhibit unusual excimer band with two sharp strong peaks which are a molecular emission peak at 455 nm and an excimer emission peak at 591 nm. Single molecular white emission of CIE (0.37, 0.31), very close to pure white, was obtained by introducing a terphenyl side group into a highly twisted core chromophore. This could be explained by the molecular orientation in the film state suitable for excimer formation. Also, when electron push and pull moieties were introduced into anthracene core, AIE effect providing highly efficient green emission of 18 cd/A with 19,000hrs (Lt50) was found.

9566-4, Session 1

High efficiency blue fluorescent organic light-emitting diodes *(Invited Paper)*

Jun Yeob Lee, Sang Kyu Jeon, Wook Song, Sungkyunkwan Univ. (Korea, Republic of)

For the last decade, there has been a big progress of the quantum efficiency of blue organic light-emitting diodes by developing blue phosphorescent materials. However, recent development demonstrated that the quantum efficiency of the blue fluorescent devices can show high quantum efficiency. In this presentation, we present high quantum efficiency blue thermally activated delayed fluorescent and blue fluorescent organic light-emitting diodes which can show comparable quantum efficiency to blue phosphorescent organic light-emitting diodes. We developed new blue thermally activated delayed fluorescent emitter derived from acridine and carbazole, and could achieve close to 20% external quantum efficiency in blue thermally activated delayed fluorescent and blue fluorescent organic light-emitting diodes.

9566-5, Session 1

Highly efficient exciplex-based OLEDs *(Invited Paper)*

Ken-Tsung Wong, National Taiwan Univ. (Taiwan)

There are different approaches for harvesting the electro-generated triplet excitons in organic light-emitting devices (OLEDs). The invention of transition metal-centered phosphors has achieved great success due to the inherent strong spin-orbit coupling effect. More recently, highly efficient OLEDs employing pure organic emitter with thermally activated delayed fluorescence (TADF) behavior has emerged as the potential alternative because of the cost-effective material preparations. To perform efficient TADF, the excited molecule needs to perform efficient reverse intersystem crossing (RISC) process, in which a small energy difference (?EST) between the singlet and triplet excited states is necessary. Efficient TADF emitters can be achieved with tailor-made molecules comprising of electron–donating and –accepting substructures to perform sufficient intramolecular charge transfer (ICT). Alternatively, the excited states with small ?EST can also be achieved by the formation of exciplex via intermolecular charge transfer between physically blended electronic donor and acceptor molecules. The physical properties of exciplex can be manipulated by the judicious combination of hole-transporting (HT) and electron-transporting (ET) materials. In this conference, our efforts of developing new HT and/or ET materials for generating efficient exciplexe OLEDs will be reported. In addition, the applications of exciplex as host material for highly efficient OLEDs and a new strategy for giving high efficiency (> 10%) pure fluorescence white OLED will also be presented.

9566-6, Session 1

Novel conjugated polymer colloids with applications in photonics *(Invited Paper)*

Alexander J. Kuehne, DWI an der RWTH Aachen e.V. (Germany)

Polymer colloids are auspicious candidates for the generation of printable and large area photonic materials via solvent-processing and self-assembly. Synthetics procedures have been developed to generate monodisperse particles from dielectric materials such as polystyrene and PMMA; however, well-defined and monodisperse colloids of semiconducting polymers, which would form excellent building blocks for self-assembled photonic materials, are not readily available.

I will present novel synthetic pathways affording monodisperse colloids, which are entirely composed of pi-conjugated polymers. Several palladium-catalyzed and metal-free dispersion polymerization procedures leading to perfectly spherical particles will be presented. By adjusting the synthetic conditions also anisotropic particles and core-shell geometries can be produced. These monodisperse conjugated polymer particles readily assemble into photonic crystals exhibiting both photonic and electronic characteristics and unprecedented photonic properties.

Through incorporation of switchable molecular units, the electronic bandgap of the pi-conjugated material can be changed leading to responsive photonic materials. Additionally, post-modification of the colloidal particles through thiol-yne click-chemistry enables functionalization with bio-medical recognition motifs. The resulting particles can be applied as imaging probes for detection and labelling of tumor cells.

9566-7, Session 2

New trends in the design of transition-metal OLED phosphors *(Invited Paper)*

Yun Chi, National Tsing Hua Univ. (Taiwan)

Luminescent third-row transition metal Os(II), Ir(III) and Pt(II) based complexes, particularly those with cyclometalating chelates and equivalents, play a key role in the recent development of optoelectronic technologies such as organic light emitting diode (OLED), light emitting electrochemical cells, and solid-state organic lighting applications. Their attractiveness comes from their higher chemical stability due to the strong metal-ligand bonding interaction, as well as the longer excitation lifetimes and higher emission quantum yields. Furthermore, the strong spin-orbit coupling induced by the central metal ion promotes an efficient intersystem crossing from the singlet to the triplet excited state manifold, which then facilitates strong electroluminescence by harnessing both singlet and triplet excitons of the as-fabricated optoelectronic devices. As a result, syntheses of these metal complexes were extensively examined. In this presentation, the recently development of new OLED phosphors, particularly those constructed with tridentate chromophores, with functional diimine, NHC carbene, azolate and even biazolate chelates, as well as those have showed bright blue phosphorescence, will be elaborated in a systematic manner.

9566-8, Session 2

Towards printed organic light-emitting devices: A solution-stable, highly soluble Cu(I)-NHetPHOS-complex for inkjet processing *(Invited Paper)*

Daniel Volz, Charlotte Fléchon, cynora GmbH (Germany); Manuela Wallesch, Karlsruher Institut für Technologie (Germany); Thomas Baumann, cynora GmbH (Germany)

In the last three years, great progress has been made on the field of iridium-free OLEDs. Extraordinary high device performance by using thermally activated delayed fluorescence – or singlet harvesting – instead of phosphorescence has been demonstrated with devices exhibiting more than 20% external quantum efficiency. This puts both organic and copper-containing emitters on eye level with modern iridium materials in terms of efficiency.

However, the release of first prototypes with printed displays emphasizes a weakness of current TADF-emitters: there are only limited results regarding the printing of such materials. While there are at least basic results with copper complexes employing lab-scale processing techniques like spin-coating, most purely organic TADF-emitters are very insoluble. Consequently, there are only a handful of organic emitters being soluble enough for solution processing.

We present the first printed TADF-OLED prototypes, moving one step further towards large-area printed TADF-OLEDs. Several new NHetPHOS-type copper emitters were developed, showing a solubility of more than 100 mg mL-1 in various printing-solvents. While this is usually achieved by introducing very long, potentially insulating, alkyl chains, we demonstrate a new strategy to achieve this goal.

Unlike other copper complexes, which dissociate and decompose readily in solution, we were able to proof that these materials are considerably more stable with advanced X-ray absorption spectroscopy on the Cu-K-edge and other techniques. Consequently, the high performance of a device prepared by spin-coating under nitrogen is maintained when processing the emission layer by inkjet printing under ambient conditions.

9566-9, Session 2

Facial and meridional N-heterocyclic carbene iridium complexes enable deep blue organic light-emitting diodes

Jaesang Lee, Univ. of Michigan (United States); Hsiao-Fan Chen, The Univ. of Southern California (United States); Xiao Liu, Caleb Coburn, Univ. of Michigan (United States); Peter I. Djurovich, Mark E. Thompson, The Univ. of Southern California (United States); Stephen R. Forrest, Univ. of Michigan (United States)

We present efficient deep blue phosphorescent organic light-emitting diodes (PHOLEDs) based on facial (fac-) and meridional (mer-) isomers of the N-heterocyclic carbene (NHC) Ir complex, Ir(pmp)3. PHOLEDs using fac- and mer-Ir(pmp)3 have chromaticity coordinates of CIE = [0.16, 0.09] and [0.16, 0.15], respectively, independent of brightness. Further, These devices achieve maximum external quantum efficiencies of EQE = 10.1 ± 0.2 and 14.4 ± 0.3 % at low luminance, and that decreases by only 50% at very high luminance of 8,200 ± 400 and 23,000 ± 600 cd/m2, respectively (corresponding to current densities of J50% = 170 ± 10 and 220 ± 10 mA/cm2). The J50% are at least a factor of three greater than those of previously reported deep blue PHOLEDs. In addition, it is notable that mer-Ir(pmp)3 based PHOLED is more efficient than the fac-isomer, which is in a striking contrast with the conventional fac- and mer-isomers of red- and green-emitting tris-cyclometalated Ir(C^N)3 complexes. We discuss this difference in terms of the distinct energetic and electronic properties of the NHC ligands, and verify our theoretical analysis with temperature- and solution-dependent photoluminescence of fac- and mer-Ir(pmp)3.

9566-10, Session 3

Organic light-emitting diodes: Multiscale charge transport simulation and fabrication of new thermally activated delayed fluorescence (TADF) materials *(Invited Paper)*

Hironori Kaji, Katsuyuki Shizu, Furitsu Suzuki, Tatsuya Fukushima, Katsuaki Suzuki, Kyoto Univ. (Japan); Chihaya Adachi, Kyushu Univ. (Japan)

(1) We have reported new type of organic light-emitting diodes exploiting reverse intersystem crossing (rISC). By designing light-emitting materials with small energy gap between singlet (S1) and triplet excited state (T1), electrically excited triplet excitons can be effectively up-converted to singlet excitons via rISC, which results in efficient thermally activated delayed fluorescence (TADF). Here, we show several recently-developed new TADF materials and the device performances.

(2) Charge transports in amorphous thin films with 100 nm thickness are investigated in silico by explicitly considering organic molecules. The amorphous layer of organic molecules was constructed using molecular dynamics simulations. The rate constants for charge hopping between two organic molecules, extracted from the amorphous layers, were calculated based on Quantum Chemical Calculations. The hopping transport in amorphous layers was simulated using a Monte Carlo method. The Monte Carlo simulation clearly shows that diffusion transport is dominant at low applied electric fields and that contribution of drift transport increases at high electric fields. The simulation in this study enable us to reveal molecular origin of charge transport. The details will be shown in the presentation.

9566-11, Session 3

N-type organic luminescent materials based on AIE-active siloles *(Invited Paper)*

Han Nie, Zujin Zhao, South China Univ. of Technology (China); Ben Zhong Tang, Hong Kong Univ. of Science and Technology (Hong Kong, China)

Simplifying the configurations of OLEDs without sacrificing device performances is of practical importance to shorten fabrication procedures and cut down cost. In view of this, organic active materials for OLEDs are anticipated to possess multiple functions, including high solid-state emission efficiency, efficient hole- and/or electron transport ability, etc. In this work, we report a series of bifunctional materials consisting of a silole core and electron-transporting functional groups, such as imidazole derivatives. These silole-based luminogens show aggregation-induced emission (AIE) characteristics and afford high emission efficiencies in the solid films. The presence of electron-withdrawing imidazole substituents lowers the LUMO energy levels as revealed by theoretical calculation and cyclic voltammetry, and allows for efficient electron transport ability of the luminogens. The bilayer OLEDs fabricated using these silole derivatives as light-emitting and electron-transporting layers simultaneously show excellent electroluminescence performances, which are better than those of trilayer OLEDs with an additional electron-transporting layer (TPBi), revealing that they are excellent n-type light emitters. These results demonstrate that the combination of AIE-active luminogens with charge transport groups at molecular level is a promising design for multifunctional solid-state light emitters.

9566-12, Session 3

High efficiency quantum dot based light-emitting devices *(Invited Paper)*

Weiran Cao, Univ. of Florida (United States); Huaibin Shen, Univ. of Florida (United States) and Henan Univ. (China); Nathan T. Shewmon, Univ. of Florida (United States); Paul Holloway, Univ. of Florida (United States) and NanoPhotonica, Inc. (United States); Lin Song Li, Henan Univ. (China); Jiangeng Xue, Univ. of Florida (United States)

Quantum-dot based light-emitting devices (QD-LEDs) have attracted great attention in recent years for their potential applications in solid-sate lighting and flat-panel displays. Here we will present our recent work on solution-processed, multilayer QD-LEDs incorporating a ZnO nanoparticle based electron transport layer. External quantum efficiencies exceeding 12% have been achieved for blue, green, and red emitting devices. We will describe the importance of surface ligand and the detailed nanostructure in the quantum dots. Our device structure also ensures good device stability, with extrapolated operating lifetime of 100,000 h (at 100 cd/m2) achieved for green and red devices.

9566-13, Session 3

Multi-stacked quantum dot light-emitting diodes and full-color displays by dry pick-and-place transfer *(Invited Paper)*

Tae-Ho Kim, Samsung Advanced Institute of Technology (Korea, Republic of)

The Light-emitting diodes (LEDs) with quantum dot (QD) luminophores show promise in the development of next-generation displays, because quantum dot luminophores demonstrate high quantum yields, extremely narrow emission, spectral tunability and high stability. Layered assembly structures composed of nanomaterials, such as quantum dots, have attracted considerable attention as promising candidates for new functional devices, whose optical, electromagnetic, and electronic behaviors are determined by the spatial arrangement of component elements. In this talk, we report a pick-and-place-based transfer printing technique which enables 3D heterogeneous multi-stacking of QD monolayers as well as fine patterning of QD films in a large area. We demonstrate a large-area full-color quantum dot display, including in flexible form, using optimized QD films by pick-and-place transfer, with control of the nano-interfaces and charge behavior. We also demonstrate 3D multi-stacked nanostructures composed of quantum dot monolayers with different sizes. This solvent-free transfer utilizes a lifting layer and allows the reliable transfer of a QD monolayer even onto flexible plastic substrates, enabling layer-by-layer design. With the controlled multi-stacking of different bandgap QD layers, we are able to probe the interlayer energy transfer among different QD monolayers. By controlling the emission spectrum through such designed monolayer stacking, we have achieved white emission with stable optoelectronic properties. The technology proposed here is versatile in its applicability over a wide range of materials and also provides routes toward developing various artificial solids as functional structures for application in large-scale flexible optoelectronic and electromagnetic devices.

9566-14, Session 4

Tandem organic light-emitting devices fabricated by solution-processes *(Invited Paper)*

Yong-Jin Pu, Yamagata Univ. (Japan)

We report the fabrication of a tandem-OLED comprising two ligh-emitting-units (LEUs) and a charge generation layer (CGL) between the anode and cathode using only solution-based processes. The individual components, 1st-LEU and 2nd-LEU are also fabricated independently. The ZnO/polyethyleneimine bilayer is used as the EIL in 1st-LEU and a molybdic acid derivative is used as the electron acceptor of the CGL. Appropriate choice of solvents during spin coating of each layer ensures that a nine-layered structure is readily fabricated using only solution-based processes. The driving voltage and efficiency of the fabricated multi-OLED are the sums of corresponding values of the component LEUs. These results demonstrate that the solution-processed CGL successfully generated electrons and holes and that the generated electrons and holes were injected into 1st-LEU and 2nd-LEU, respectively, when a voltage was applied, resulting in charge recombinations in each LEU.

9566-15, Session 4

Solution-processed flexible organic light emitting diodes *(Invited Paper)*

Jiajie Liang, Shu-Yu Charlotte Chou, Fangchao Zhao, Lu Li,

Qibing Pei, Univ. of California, Los Angeles (United States)

Flexible OLEDs tend to exhibit low performance thanks to the low surface conductivity, transmittance, and surface smoothness of ITO/PET as compared to ITO/glass. We are developing a flexible nanocomposite electrode comprising silver nanowires and light scattering nanoparticles that exhibit figures of merit exceeding ITO/glass. Light extraction efficiency of OLEDs employing the solution-processed transparent electrode is substantially higher than those on ITO/glass. Multiple-layer OLED structures using solution-processed small molecules and polymers have been fabricated on the new integrated substrate. Flexible OLEDs with high external quantum efficiency and luminous efficacy have been demonstrated and are being investigated for solid state lighting application.

9566-16, Session 4

Advantages and disadvantages of vacuum- and solution-processed OLED films: Differences in molecular orientation, thermal stability, and interfacial mixing *(Invited Paper)*

Daisuke Yokoyama, Maki Shibata, Yoshiya Sakai, Yamagata Univ. (Japan)

Most of commercialized OLEDs are currently based on vacuum-processed films because vacuum process enables us to fabricate ideal multilayer structures with a very high purity. On the other hand, the use of solution-processed films of OLED materials has recently drawn increasing attention to realize a low-cost fabrication of large-are devices. Each process has advantages and disadvantages when compared to the other. Thus, when we select an appropriate process for production of OLED displays or lighting according to the demand of the situation, it is very important to know what is the advantages and disadvantages of each film systematically and quantitatively from a viewpoint of physical properties of the films.

In this presentation, we will show systematic comparisons of the physical properties of (a) vacuum-processed small-molecule films, (b) solution-processed small-molecule films, and (c) solution-processed polymer films. In particular, three properties are focused on. The first is molecular orientation, which of emitters and transporters significantly affect outcoupling efficiency and charge transport, respectively [1]. Although vacuum-deposited small molecules can be highly oriented in the horizontal direction by choosing an appropriate molecular structure, we found that spin-coated small molecules tend to be randomly oriented regardless of experimental conditions. Thus, when we use small molecules in solution processes, we have to take into account the possible loss of the benefit from the horizontal orientation. The second is thermal stability. We found that glass transition of spin-coated films occurs at the temperature lower than that for transition of vacuum-deposited films. In particular, it should be noted that molecular orientation and glass transition temperature of spin-coated films are identical to those of the “deteriorated” vacuum-deposited films that experienced transition through thermal annealing. The third is interfacial mixing. We demonstrated that it is possible to analyze interfaces between layers of many kinds of OLED materials non-destructively by laboratory-scale experiments using ellipsometry. The difference of interfaces is also important to understand device characteristics. Through the comparisons of mainly these three factors, the advantages and disadvantages of each film will be discussed comprehensively.

9566-17, Session 4

Charge generation layers for all-solution processed organic tandem light emitting diodes with regular device architecture

Stefan Hoefle, Christoph Bernhard, Michael Bruns, Christian Kuebel, Torsten Scherer, Alexander Colsmann, Karlsruher Institut für Technologie (Germany)

We present multi-photon OLEDs where enhanced light emission was achieved by stacking two OLEDs utilizing a regular device architecture (top cathode) and an intermediate charge carrier generation layer (CGL) for monolithic device interconnection. With respect to future printing processes for organic optoelectronic devices, all functional layers were deposited from solution. The CGL comprises a low-work function zinc oxide layer that was applied from solution under ambient conditions and at moderate processing temperatures and a high-work function interlayer that was realized from various solution processable precursor-based metal oxides, like molybdenum-, vanadium- and tungsten-oxide. Since every injected electron-hole pair generates two photons, the luminance and the current efficiency of the tandem OLED at a given device current are doubled while the power efficiency remains constant. At a given luminance, the lower operating current in the tandem device reduces electrical stress and improves the device life-time. ToF-SIMS, TEM/FIB and EDX analyses provided evidence of a distinct layer sequence without intermixing upon solution deposition.

9566-18, Session 4

R2R processed flexible OLEDs for lighting and their mechanical stress testing

Takashi Minakata, Mitsuru Tanamura, Yasuhiro Mitamura, Masayuki Imashiro, Akira Horiguchi, Akira Sugimoto, Masahiko Yamashita, Yukito Yada, Nobuki Ibaraki, Hiroshi Tomiyasu, CEREBA (Japan)

Recently flexible OLEDs attracts significant attentions for emerging lighting applications.

In addition, R2R process is considered to be an ultimate goal for flexible device fabrication.

The authors have successfully fabricated flexible OLEDs by fully R2R process, which started from film washing, gas-barrier layer deposition, planarization, vacuum depositions of core-layers and finally encapsulated with film lamination.

Influence of fabrication conditions on OLEDs performance has been studied and R2R fabricated OLEDs showed good performance almost comparable with sheet to sheet (S2S) processed OLEDs by controlling fabrication conditions. This indicates that reduction of device performance caused by the fabrication process has been minimized.

In order to confirm this, effects of mechanical stress on device performance has been studied.

Other important issues such as encapsulation, protection for moisture permeation and R2R related process damages will be discussed at the conference.

9566-50, Session 4

High-index substrates with optical haze as a low-cost platform for efficient flexible OLEDs: Joint theoretical and experimental study *(Invited Paper)*

Eunhye Kim, Jinouk Song, Seunghyup Yoo, KAIST (Korea, Republic of)

Industrial grade PEN (I-PEN) substrates are studied as a simple, ideal platform enabling highly efficient flexible OLEDs at low cost. Their high refractive index (~1.75) and built-in optical haze (20-50%) are utilized to outcouple the light that would otherwise be confined as waveguide modes or substrate-confined modes. With an index-matched planarization layer and low-temperature-annealed indium zinc oxide (IZO) deposited on its top, total internal reflections occurring at the IZO/substrate interface are effectively suppressed, delivering most of the internally generated light into the bulk of I-PEN substrates. Those delivered to a substrate are then

extracted efficiently with the help of scattering from nano-scale particles already embedded inside I-PEN substrates during manufacturing.

With the proposed strategy, external quantum efficiency reaching ~40% is demonstrated for flexible OLEDs without any additional lenticular structure or internal patterning. An equivalent-model based on Henyey-Greenstein phase function and a full microscopic model based on a Mie-scattering are both employed, respectively, to account for the effect of scattering in the trans-scale optical simulation, which explains the structure-dependent enhancement and provides a guideline for further optimization, all in both qualitative and quantitative fashions.

9566-55, Session 4

Direct observation of surface anions relaxed by spontaneous orientation polarization in OLED films by high sensitivity photoemission *(Invited Paper)*

Hiroumi Kinjo, Tomoya Sato, Junki Yamazaki, Chiba Univ. (Japan); Yutaka Noguchi, Meiji Univ. (Japan); Yasuo Nakayama, Hisao Ishii, Chiba Univ. (Japan)

OLED materials often show spontaneous orientation polarization in evaporated films with giant surface potential (GSP). This polarization induces positive and negative fixed charges on both ends of the polarized layer. Due to this fixed charge, OLED films often contain surface/interface carriers that play important role in device performance. This is a kind of self-field effect carrier doping. In this study, we will report on the direct observation of anions fixed by GSP for various OLED materials by using high-sensitivity photoemission. The spectra for Alq3, alpha-NPB, TPBi, and BCP show unusual low energy photoemission in visible or near UV photon energy. The relaxation of anion states of these materials will be discussed in relation to injection properties. This method can be also applied to measure the electron affinity of organic semiconductors.

The above materials are often used as electron transporting material in OLED, and as buffer layer in organic solar cell. In both cases, the orientation polarization will capture some carrier and relaxed their energy. This relaxation should be a key to understand the role of such buffer layer. The relation between the observed electronic structure and device performance will be also discussed.

9566-19, Session 5

Triplet related losses in organic thin film lasers *(Invited Paper)*

Thomas Riedl, Bergische Univ. Wuppertal (Germany)

Organic solid state lasers (OSL) based on semiconducting polymers or small molecules progressed enormously over the past decade. A range of highly efficient organic gain media enable OSLs optically pumped by simple inorganic laser diodes or even LEDs. Still continuous wave (cw) or electrical operation remain challenges yet to be achieved. Both are impeded by losses that are associated with the particular photo-physics of organic gain media. In the quest to find strategies to overcome these losses, it is essential to careful analyze the underlying photo-physical mechanisms.

As an example, OSL pumped under cw conditions or long pulses stop lasing within 10 ns. This is a general phenomenon found in various gain media. It can be show that triplet state absorption and triplet singlet annihilation are the key processes that explain the dynamics of OSLs. We present techniques that allow us to measure the density, the spectral absorption and the lifetime of triplet excitons at room temperature in a number of neat and host gain-media. It turns out that in low-threshold guest-host systems, the lifetime of triplets may be significantly increased which lead to a preferred pile-up of triplet excitons trapped on the dopant molecules. Various concepts to overcome triplet related losses will be discussed. In addition, we will present evidence that there exist gain-media in which the optical gain is spectrally separated from the triplet-related absorption This opens an avenue to cw-lasing in organic thin films.

9566-20, Session 5

Solid-state fluorescent protein as a novel optical gain material for lasers and amplifiers *(Invited Paper)*

Malte C. Gather, Univ. of St. Andrews (United Kingdom)

Most currently used solid-state luminescent materials are based on inorganic semiconductors, phosphors and quantum dots or consist of synthetic hydrocarbon compounds. Here, we describe a distinctly different, novel class of solid-state emitters offering unique optical properties – the biologically produced fluorescent proteins. In contrast to many organic dyes, the special molecular structure of these proteins ensures that in solid-state the protein fluorophores have a fixed interspacing of 3-4 nm. This suppresses concentration quenching and enables strong optical amplification (g = 22 cm-1) in thin protein films. We use protein films to fabricate efficient solid-state vertical cavity surface emitting micro-lasers with thresholds below 100 pJ and single-frequency operation. We also demonstrate a self-assembly scheme to fabricate protein ring resonator lasers. Moreover, we find that solid-state blends of proteins emitting light of different color support strong Förster resonance energy transfer (FRET). The sensitivity of self-quenching and FRET to the intermolecular distance allows all-optical sensing. Our results demonstrate that the naturally optimized, unique structure of fluorescent proteins can be harnessed in various settings, and provide bio-inspiration for further improvement of synthetic luminescent molecules or nanoparticles.

9566-21, Session 5

Laser nanostructuring for high-performance organic optoelectronic devices *(Invited Paper)*

Hong-Bo Sun, Jing Feng, Yue-Feng Liu, Jilin Univ. (China)

Organic optoelectronic devices particularly organic light-emitting devices (OLEDs) and organic photovoltaics (OPVs) have been attracting increasing attention owing to their advantages of being thin, lightweight, and portable. High efficiency is a key issue for their commercial applications. While a very low light extraction efficiency of less than 20% is a stumbling block for high efficiency of OLEDs. More than 80% photons produced by exciton decay are trapped inside OLEDs in the form of waveguide (WG) modes in organic/ITO layers, surface plasmon–polariton (SPP) modes, and substrate modes from total internal reflection at the glass substrate/air interface. In the other hands, the organic film has to be very thin due to its short exciton-diffusion length and low carrier mobility, which results in low light absorption efficiency and limited the conversion efficiency of the OPVs.

In our work, integration of nanostructures into OLEDs and OPVs have been demonstrated not only an effective approach to out-couple WG and SPP modes within OLEDs but also improve the light absorption by coupling SPP resonance in OPVs. The nanostructures have been fabricated by holographic lithography and laser ablation, which are simple approach with high controllability and reproducibility. Both experimental and numerical results show and support obvious enhancement in efficiency of OLEDs and OPVs compared to those of the conventional planar devices. In conclusion, we have confirmed that laser nanostructuring is an efficient method to realize organic optoelectronic devices with high performance, which are promising candidates for commercial application in display, lighting and energy harvesting devices.

9566-22, Session 5

Solution-processable, photo-stable, low-threshold, and broadly tunable thin film organic lasers based on novel high-performing laser dyes *(Invited Paper)*

Maria A. Diaz-Garcia, Marta Morales-Vidal, Manuel G. Ramirez, Jose M. Villalvilla, Pedro G. Boj, Jose A. Quintana, Univ. de Alicante (Spain); Aritz Retolaza, Santos Merino, Tekniker (Spain)

Thin film organic lasers represent a new generation of inexpensive, mechanically flexible devices for spectroscopy, optical communications and sensing requiring an organic, efficient, stable, wavelength-tunable and solution-processable laser material. In this presentation we will report amplified spontaneous emission (ASE) and distributed feedback (DFB) laser applications of novel high performing materials of two different classes, both dispersed in polystyrene (inert matrix): perylenediimide (PDI) dyes and oligo-p-phenylenevinylenes (OPVs). Films containing a new bay-substituted PDI compound show efficient ASE emission at wavelengths between 610 and 630 nm, widening the use of PDIs in laser applications, up to now restricted to bay-unsubstituted PDIs, all with ASE at around 579 nm. We will also show results for a new class of OPVs, which undergo ASE from 385 nm to 583 nm, depending on the oligomer length, with remarkably low threshold and high photostability. Second-order DFB lasers with standard gratings (single period), have shown single mode emission, wavelength tunability across the visible spectrum, long operational lifetimes of >105 pump pulses, outstandingly larger than previously reported PPV compounds, and thresholds close to pumping requirements with light-emitting diodes, i.e. only 0.7 kW/cm2, which is among the lowest values reported to date for dye-doped materials. It is also remarkable that the two types of materials discussed show high thermal stability, thus allowing the use of thermal nanoimprint lithography to engrave the DFB resonators directly onto the active films. This constitutes an important aspect for the prospect of preparing mechanically flexible inexpensive devices.

9566-23, Session 5

Coherence measurements of organic light-emitting diodes and lasers *(Invited Paper)*

Ifor D. Samuel, Univ. of St. Andrews (United Kingdom)

Organic semiconductors are compact and convenient light courses for displays and lighting. However, can they also exhibit significant coherence, and can it be controlled? This is a topic that has received very little attention and yet is a fundamental property of light and highly relevant to shaping light emission from such sources to make “structured light.” We describe a method for the quantitative measurement of the coherence of organic light sources. The results of spatial coherence measurements of organic light-emitting diodes (OLEDs) and lasers will be reported and compared. We also explore the effect of wavelength scale microstructure on the coherence of light emission from OLEDs.

9566-24, Session 5

Photonic lattices in organic microcavities: Bloch states and control of lasing

Andreas Mischok, Robert Brückner, Hartmut Fröb, Vadim G. Lyssenko, Karl Leo, Technische Univ. Dresden (Germany)

Organic microcavities comprising the host:guest emitter system Alq3:DCM offer an interesting playground to experimentally study the full dispersion characteristics of laterally patterned microlasers due to the broad emission spectrum and large oscillator strength of the organic dye.

By structuring of metallic or dielectric sublayers directly on top of the bottom mirror, we precisely manipulate the mode structure and influence the coherent emission properties of the device. Embedding silver layers into a microcavity leads to an interaction of the optical cavity-state in the organic layer and the neighbouring metal which red-shifts the cavity resonance, creating a Tamm-Plasmon-Polariton state. A patterning of the metal can in turn be exploited to fabricate deep photonic wells of micron-size, that efficiently confine light in the lateral direction. In periodic arrays of silver wires we create a Kronig-Penney-like optical potential in the cavity and in turn observe optical Bloch states spanning over several photonic wires. We modify the Kronig-Penney theory to analytically describe the full far-field emission dispersion of our cavities and show the emergence of either zero- , pi-, or 2pi- phase-locking in the system. By investigating periodic SiO2 patterns, we experimentally observe stimulated emission from the ground and different excited discrete states at room temperature and are able to directly control the laser emission from both extended and confined modes of the photonic wires.

The introduction of defects in the periodicity further opens the possibilities of photon confinement in three dimensions as well as studying the analogy between crystal- and photonic lattices.

9566-25, Session 6

AC quantum efficiency harmonic analysis of exciton annihilation in organic light emitting diodes *(Invited Paper)*

Noel C. Giebink, The Pennsylvania State Univ. (United States)

Exciton annihilation processes impact both the lifetime and efficiency roll-off of organic light emitting diodes (OLEDs), however it is notoriously difficult to identify the dominant mode of annihilation in operating devices (exciton-exciton vs. exciton-charge carrier) and subsequently to disentangle its magnitude from competing roll-off processes such as charge imbalance. Here, we introduce a simple analytical method to directly identify and extract OLED annihilation rates from standard light-current-voltage (LIV) measurement data.

The foundation of this approach lies in a frequency domain EQE analysis and is most easily understood in analogy to impedance spectroscopy, where in this case both the current (J) and electroluminescence intensity (L) are measured using a lock-in amplifier at different harmonics of the sinusoidal dither superimposed on the DC device bias. In the presence of annihilation, the relationship between recombination current and light output (proportional to exciton density) becomes nonlinear, thereby mixing the different EQE harmonics in a manner that depends uniquely on the type and magnitude of annihilation.

We derive simple expressions to extract different annihilation rate coefficients and apply this technique to a variety of OLEDs. For example, in devices dominated by triplet-triplet annihilation, the annihilation rate coefficient, K_TT, is obtained directly from the linear slope that results from plotting EQE_DC-EQE_1? versus L_DC (2EQE_1?-EQE_DC). We go on to show that, in certain cases it is sufficient to calculate EQE_1? directly from the slope of the DC light versus current curve [i.e. via (dL_DC)/(dJ_DC)], thus enabling this analysis to be conducted solely from common LIV measurement data.

9566-26, Session 6

Degradation of wide band-gap electrolumienscent materials by exciton-polaron interactions *(Invited Paper)*

Hany Aziz, Qi Wang, Univ. of Waterloo (Canada)

The limited performance stability and gradual loss in the electroluminescence efficiency of OLEDs utilizing wide band-gap materials, such as blue-emitting phosphorescent and fluorescent devices, continues to be a challenge for wider technology adoption. We recently found that interactions between excitons and polarons play an important role in the aging behavior of electroluminescent materials, and that a correlation

exists between the susceptibility of these materials to this aging mode and their band-gap. This degradation mode is also found to be often associated with the emergence of new bands – at longer wavelength - in the electroluminescence spectra of the materials, that can often be detected after prolonged electrical driving. Such bands contribute to the increased spectral broadening and color purity loss often observed in these devices over time. Exciton-polaron interactions, and the associated degradation, are also found to occur most significantly in the vicinity of device inter-layer interfaces such as at the interface between the emitter layer and the electron or hole transport layers. New results obtained from investigations of these phenomena in a wide range of commonly used host and guest OLED materials will be presented.

9566-27, Session 6

Exciton formation and diffusion in OLEDs *(Invited Paper)*

Grayson L. Ingram, Zheng-Hong Lu, Univ. of Toronto (Canada)

This talk will discuss recent experiments designed to study the formation of excitons and their subsequent diffusions in OLEDs. These experimental results suggest that contrary to conventional wisdom, host singlet exciton diffusion can occur over long distances, while host triplet excitons are confined close to the exciton formation region for the archetype host and hole transport layer CBP. The exciton formation mechanism is studied and we show that the ratio of excitons formed on the host to excitons formed on the dopant varies strongly with the applied voltage. Refinements to models of efficiency roll off are discussed in light of the improved understanding of exciton formation and we suggest design guidelines to improve efficiency by engineering exciton formation.

9566-28, Session 6

Analysis of self-heating in organic semiconductor devices

Evelyne Knapp, Beat Ruhstaller, Zürcher Hochschule für Angewandte Wissenschaften (Switzerland)

So far self-heating has been of concern in large area devices where the resistive anode leads to a potential drop resulting in inhomogeneous current, brightness and temperature distributions. In this work we show that also small lab devices suffer from self-heating effects originating from the semiconductor layers. A clear indication for this is a negative capacitance value in unipolar devices. In bipolar devices other processes such as recombination or trapping can also cause a negative capacitance value. We compare the slope of the negative capacitance vs. frequency for uni- and bipolar devices to quantify the different processes. The overall device structure does affect the negative capacitance. Further impacts of self-heating are discussed: in DC an increased current density is measured after the device has heated up, in dark-injection transient current experiments an increase in the current density is seen after a while.

With the aid of a Fourier method we can transform time-dependent results to the frequency domain which allows for an effortless interpretation of the negative capacitance.

We compare our results with measurements and emphasize the importance of our analysis for OLEDs and organic solar cells. In one study, a device is cooled with a copper block leading to a less negative capacitance confirming self-heating as an origin of the negative capacitance [H. Okumoto and T. Tsutsui, Appl. Phys. Express 7, 061601 (2014)].

We have provided clear evidence of self-heating of organic semiconductor devices and conclude that a comprehensive model requires the inclusion of heat conduction and heat generation in the drift-diffusion model.

9566-29, Session 7

Determining the rate-limiting steps for the purification of organic semiconductors by thermal gradient sublimation *(Invited Paper)*

Nathan T. Morgan, Yi Zhang, Univ. of Minnesota, Twin Cities (United States); Matthew L. Grandbois, Bruce M. Bell, The Dow Chemical Co. (United States); E. L. Cussler, Russell J. Holmes, Univ. of Minnesota, Twin Cities (United States)

Small molecule organic semiconductors have been successfully integrated into a variety of optoelectronic platforms including light-emitting devices (OLEDs), photovoltaic cells and field-effect transistors. In all cases, materials purity plays a significant role in the realization of robust devices with high performance. Most frequently, these materials are purified using thermal gradient sublimation. The successful separation of the target molecular species from its impurities relies on differences in the vapor pressure of each component in the starting material. Here, we explore the fundamental mechanisms that limit sublimation rate and control material deposition. For the archetypical hole transport materials, N,N'-bis(naphthalen-1-yl)-N,N'-bis(phenyl)-benzidine (NPD) and 4,4',4''-tris(carbazol-9-yl) triphenylamine (TCTA), a combination of diffusion to the deposition zone and physical vapor deposition are shown to be rate-limiting at constant sublimation temperature. Surprisingly, diffusion within the solid feed, reaction at the feed particle surface, and mass transfer within the bed of feed particles are not limiting. Interestingly, in cases where the feed consists of a mixture of NPD and TCTA, the sublimation rate shows the same diffusive behavior, and the separation efficiency can be manipulated by engineering the temperature gradient in the collection zone. These results can be used to guide the design and operation of future large-scale purification systems, which are critical for the scale-up of materials synthesis and supply efforts.

9566-30, Session 7

Optically and electrically detected magnetic resonance (ODMR and EDMR, respectively) of phosphorescent, thermally activated delayed fluorescence (TADF), and exciplex OLEDs *(Invited Paper)*

Chamika Hippola, Dusan Danilovic, Min Cai, Ruth Shinar, Joseph Shinar, Iowa State Univ. of Science and Technology (United States)

It is widely recognized that nonradiative quenching of singlet excitons (SEs) by other SEs, triplet excitons (TEs), polarons, and bipolarons becomes the dominant decay mechanism of these excitons at high excitation densities. These quenching processes cause the roll-off in the efficiency of OLEDs and prevent lasing at high injection current densities, and they result in the observed ODMR and EDMR in conventional fluorescent OLEDs. A previous ODMR study on phosphorescent OLEDs has suggested that such quenching of the host SEs is also significant. This talk will focus on the ODMR and EDMR of additional phosphorescent, TADF, and exciplex OLEDs, and on the potential role of bipolarons in device degradation.

9566-31, Session 7

Kinetic Monte Carlo simulation of the efficiency roll-off, emission color, and degradation of organic light-emitting diodes *(Invited Paper)*

Reinder Coehoorn, Philips Research Nederland B.V. (Netherlands); Harm van Eersel, Peter A. Bobbert, Rene A.

J. Janssen, Technische Univ. Eindhoven (Netherlands)

The performance of Organic Light Emitting Diodes (OLEDs) is determined by a complex interplay of the charge transport and excitonic processes in the active layer stack. We have developed a three-dimensional kinetic Monte Carlo (kMC) OLED simulation method which includes all these processes in an integral manner. The method employs a physically transparent mechanistic approach, and is based on measurable parameters. All processes can be followed with molecular-scale spatial resolution and with sub-nanosecond time resolution, for any layer structure and any mixture of materials. In the talk, applications to the efficiency roll-off, emission color and lifetime of white and monochrome phosphorescent OLEDs [1,2] are demonstrated, and a comparison with experimental results is given. The simulations show to which extent the triplet-polaron quenching (TPQ) and triplet-triplet-annihilation (TTA) contribute to the roll-off, and how the microscopic parameters describing these processes can be deduced properly from dedicated experiments. Degradation is treated as a result of the (accelerated) conversion of emitter molecules to non-emissive sites upon a triplet-polaron quenching (TPQ) process. The degradation rate, and hence the device lifetime, is shown to depend on the emitter concentration and on the precise type of TPQ process. Results for both single-doped and co-doped OLEDs are presented, revealing that the kMC simulations enable efficient simulation-assisted layer stack development.

9566-32, Session 7

Modeling of organic light emitting diodes: From molecular to device properties *(Invited Paper)*

Pascal Kordt, Jeroen J. M. van der Holst, Max-Planck-Institut für Polymerforschung (Germany); Mustapha Al Helwi, BASF SE (Germany) and Technische Univ. Braunschweig (Germany); Wolfgang Kowalsky, Technische Univ. Braunschweig (Germany); Falk May, Alexander Badinski, Christian Lennartz, BASF SE (Germany); Denis Andrienko, Max-Planck-Institut für Polymerforschung (Germany)

We review the progress in modeling of charge transport in disordered organic semiconductors on various length-scales, from atomistic to macroscopic. This includes evaluation of charge transfer rates from first principles, parametrization of coarse-grained lattice and off-lattice models, and solving the master and drift-diffusion equations. Special attention is paid to linking the length-scales and improving the efficiency of the methods. All techniques are illustrated on an amorphous organic semiconductor, DPBIC, a hole conductor and electron blocker used in state of the art organic light emitting diodes (OLEDs). The outlined multiscale scheme can be used to predict OLED properties without fitting parameters, starting from chemical structures of compounds.

9566-33, Session 7

Development of operationally stable inverted organic light-emitting diode prepared without using alkali metals *(Invited Paper)*

Hirohiko Fukagawa, NHK Japan Broadcasting Corp. (Japan); Katsuyuki Morii, Munehiro Hasegawa, Shun Gouda, NIPPON SHOKUBAI CO., LTD. (Japan); Toshimitsu Tsuzuki, Takahisa Shimizu, Toshihiro Yamamoto, NHK Japan Broadcasting Corp. (Japan)

The OLED is one of the key devices for realizing future flexible displays and lightings. One of the biggest challenges left for the OLED fabricated on a flexible substrate is the improvement of its resistance to oxygen and moisture. A high barrier layer [a water vapor transmission rate (WVTR) of about 10-6 g/m2/day] is proposed to be necessary for the encapsulation of conventional OLEDs. Some flexible high barrier layers have recently been demonstrated; however, such high barrier layers require a complex process, which makes flexible OLEDs expensive. If an OLED is prepared without using air-sensitive materials such as alkali metals, no stringent encapsulation is necessary for such an OLED. In this presentation, we will discuss our continuing efforts to develop an inverted OLED (iOLED) prepared without using alkali metals. iOLEDs with a bottom cathode are considered to be effective for realizing air-stable OLEDs since the electron injection layer (EIL) can be prepared by fabrication processes that might damage the organic layers, resulting in the enhanced range of materials suitable for EILs. We have demonstrated that a highly efficient and relatively air-stable iOLED can be realized by employing poly(ethyleneimine) as an EIL. Dark spot formation was not observed after 250 days in the poly(ethyleneimine)-based iOLED encapsulated by a barrier film with a WVTR of 10-4 g/m2/day. In addition, we have demonstrated the fabrication of a highly operational stable iOLED utilizing a newly developed EIL. The iOLED exhibits an expected half-lifetime of over 10,000 h from an initial luminance of 1,000 cd/m2.

9566-34, Session 8

Next generation organic light-emitting materials and devices *(Invited Paper)*

Bernard Kippelen, Georgia Institute of Technology (United States)

In this talk, we will discuss recent innovations in organic light-emitting materials and devices. First, we will report on organic light-emitting diodes (OLEDs) based on thermally activated delayed fluorescence (TADF). We will show that devices based on the emitter 4CzIPN doped in a novel ambipolar host can yield a current efficacy of 81 cd/A and a maximum external quantum efficiency of 26.5%. These devices exhibit a low turn-on voltage of 3.2 V at 10 cd/m2, as well as reduced efficiency roll-off at high current densities. The performance of these devices is comparable to that of electrophosphorescent devices based on organic-metallic compounds that contain precious metals such as Iridium. In a second part we will report on highly efficient green-emitting organic light-emitting diodes (OLEDs) fabricated on shape memory polymer (SMP) substrates for flexible electronic applications. SMPs are a class of mechanically active materials that can change and store shape upon activation by a stimulus. The combination of the unique properties of SMP substrates with the light-emitting properties of OLEDs pave to the way for new applications, including conformable smart skin devices, minimally invasive biomedical devices, and flexible lighting/display technologies. Finally, we will present OLEDs fabricated on substrates made from cellulose nanocrystals (CNC) and discuss how such substrates can reduce the environmental footprint of printable organic electronics.

9566-35, Session 8

Construction of charge generation layer for high efficiency tandem organic light-emitting diodes *(Invited Paper)*

Dongge Ma, Changchun Institute of Applied Chemistry (China)

Tandem or stacked OLED is a promising device structure that can potentially achieve both high efficiency and long operating hours. A typical tandem OLED is fabricated by vertically connecting several individual electroluminescent (EL) units together in series via the so-called charge

generation layer (CGL), with the entire device driven by a single power source. When certain voltage is applied on the electrodes, each EL lights up individually under the same current that flow through the whole device. Since tandem OLED can obtain the same brightness under several folds of lower current density, its lifetime can be significantly lengthened. Furthermore, the tandem structure provides the feasibility that EL units of different colors can be vertically stacked together for color tuning and white emission. In tandem OLEDs, the CGL obviously plays a very important role. Therefore, how to construct an effective CGL become a key in the fabrication of high efficiency tandem OLEDs.

Here, we presented an effective organic heterojunction CGL composed of a p-type organic material 4,4',4''-Tris(N-3-methylphenyl-N-phenylamino) triphenylamine (m-MTDATA) and an n-type organic material 1,4,5,8,9,12-hexaazatriphenylene -hexacarbonitrile (HAT-CN) bilayer and fabricated an ultra-high efficiency tandem OLED based on it as CGL. The maximum power efficiency reaches 120 lm/W, and yet remains 110.3 lm/W at 1000 cd/m2, which is greatly enhanced from the corresponding optimized green single-unit device. Also its maximum current efficiency and external quantum efficiency is as high as 201cd/A and 54.5%, all among the best result published by now. Furthermore, the working principles of the organic heterojunction as CGL are studied in detail and well explained by using a Zener tunneling model.

Ultraflexible high-efficiency organic light-emitting diodes using graphene anode *(Invited Paper)*

Tae-Woo Lee, Tae-Hee Han, Min-Ho Park, Sung-Joo Kwon, Pohang Univ. of Science and Technology (Korea, Republic of); Sang-Hoo Bae, Yonsei Univ. (Korea, Republic of); Hong-Kyu Seo, Pohang Univ. of Science and Technology (Korea, Republic of); Jong-Hyun Ahn, Yonsei Univ. (Korea, Republic of)

Organic light-emitting diodes (OLEDs) have been considered as devices for next-generation flexible displays and solid-state-lighting. However, mostly used indium-tin-oxide (ITO) electrode has poor tolerance to the mechanical stress. Therefore, brittle ITO electrode should be replaced with flexible transparent conducting electrodes to realize flexible organic opto-electronic devices. In this point of view, the use of graphene electrode in flexible OLEDs has been increasingly studied because graphene exhibits excellent electrical and mechanical properties. To approach toward ultimate flexible OLEDs, device should have i) ultra-high efficiency, ii) low efficiency roll-off characteristics at high luminance and iii) excellent flexibility for practical applications of flexible electronics. . Here, we fabricated flexible tandem OLEDs by stacking two electroluminescent (EL) units vertically on the graphene anode to enhance the luminous efficiency of flexible OLEDs. To avoid thermal damage of flexible plastic substrate which has low thermal resistance, we inserted low-temperature processable charge generation layer which is suitably developed for flexible OLEDs between two EL units. Flexible tandem OLEDs with graphene anode showed ultra-high efficiency (205.9 cd/A and 45.2 %) with low efficiency roll-off characteristics. By using hemi-spherical lens to improve light out-coupling, significantly enhanced current efficiency (396.4 cd/A) and external quantum efficiency (~87.3 %) were achieved in flexible OLEDs with graphene anode. Furthermore, the flexible tandem OLEDs with graphene anode showed excellent flexibility against bending stress up to ~7% of bending strain. Our results provide a significant step toward the next generation flexible displays and solid-state-lighting.

Emitting dipole orientation of iridium complexes in OLEDs *(Invited Paper)*

Jang-Joo Kim, Kwon-Hyeon Kim, Chang-Ki Moon, Seoul National Univ. (Korea, Republic of); Jae-yeol Ma, Yun-Hi Kim, Gyeongsang National Univ. (Korea, Republic of)

Phosphorescent iridium complexes have long been thought to have random orientation when doped in an emitting layer due to their octahedron structures. Recently, however, some heteroleptic iridium complexes which have the ancillary ligands of ?-diketonate or picolate have been reported to have preferred orientation of emission dipoles along horizontal direction (parallel to substrates). The outcoupling efficiency of the emitted light from the horizontally oriented emitting dipoles in an OLED can reach 45% which is much higher than isotropically oriented transition dipoles.[1] However, the origin of the preferred emitting dipole orientation (EDO) and the factors influencing the orientation have not been studied much.

In this presentations we will report the recent findings on the emitting dipole orientation of iridium complexes, which can be summarized as follows: (1) Heteroleptic iridium complexes are more likely to have preferred orientation in host materials than homoleptic iridium complexes. (2) Tetramethylheptadionate (tmd) ancillary ligand results in higher horizontal EDO than acetylacetonate (acac). (3) There is a linear correlation between the EDO in films and the orientation of the transition dipole moments against the C2 axis of the heteroleptic Ir complexes. (4) The EDO of the heteroleptic Ir-complex varies from horizontal to isotropic, or even to vertical direction depending on host molecules. (5) The preferred molecular orientation of the host molecules does not induce the preferred molecular orientation of the dopant molecules. (6) Intermolecular interaction between complex dopants and the aromatic rings in the host molecules induces preferred orientation of dopant molecules. (7) The preferred horizontal orientation of dopant emitting dipoles is due to the formation of planar-structure supra-molecular assemblies of host and dopant molecules. (8) The vertical EDO is induced when they interact repulsively during the film deposition to form non-linear binding geometry.

High thermal conducting diamond/gold-grids as transparent electrode for organic light emitting diodes

Koen Gilissen, Univ. Hasselt (Belgium) and IMEC (Belgium); Pieter Robaeys, Univ. Hasselt (Belgium); Matthew Mcdonald, Emilie Bourgeois, Jan D'Haen, Univ. Hasselt (Belgium) and IMEC (Belgium); Zdenek Remes, Institute of Physics of the ASCR, v.v.i. (Czech Republic); Ken Haenen, Jean V. Manca, Michael Daenen, Milos Nesladek, Wim Deferme, Univ. Hasselt (Belgium) and IMEC (Belgium)

Since the discovery of organic light-emitting diodes (OLEDs), indium tin oxide (ITO) is the most commonly used transparent electrode due to its high optical transparency and excellent electrical properties. However, indium is scarce, expensive and has the tendency to diffuse into the active layer. Furthermore, ITO is unstable at high temperatures and has a poor thermal conductivity. In this work the thermal conductivity and the local heat generation and dissipation of organic light-emitting diodes (OLEDs) are investigated, by comparing OLEDs, with equal luminous power efficiency, utilizing ITO and heavily boron doped nanocrystalline diamond (BNCD) embedded with a gold (Au) grid as anode material. It is shown that the BNCD:Au grid anode OLEDs, under operation, have a lower temperature increase due to a more efficient heat dissipation. Furthermore it is also shown that the thermal decay of the localized hotspots generated during operation is much faster for the BNCD:Au grid anode OLEDs compared to the ITO anode OLEDs. With these excellent thermal properties and the outstanding chemical stability of diamond, increased lifetimes are expected.

Hybrid structure of AgNWs-graphene-PEDOT as anode for organic light-emitting diodes

Xiaoqing Du, Chongqing Univ. (China)

The advent of graphene, with its combination of high transparency, electron mobility and chemical stability, opens the possibility of metal-free all-organic light-emitting devices. However, graphene has higher sheet resistance and lower work function comparable to tranditional ITO as anode electrodes. Therefore, graphene-based electrodes need to be performance improved to meet the combination requirements of high optical transparency, electrical conductivity and current injection efficiency for OLEDs application.

A hybrid structure of silver nanowires(AgNWs)-graphene-PEDOT on PET was adopted to act as the anode of FOLEDs. AgNWs can decrease the resitivity of graphene significantly for AgNWs provide a large number of free electrons and effective conductive path network. The work function of PEDOT can be at 5.1eV, which is about 0.5eV higher than the work function of graphene. AgNWs film was firstly coated on PET by spin-coating, and then CVD-grown graphene was tranferred from copper substrate to the AgNWs film by PMMA-aided transfer technology. Subsequently, PEDOT with 30nm thicknes was spin-coated on the graphene. The hole transport layer(HTL), light-emitting layer(LEL), electron transport layer(ETL) and cathode were coated by vacuum evaporation to form a whole device. Our experiments show that the optical transmittance and electrical conductivity of the hybrid structure can be optimized by adjusting the thickness of AgNWs film. The hybrid structure with AgNWs-graphene-PEDOT can achieve the lowest sheet resistivity and highest hole injection current compared with single graphene, AgNWs and PEDOT. The OLED with the hybrid electrode has the best uniform current spreading and the lowest turn-on voltage.

Influence of electrode materials on current characteristic of flexible organic electroluminescent devices

Jun Bao, Xiaoqing Du, Chongqing Univ. (China)

• Flexible organic electroluminescent devices (FOLEDs) have recently attracted a considerable amount of attention because of their potential applications in foldable screen. Compared with traditional OLEDs, FOLEDs need flexible electrode such as carbon nanotubes(CNTs), silver nanowire netwoks or graphene. These electrode materials have relative high resistivity due to their thin thickness, which often results in non-uniformity of luminescence and reduction of efficiency.

• An equivalent impedance model and current spread model were setup to describe the current-voltage(I-V) characteristics and current uniformity of FOLEDs respectively. The influences of resistivity, work function and contactresistance of electrode materials on current characteristics of FOLEDs were analyzed. The Finite element method and PSPICE were used to simulate the current distribution in three dimensions and the I-V characteristics FOLEDs, respectively.

• By quantitatively comparing the current characteristics of FOLEDs with different flexible electrode materials, which includes PEDOT:PSS, PANI, CNTs, graphene, silver nanowires and graphene-silver nanowire hybrid, we find the FOLED with the graphene-silver nanowire hybrid electrode has the best uniform current spreading and the lowest turn-on voltage due to its lower resistivity and contactresistance.

High-efficiency flexible organic light-emitting diodes with novel light outcoupling structures

Jianxin Tang, Yan-Qing Li, Lei Zhou, Hengyang Xiang, Soochow Univ. (China)

Because of their mechanical flexibility, organic light-emitting diodes (OLEDs) hold great promise as a leading technology for display and lighting applications in wearable electronics. The development of flexible OLEDs requires high-quality transparent conductive electrodes with superior bendability and roll-to-roll manufacturing compatibility to replace indium tin oxide (ITO) anodes. Here we present a flexible transparent conductor on plastic with embedded silver networks which is used to achieve flexible, highly power-efficient large-area green and white OLEDs. By combining an improved outcoupling structure for simultaneously extracting light in waveguide and substrate modes and reducing the surface plasmonic losses, flexible white OLEDs exhibit a power efficiency of 106 lm/W at 1000 cd/m2 with angular color stability, which is significantly higher than all other reports of flexible white OLEDs. These results represent an exciting step towards the realization of ITO-free, high-efficiency OLEDs for use in a wide variety of high-performance flexible applications.

Control of the orientation of the light-emitting molecules in spin-coated glassy organic films

Li Zhao, Kyushu Univ. (Japan); Takeshi Komino, Kyushu Univ. (Japan) and Japan Science and Technology Agency (Japan); Munetomo Inoue, Ju-Hyung Kim, Kyushu Univ. (Japan); Jean-Charles Ribierre, Kyushu Univ. (Japan) and Japan Science and Technology Agency (Japan); Chihaya Adachi, Kyushu Univ. (Japan) and Japan Science and Technology Agency (Japan)

Horizontal molecular orientation in organic light-emitting diode (OLED) materials has been already reported in a variety of vacuum-deposited glassy thin films. It is now well-established that such a horizontal molecular orientation is essential to improve the light outcoupling efficiency and the overall performance of the light-emitting devices. However, this preferential orientation has not been observed so far in spin-coated glassy organic films. Because of the current need to develop high performance solution-processed OLEDs for low cost and large area applications, control of the molecular orientation in spin-coated glassy organic thin films would be very significant to the field. Here, we show that the horizontal orientation of light-emitting molecules can be obtained in spin-coated glassy thin films based on a blend of a heptafluorene derivative in a 4,4'- bis(N-carbazolyl)-1,1'-biphenyl (CBP) host. Variable angle spectroscopic ellipsometry and angle dependent photoluminescence measurements are carried out to investigate the molecular orientation in heptafluorene neat film and in CBP blends. In particular, influence of the concentration of the heptafluorene molecules in the CBP blend is studied to provide information on the mechanism of these molecular orientational processes. Solution-processed fluorescent OLEDs with horizontally oriented heptafluorene emitters are then fabricated and exhibit deep blue electroluminescence with an external quantum efficiency as high as 5.3 %.

Photopolymerizable fluorescent small molecule-based materials: An all-in approach for solution-processed OLEDs

Simon Olivier, Commissariat à l'Énergie Atomique (France)

and Univ. de Nantes (France); Lionel Derue, Bernard Geffroy, Ecole Polytechnique (France) and CEA Saclay (France); Eléna Ishow, Univ. de Nantes (France); Tony Maindron, CEA Grenoble (France)

The elaboration of organic light-emitting diodes (OLEDs) has been boosted by the use of charge transporting and emissive small molecules, leading to multilayer devices through successive steps of thermal vacuum evaporation. Although small molecule-based OLEDs display higher performances compared to those involving polymers, the vacuum evaporation of small molecules faces strong technical constraints like shadow mask handling, scaling up to large substrate and is usually associated with large product waste. In order to address these issues, wet deposition processes implying small molecules have been proposed so that to full OLED architectures [1]. Yet, they appeared quite troublesome due to high solubility of the resulting thin layers, making successive depositions very difficult.

In order to conjugate the performances of small molecules with the structural stability of polymerized layers, we have synthesized a series of novel promising fluorescent materials that successfully photopolymerize after wet deposition. These compounds show various emission colors (blue, green and orange) and high fluorescence quantum yields in the solid state before (0.40), even after photopolymerization (0.32), and form stable amorphous materials without crystallites or aggregates. After photopolymerization, the thin film becomes totally insoluble in common organic solvents, allowing for the deposition of the subsequent layer following a wet process. By associating these fluorescent compounds with photopolymerizable charge carriers like QUPD [2], we have been able to build a multi-layered OLED through a wet process without using orthogonal solvents.
